There is no specific treatment for PCOS, but it can be managed with certain medications and ethno-medicines. Due to societal pressures, patients may feel ashamed to consult a physician, and in some cultures, norms restrict patients from seeking medical treatment, leading to delayed consultations and increased complications. Research has shown that many chronic diseases cannot be permanently cured; however, their symptoms can be managed, and patients can improve their quality of life through healthy lifestyle changes. PCOS, being a lifelong disorder, can be managed with proper medical care. This includes symptom management through healthy lifestyle changes, cultural practices, and medications (Pal, 2014).

Many patients initially try to avoid medications and instead focus on healthy lifestyle changes as the first step in managing PCOS. To improve their lifestyle, PCOS patients are advised to increase daily physical activities, engage in regular moderate exercise, and prevent insulin resistance. An active routine can help maintain a healthy weight and reduce the risk of diabetes. This routine might include a daily 20–30-minute walk after meals (Shahid et al., 2022). PCOS is a hormonal disorder (Azziz, 2011). To regulate hormone levels and address related issues, some Ayurvedic treatments are also utilized. These treatments include herbal therapies and lifestyle changes. Ayurvedic herbs used for PCOS include Ashwagandha (also known as winter cherry), which helps regulate cortisol levels to reduce stress; Cinnamon, which aids in managing insulin resistance; and Turmeric, which acts as an anti-inflammatory agent. Ayurvedic therapies also incorporate yoga to alleviate anxiety. Recommended yoga poses, known as asanas, include Supta Baddha Konasana (butterfly pose), Bharadvajasana (twist), Chalanasana (mill churning pose), and Shavasana (corpse pose) (Forthingham, 2020).

In certain cultures, religious treatments are also employed to manage PCOS. Patients may visit Darbars, recite verses from the Quran, or seek the assistance of practitioners who provide taweez (amulets). Taweez, often inscribed with Quranic verses or prayers, is a cultural practice among some Muslims believed to offer protection or healing. However, Islamic scholars advise against relying exclusively on these practices and emphasize that they should complement, not replace, professional medical treatment. Consulting unqualified practitioners or quacks is generally discouraged, as it can lead to misinformation and potential harm (Kaur et al., 2021).

In medical anthropology, some biomedicines are also considered traditional medicines, as they are commonly used as initial treatments by physicians within a given society. For PCOS, traditional treatments include medications such as Metformin and oral contraceptive pills (birth control), as well as natural supplements like Berberine, Chromium, and Inositol, which aid in managing PCOS symptoms. Additionally, significant lifestyle changes, including weight loss and regular exercise, are crucial for symptom management and overall recovery (Andonian, 2023).

Theoretical Framework

The present study aligns with various theories in anthropology and medical anthropology. From a socio-cultural perspective on PCOS, it relates to the theory of cultural relativism, proposed by Franz Boas the theory posits that cultural beliefs and practices should be understood within the context of the specific culture in which they occur, rather than through the lens of external absolutes (Kendra, 2023). The theory of cultural relativism can be applied to the socio-cultural context surrounding PCOS by examining how cultural beliefs, values, and practices shape the perception, experience, and management of the condition. For instance, in cultures where fertility is highly valued, symptoms of PCOS such as irregular menstrual cycles or infertility may have profound social and emotional consequences (Tzuriel & Tzuriel, 2021). Additionally, cultural attitudes toward body image, gender roles, and healthcare-seeking behaviors influence how individuals with PCOS are perceived and supported within their communities. Adopting a cultural relativist perspective allows researchers to understand the diverse global interpretations and responses to PCOS, leading to more culturally sensitive approaches in diagnosis, treatment, and support for affected individuals (Forthingham, 2020; Rashid et al., 2019).

The perspective discussed previously is rooted in anthropological theory; however, given that PCOS is a medical condition, it is also relevant to theories in medical anthropology. PCOS can be analyzed through both epidemiological and ecological approaches. These approaches examine the interplay between biological and cultural factors in health and disease. They focus on understanding how certain factors can influence the likelihood of developing a disease, including cultural practices that may either contribute to illness or compel individuals to adopt a sick role (Robbins, 2016).

For instance, studies on PCOS using these approaches explore how factors such as genetics, lifestyle, and environmental influences contribute to the condition's development and manifestation across different demographic groups. They also investigate how cultural beliefs, social norms, healthcare systems, and environmental conditions affect the prevalence, diagnosis, and management of PCOS (Sheehan, 2004). By integrating epidemiological and ecological perspectives, medical anthropologists can achieve a comprehensive understanding of PCOS, considering both individual and broader societal factors. This approach aids in developing more effective interventions and healthcare policies tailored to diverse populations (Rashid et al., 2019; Robbins, 2016; Scott & Palincsar, 2013).

Review of Literature

Medical anthropology as a sub field of applied anthropology has interrelated the biological and cultural aspects of human health to explain the impact of culture on health and diseases. "Medical anthropology deals with the collective study of biological and cultural aspects about humans to explain the influence of culture on human health and disease. Cultural factors engage

symbols with biology in a minds-body dynamics manifested in traditional healing practices, psychosomatic illness and many other ways by which beliefs effect the health" (Winkelman, 2009).

The study of human beings first clicks to the study of health of human being. There are many aspects other than medicine to study humans. When culture and health behavior and social programs related to public health are involved with medicine then a new field evolves belongs to applied anthropology called medical anthropology. "Medical anthropology is the primary discipline addressing the interfaces of medicine, culture and health behavior and incorporating cultural perspectives into clinical settings and public health programs" (Doda, 2005).

The topic of the study is "Polycystic Ovary Syndrome (PCOS): An Anthropo-medical study of women's reproductive health narratives in selected public hospitals of Rawalpindi". The topic briefly discusses the cause and effects of PCOS, it highlights the socio-cultural impact on PCOS patient and how they cope from these social stigmas, and it discusses about knowledge and treatment strategies adopted by women having PCOS. PCOS is an endocrine disorder. It can affect individual's assigned female at birth, typically during their reproductive years. It is characterized by a combination of symptoms, including irregular menstrual cycles, excess androgen levels (male hormones), and the presence of multiple cysts on the ovaries. This hormone release in females when females do not ovulate due to insufficient number of ovulatory hormones. Because of these ovaries develop small cysts. These cysts then secrete the androgen hormone. PCOS patients have high level of androgen hormone which create complication in menstrual cycle, and other symptoms of PCOS (Altman, 2023).

A follicle is a sac in which egg development occurs, 'PCOS ovary contains large number of follicles, and they are up to 8mm (approx. 0.3) in size. In PCOS follicles are unable to release egg that is why no ovulation take place. This is very common disease affecting 1 in 10 women in UK. PCOS often manifests with a range of symptoms, such as acne, excessive hair growth (hirsutism), weight gain, and infertility. The exact cause of PCOS is not fully understood, but it is believed to involve a combination of genetic, hormonal, and environmental factors. Insulin resistance, where the body's cells do not respond effectively to insulin, is also commonly associated with PCOS. This hormonal imbalance can disrupt the normal functioning of the reproductive system, leading to difficulties with ovulation and fertility (Altomara, 2021). PCOS patients suffer a lot psychologically and socially as well. PCOS not only affects physical health but can also have significant psychological, socio-cultural and emotional impacts, including depression, anxiety, social stigmas and body image concerns. Management of PCOS typically involves a combination of lifestyle modifications, such as dietary changes and exercise, along with medications to regulate menstrual cycles, manage symptoms like acne and excess hair growth, and improve fertility outcomes. Early diagnosis and comprehensive management are crucial in minimizing the long-term health risks associated with PCOS, including type 2 diabetes, cardiovascular disease, and endometrial cancer (Deanna & Sachdev 2023).

The term socio-cultural can be better explained by socio-cultural theory. 'Socio-cultural theory has both sociological and psychological dimensions and both of these dimensions deal with the importance of culture and society in the development and shaping of an individual in a society. It elaborates that how friends, parents and the society interact in the development of an individual's cognitive, learning and socio-cultural abilities'(Main, 2023).

Socio-cultural theory under the umbrella of anthropology underpins that “socio-cultural anthropology studies the social, symbolic, or nonmaterial and material lives of contemporary and historically recent human societies, taking the concept of culture central to its goal. It discusses the social and cultural aspect of an individual of a society, by describing and analyzing the lives of people and their traditions” (Doda, 2005). While discussing the socio-cultural perspective about the PCOS patient, it has been seen that ‘women that suffering from PCOS have high level of anxiety and depression, which impart a great effect on patient’s identity, mental health and quality of life. The disorders related to anxiety and depression in PCOS patients ranges from 28% to 39% for anxiety and 11% to 25% for depression (Dewani, 2023).

A patient with PCOS often faces additional challenges due to societal expectations. The societal and cultural pressures can exacerbate feelings of depression and frustration. Symptoms such as hirsutism, menstrual irregularities, and obesity can contribute to mental health issues. Of particular concern is infertility, especially in cultures where fertility is closely tied to notions of femininity. This can place significant emotional strain on married women, adversely affecting their quality of life and marital relationships (Arlt, 2022).

Research indicates that there is no definitive or permanent cure for PCOS in women. However, the symptoms can be managed through a combination of medical or ethno-medical treatments and lifestyle modifications. Studies have shown that lifestyle changes, including a healthy diet, regular exercise, and weight management, are prioritized in the treatment of PCOS (Dunne, 2006). These modifications help regulate hormone levels in both married and unmarried women. Additionally, medical practitioners typically initiate treatment with birth control pills to normalize menstrual cycles and may also prescribe medications for insulin resistance, such as those used to manage diabetes (Lucidi, 2023).

Traditional treatments for PCOS vary widely across cultures and regions of the world. These treatments often draw upon traditional medicine systems that have been practiced for centuries and are deeply rooted in local beliefs and customs. ‘Many traditional medicine systems, such as Traditional Chinese Medicine (TCM), Ayurveda, and Indigenous healing practices, utilize herbal remedies to address symptoms associated with PCOS. These herbs may include Fenugreek, Cinnamon, Licorice root, Saw Palmetto, Chaste Berry, and others, believed to regulate menstrual cycles, balance hormones, and improve fertility (Forthingham, 2020).

When seeking treatment, patients should consider the symptoms of irregular menstrual cycles, acne, hirsutism, weight gain, and, for married women, infertility. Addressing these symptoms often involves managing insulin resistance and regulating hormones. Initial steps should include dietary changes: avoiding processed or preserved foods, incorporating whole foods, and balancing carbohydrates and proteins. Additionally, the diet should include sources of healthy fats such as olive oil, fatty fish, and tree nuts. Ensuring adequate intake of iron, magnesium, and fiber is also crucial (Watson, 2023).

Besides all this there are some religious practices that are done for the treatment of some symptoms of PCOS. ‘It is guided by some religious Islamic scholars that recitation of Surah Al- Fatiha helps in the cure of menstrual cycle irregularity. Fasting in the month of Ramadan also lesson the stress and help in weight balance. The verses for the cure of infertility due to PCOS are the verses of Surah Al- Bakarah, the translation of that surah is in surah 21: 89–90, Allah says: “And (remember) Zakaria, when he cried to his Lord: “O my Lord! Leave me not without offspring, though Thou are the best of inheritors.” So we listened to him and granted

him Yahya (John). We cured his wife (barrenness) for him.” Similarly, the Prophet PBUH says: “Marry the kind and fertile women who will give birth to many children for I shall take pride in the great numbers of my ummah” (Nation) (Al-Bar et al., 2015; Altman, 2023; Deanna & Sachdev 2023; Forthingham, 2020; Society, 2008).

Materials and Methods

The researcher utilized anthropological research methods, specifically employing a descriptive approach covering Case Studies, In-depth interviews, and life histories. The study has provided detailed descriptions of these tools to explore the research questions (Singh, 2023). Case studies and life histories made it possible to gather thorough and specific information from a variety of sources, including observations, interviews, and documents, to have a deeper comprehension of the instances that were being investigated (Shahzad et al., 2017). Furthermore, the case study method was especially helpful for examining complicated or unusual phenomena in the real-world settings surrounding PCOS, providing insights into behaviors, processes, and outcomes that might not be captured through other research methods and offering workable solutions to particular problems or challenges faced by women with PCOS (Rashid et al., 2019).

Materials and Methods

For the present research, the research made use of purposeful sampling based on understanding of the study’s objectives. Firstly, female obstetric patients within a larger group of gynecology patients were identified. The focus was then narrowed to those diagnosed with Polycystic Ovary Syndrome (PCOS), as determined by their Luteinizing Hormone (LH) test and abdominal ultrasound results, reviewed by physicians. The study specifically targeted married women experiencing infertility who were in their reproductive age and unmarried women who had reached puberty and were 14 years old and above. Given the qualitative nature of the study, a large sample size was not required. A total of 20 in-depth interviews, 06 case studies & 03 life histories were conducted.

Results and Discussion

Relationship between Occupation and Household Income

The correlation analysis revealed a significant relationship between the two variables in the socio-economic survey: occupation and household income, as shown in Table 1. Socio-economic status has been linked to Polycystic Ovary Syndrome (PCOS). Specifically, women from lower socio-economic backgrounds were found at a higher risk of developing PCOS, which is often exacerbated by financial stress. Additionally, women who experienced low socio-economic status during childhood were also at increased risk (Azziz, 2011).

Table 1: Table showing Relationship between Occupation and Household Income

Household Income	Pearson Correlation	.203*	1
	Sig. (2-tailed)	.015	
	N	143	143

*. Correlation is significant at the 0.05 level (2-tailed).

PCOS Patient's: Family type and their interpersonal relationships

The correlation analysis of the socio-economic survey indicated a significant relationship between the variables of household members and family structure, as presented in Table 2. The study found that common family types were joint, nuclear experiencing childlessness associated with Polycystic Ovary Syndrome (PCOS). The type of family structure can influence the management of PCOS symptoms, either positively or negatively, depending on the support network and coping mechanisms available to the patients (Stephens, 2006).

Table-2: Table showing Relationship between Members in Household and Family Type

**. Correlation is significant at the 0.01 level (2-tailed).

Relationship between Marital Status of PCOS Patients and Family Type

The correlation analysis revealed a significant relationship between marital status and family type, as illustrated in Table 3. This analysis indicated that married patients, particularly those living in joint family structures, experience higher levels of stress related to infertility compared to their unmarried counterparts. In cultures where fertility is highly valued as a marker of femininity, married women with PCOS face greater stress due to societal pressure and cultural expectations than unmarried women (Mumtaz & Salway, 2007).

From a socio-cultural perspective, patients with PCOS, particularly those experiencing infertility, face significant challenges in societies where fertility is equated with femininity. PCOS patients encounter complex difficulties shaped by cultural attitudes, societal expectations, and gender norms. The condition often carries considerable stigma due to its association with infertility and irregular menstrual cycles. Women with PCOS may feel pressured to conform to traditional maternal roles, leading to feelings of inadequacy and social isolation. Additionally, cultural beliefs and misconceptions about PCOS can impact their willingness to seek treatment and adhere to medical recommendations. To enhance the well-being and quality of life for PCOS patients, it is essential to address these socio-cultural factors through education, awareness campaigns, and culturally sensitive healthcare practices (Dunaif, 2017).

Qualitative Findings

Thematic categories were extracted from qualitative in-depth interview, case studies and life histories. Thematic analysis is presented in subsequent headings surrounding women with PCOS. Qualitative analysis of the 20 respondents revealed 05 main themes : 1) “Link between PCOS and Stress”; 2) “Stress of PCOS Associated with Previous Medical History”; 3) “Stress

Linked with Symptoms of PCOS and Societal Response” ; 4) “Straining Marital Relationship: PCOS, Painful Sexual Experiences”; and 5) “Reliance on Ethno-Medicinal Treatment and Spiritual Engagement”. The study found that existing literature on PCOS is more generalized and needs to be contextualized to have local insights into the problem. This study’s findings not only resonate with existing literature but also attempts to bridge the gap in capturing experiences of women of reproductive age group in accessing care in localized context. Nearly all participants connected “stress” with PCOS. Women with PCOS experienced barriers to care, structural violence, stigma and mental health, meaninglessness in life, historical experiences or traumas and negative societal trends of husbands, in-laws and overall society. It draws our attention to the dominance of traditionality and lack of information at multiple ends. In this context, there is a continued need for awareness and access to information and health facility to be addressed in reproductive health policy to lessen the burden of PCOS and associated mental and wellbeing issues among women of reproductive age group. Some of the socio-cultural perceptions faced by PCOS patients are presented in the subsequent sections.

Link between PCOS and Stress

Stress prior to having PCOS

The theme brings together many challenging concerns related to PCOS among both married and unmarried women. Study found that excessive stress among such women led to significant hormonal disturbances. Studies found that chronic stress disrupts the delicate balance of hormones involved in ovarian function, such as cortisol and insulin, which are already dysregulated in PCOS. Stressors can range from psychological factors, such as work pressure or emotional strain, to physical factors, such as illness or inadequate sleep. These stressors can exacerbate insulin resistance a common characteristic of PCOS and further impair ovarian function, resulting in irregular menstrual cycles and ovarian cyst formation. Additionally, heightened stress may aggravate PCOS symptoms, including weight gain and acne (Chaudhuri, 2023; Dokras, 2011).

Majority of the participants reported experiencing considerable stress before the onset of PCOS symptoms. For instance, one respondent described significant familial stress, attributing it to difficulties in adjusting to her in-laws and mistreatment from the beginning of her marriage. Another respondent noted that a stressful home environment exacerbated her condition, stating that she only found relief when away from home. These observations suggest that individuals who face elevated stress levels or live in high-stress environments may be more prone to hormonal imbalances, which can contribute to chronic conditions such as PCOS.

Stress of PCOS Associated with Previous Medical History

Since many deliberations were about the relationship between the previous medical history of the respondents with PCOS. Many respondents reported an increase in negative mental health associated with their previous medical history that was perceived to have an impact on having PCOS, one respondent was of the view that stress of any previous chronic disease also cause hormonal imbalance. Similar findings were stated in a study that chronic diseases preceding PCOS can induce stress responses that exacerbate hormonal imbalances and contribute to the development or worsening of PCOS symptoms. The psychological burden of managing chronic diseases alongside PCOS can compound stress levels, impacting overall health and well-being (Huang, 2016). Related to PCOS, most of the participants spoke about it with the following expressions.

One of the respondents shared that,

"I was experiencing constipation over the past 3-4 years, accompanied by severe abdominal pain, a sensation of stretching during bowel movements, and the presence of blood in the stool due to having PCOS" (IDI-UM3).

A carrier of minor thalassemia, indicated her problem in the following manner,

"I was having persistent anxiety about her condition led to hormonal imbalances, which contributed to the development of PCOS" (IDI-UM7).

A 20-year-old respondent narrated that,

"I was suffering from H. pylori infection, noting that the heavy medications required for treatment caused hormonal disruptions, which also resulted in PCOS" (IDI-UM10).

Majority of the respondents of the study mentioned hormonal disturbances due to their pre-existing conditions, which ultimately contributed to the onset of PCOS. In summary, this discussion underscores those various diseases, whether chronic or not, can cause significant hormonal disturbances. Furthermore, treatments for certain conditions can exacerbate these hormonal imbalances, potentially leading to the development of PCOS.

Stress Linked with Symptoms of PCOS and Societal Response

The symptoms of PCOS such as obesity, hirsutism, hair loss, acne, irregular menstrual cycles, and infertility can significantly impact an individual's self-esteem and mental well-being. The societal pressures associated with beauty standards and fertility expectations can intensify these effects. As a result, PCOS patients often face heightened stress due to both the physical manifestations of the condition and the societal stigma and criticism they encounter. The societal expectations related to fertility and body image can further exacerbate feelings of inadequacy and isolation among affected individuals. The pressure to adhere to traditional feminine roles and the stigma surrounding reproductive health issues contribute to the emotional strain experienced by those with PCOS (Benson et al., 2009; Chaudhuri, 2023; Damone et al., 2019).

Body Image Distress due to PCOS

The symptoms of PCOS including hirsutism, hair loss, and acne, and obesity can contribute to a sense of inferiority among affected individuals, leading to increased stress. These visible symptoms frequently clash with societal beauty standards, resulting in feelings of inadequacy and reduced self-esteem. The pressure to conform to traditional beauty ideals can intensify the psychological burden experienced by women with PCOS, often resulting in elevated levels of anxiety and depression.

Patients, whether married or unmarried, commonly experienced stress related to these visible symptoms. For example, one patient noted that her obesity and facial hair led to the rejection of her initial marriage proposal, exacerbating her concerns about her appearance and deepening her sense of inferiority. In summary, the visible manifestations of PCOS, such as hirsutism,

obesity, acne, and hair loss, often draw societal criticism and stigma. This external scrutiny can contribute to a pronounced inferiority complex regarding personal appearance, significantly increasing the stress experienced by those affected.

PCOS, Infertility, and Irregularity of Menstrual Cycle

In cultures where fertility is highly valued as a marker of femininity, infertility becomes a significant issue, leading to the development of numerous social stigmas surrounding this condition. These stigmas contribute to the stress experienced by patients. The irregularity of menstrual cycles or severe menstrual cramps can heighten stress and anxiety related to the fear of infertility, often exacerbated by societal myths and expectations.

In such cultural contexts, the expectation for women to fulfill traditional maternal roles places additional pressure on those unable to conceive. This inability to achieve pregnancy can result in social stigma, criticism, and increased pressure from family and community members, further compounding the emotional distress experienced by women with PCOS. The societal demand for normative reproductive health intensifies stress related to irregular menstrual cycles and contributes to the overall negative impact on the mental health and well-being of affected individuals (Bai & Ding 2019).

The data gathered from the study reveals that nearly all married individuals with PCOS experience infertility, with only 1% reporting a diagnosis of PCOS after childbirth. Both married and unmarried patients frequently encounter challenges with irregular or painful menstrual cycles. For instance, one respondent, who had been married for six years, reported an inability to conceive due to PCOS, accompanied by painful periods and frequent watery discharge causing considerable discomfort. Another respondent experienced divorce after three years of marriage, attributing it to infertility. Additionally, a divorced respondent described a severe episode of menstrual pain following a four-month gap, which required an emergency hospital visit.

These observations indicate that irregular menstrual cycles, which can occur as often as twice a month or as infrequently as every four to six months, are a significant source of stress. Moreover, societal stigmas associated with infertility often lead to negative social consequences, such as divorce, which further exacerbates stress among affected women.

PCOS and Women Lifestyle

Unhealthy lifestyle and bad routine habits lead to adverse changes in the body metabolism, causes hormonal disturbance which can lead to chronic diseases like PCOS. ‘PCOS can be influenced by unhealthy lifestyle and routine habits, such as poor diet, lack of exercise, and irregular sleep patterns. These habits can contribute to obesity and insulin resistance, which are key factors in the development and exacerbation of PCOS symptoms. A diet high in processed foods and sugars can lead to weight gain and insulin spikes, aggravating hormonal imbalances. Sedentary lifestyles further worsen these effects, as physical inactivity is associated with higher insulin resistance. Irregular sleep patterns and chronic stress also disrupt hormonal regulation, exacerbating PCOS symptoms’(Marshall, 2020).

When discussing lifestyle changes appeared to be a relevant issue. When asked about its relevance some patients reported having PCOS due to their bad routine and bad eating habits, one respondent named Salma responded definitively, she said:

"I used to sleep at 4:00 am in the morning and wake up at 2:00 pm in the afternoon. In breakfast I use to have a cup of tea with some rusks and then I had meal at 9:00 pm at night. Later I was diagnosed with irregular periods and infertility" (IDI-UM2).

There was another respondent Misbah who described her PCOS issue in the following manner.

"I used to work online till late night for 10 hours with a habit of eating fast food. Later I was diagnosed with PCOS due to irregular periods and obesity" (IDI-UM6).

Likewise, there were many other patients from the study sample who were experiencing a disturbed routine coupled with bad eating habits ultimately leading to PCOS. Such findings endorsed that sedentary lifestyles, insomnia and bad food habits lead to worst metabolic and hormonal changes that causes PCOS.

Low Socio-economic Status and PCOS

PCOS patients with low Socio-economic status feel difficulty in getting treatment and having healthy diet due to financial crisis. Low socio-economic status (SES) is closely linked to the prevalence and severity of PCOS due to limited access to healthcare, nutritious food, and health education. Women from lower SES backgrounds often face barriers in obtaining timely and effective medical care, which can lead to delayed diagnosis and inadequate management of PCOS. Financial constraints may limit their ability to purchase healthy foods, leading to diets high in processed foods and low in essential nutrients, exacerbating insulin resistance and obesity associated with PCOS. Furthermore, stress related to financial instability and poor living conditions can worsen hormonal imbalances and PCOS symptoms (Marzullo, 2019).

There were approximately fifty to sixty percent patients from the sample who were from low socio-economic status making it very hard for them to get treatment, majority of them were married and had infertility issues.

One respondent named Sana 30 years of age reflected on the severity of the problem in the following way,

"My husband is the only one who makes money in our household, so it is very difficult for me to get treatment. Should we eat or should we get treatment in such inflation?" My in-laws "do not understand and always criticize me for infertility." (IDI-M13)

While another respondent Malika 32 years of age reported that,

"I had faced a low socio-economic position since childhood, and my family lived in constant stress owing to financial hardships. I also suffered from severe baldness and had last menstruation seven months ago" (IDI-UM5).

She claimed that it is very difficult for her to receive PCOS treatment owing to the financial crunch of the family and overall inflation. She was just receiving medication for PCOS related to hair loss since she was unmarried.

From these cases it can be safely concluded that low socio-economic status has a direct link with cure of PCOS. Having low status causes stress and it becomes difficult for the patients to get treatment, knowledge and healthy diet or supplements suggested by the physicians. Many participants spoke of having access to quality health and awareness surrounding the myths and stigma related to PCOS and increasing community-based knowledge around mental health and wellbeing issues is essentially important where women cannot openly talk about their health concern and do not have free access to health care facility. Medical facilitation needs to be provided at their doorsteps.

Straining Marital Relationship: PCOS, Painful Sexual Experiences

Straining Marital Relationship: PCOS, Painful Sexual Experiences is a theme that was developed to reflect the underlying stress connections of a married women with their partners. Researchers have shown that in married women who are diagnosed of PCOS had to face painful intercourse and the is more than normal which make them mentally disturbed that they were not mentally ready for that but if they refuse, they had to face strain in their relationship. 'PCOS patients often face criticism and strain in their marital relationships due to dyspareunia, or painful intercourse, which is a common symptom of the condition. This pain can be caused by hormonal imbalances, ovarian cysts, or vaginal dryness associated with PCOS. Such issues can lead to reduced sexual satisfaction and intimacy, causing frustration and misunderstanding between partners. Husbands may not fully understand the medical complexities of PCOS, leading to unwarranted criticism or feelings of rejection. This can exacerbate the emotional stress and mental health challenges faced by women with PCOS (Zhang, 2019).

There were some married women who participated in this study complained about having misunderstanding with their partner and mental disturbance due to painful sexual experiences.

One respondent Samra, 35 years of age reported that,

"My husband has threatened me of second marriage if I do not have a satisfying sex with him". She further said that "my husband works in a public hospital for night duty, we only had a met up at weekends so, my husband gets angry that after a week I came and you are not ready and refusing me, for this reason we were having complexities in our relationship" (IDI-M14)

Such cases signify that PCOS causes misunderstanding and complexities in marital relationships due to painful sexual relationships. The patients do not feel mentally satisfied because of pain and it causes emotional distress and strain in their relationship.

Case Study 1: Women with PCOS facing Societal Pressure

In this case, a 26-year-old patient Wajiha, who was married for six years, has struggled with infertility issues. Over a span of two to three years, she experienced a significant weight gain from 52-79 kgs, despite having a height of 5'6". Her infertility issues led to painful sexual experiences and considerable mental distress. Her husband threatened to give her divorce and going for a second marriage on this stance her in-laws offered no support. To manage her stress, she began working as a teacher at a school, with additional evening teaching at a coaching academy and taught Quran at a local center. Her busy schedule helped her to avoid dwelling on societal negativity. She acquired substantial information about PCOS through online

research, although she still experienced hidden stress related to infertility and obesity, she found ways to cope up.

This case underscores that PCOS not only leads to infertility but also significantly heightens stress due to societal pressures. The patient's experience illustrates how societal expectations surrounding fertility and parenting, which are often regarded as central to a woman's identity and social role, can intensify psychological distress. Such pressures from family, friends, and society can exacerbate the emotional difficulties associated with PCOS, affecting overall mental health and wellbeing (Helm, 2017).

Case Study 2: PCOS, Infertility, and Divorce

Another 25 years patient Noureen 5'4" tall women experienced considerable weight gain of 72 kgs was diagnosed with PCOS four years ago. She was still struggling with this condition since she was 19 years old. Despite having PCOS before marriage, she did not disclose it to her fiancé, nor did she seek any kind of treatment initially. After three years of marriage, her husband remarried, leading to their divorce, which was attributed to infertility aimed PCOS. The patient experienced significant emotional trauma following the separation but later engaged in a nursing course at a local hospital as a means of coping.

Her diet predominantly consisted of fast food and soft drinks, and she frequently ruminated on her situation. She received medical treatment, including injections, and was advised to follow an exercise regimen and a structured routine, which she found challenging. The patient reported mood swings and irregular menstrual cycles. Through her nursing course and social media research, she gained extensive knowledge about PCOS.

This case study underscores that overcoming excessive worry and adhering to medical advice are crucial for managing PCOS. Effective management of PCOS requires the patient's commitment to following physician recommendations and maintaining a healthy lifestyle, including a balanced diet. Women with PCOS may face significant marital strain due to infertility, which can lead to divorce in many cultural contexts. Fertility is often highly valued and considered essential for marital stability and fulfillment. Infertility related to PCOS can result in not only personal distress but also substantial societal and familial pressure, exacerbating tensions and potentially leading to marital dissolution (Alnaeem, 2019).

Case Study 3: Stressful Environment, low Socio-economic Status and treatment of PCOS

Another patient Amina, a 25-year-old woman was diagnosed with PCOS a year ago when she was preparing for marriage in a few months. She has faced significant socio-economic challenges throughout her life, which have contributed to her PCOS diagnosis. The stress associated with her financial difficulties and educational struggles has exacerbated her condition.

The patient reported an absence of menstruation from the previous eight months, with her periods now extending beyond two weeks. She also experienced severe hair loss and academic pressure, as she was currently pursuing a bachelor's degree. Additionally, she reported emotional distress related to her marriage and ongoing familial conflicts associated both with her studies and PCOS.

Despite applying various treatments, such as topical oils and natural remedies, her hair loss persisted. She has been prescribed supplements and medications to regulate her menstrual cycles but is facing financial strain in affording these treatments. The patient had adopted a healthier lifestyle, including improved dietary habits, and has sought information about PCOS from peers and social media.

This case highlights the impact of socio-economic status on the development and management of PCOS. Low socio-economic status (SES) is a significant stressor that can both contribute to and exacerbate PCOS. Women from lower SES backgrounds often experience chronic stress due to financial instability, limited healthcare access, inadequate nutrition, and poor living conditions. This case underscores the importance of addressing socio-economic factors and maintaining focus on personal health goals despite external challenges (Baghla, 2023).

Life History of A PCOS Patient

Areeba, was diagnosed with PCOS one year ago. Currently she was 22 years old. She was born in a low socio-economic household. Despite financial constraints, her parents ensured that she and her two brothers received education from a local school and later from a college located in the city. Areeba got married at the age of 19 while pursuing her graduation. Her father, who had worked in Saudi Arabia for many years, had returned permanently to Pakistan by the time she got married. During her marriage, Areeba encountered several challenges. Her in-laws mistreated her and tried to keep her from her husband by causing controversies. Her husband did not show any support either. This led to a fight between the couple. Areeba contracted an *H. pylori* infection, which worsened due to lack of treatment. She told her in-laws and husband about these problems, but they did not believe her. On the basis of misunderstanding and noncooperation she often returned to her parents' house where she also endured terrible mistreatment, including an attempted suicide by her mentally sick sister-in-law.

Areeba's marriage lasted only three months, and she suffered from serious emotional stress. She experienced irregular menstrual periods and obesity, which resulted in a combined diagnosis of PCOS and *H. pylori* infection. After having divorce, she sought help from a psychologist later she is working at a local hospital. Over time, she has made significant progress in managing her stress related to PCOS. This case underscores that low socio-economic status is closely linked to PCOS. Additionally, severe traumatic experiences can lead to hormonal imbalances that contribute to chronic conditions such as PCOS. Trauma-induced stress can disrupt the hypothalamic-pituitary-adrenal (HPA) axis, leading to elevated cortisol and androgen levels, which are associated with PCOS. Furthermore, stress from trauma may lead to unhealthy behaviors, such as overeating or physical inactivity, which exacerbate conditions like obesity and insulin resistance that are commonly linked to PCOS (Cooney 2017).

Reliance on Ethno-Medicinal Treatment and Spiritual Engagement

In anthropology ethno-medical treatment refers to treatments other than bio medical treatment. 'Ethno-medical treatments for PCOS encompass a range of traditional and cultural practices that communities utilize to manage symptoms and improve wellbeing. These practices often include herbal remedies, dietary modifications, and lifestyle adjustments that have been passed down through generations and rooted in cultural beliefs. For example, in some cultures, specific herbs or teas are believed to regulate menstrual cycles or alleviate symptoms like hirsutism.

Dietary changes may focus on avoiding certain foods or incorporating others believed to have therapeutic benefits' (Acharya, 2021),

The sample data indicates that many PCOS patients have utilized various home remedies in addition to conventional medical treatments. For instance, one respondent mentioned that her mother prepared fresh vegetable juices specifically for managing PCOS. Others reported using specialized herbal teas or drinking ample water, which they believe helps in reducing stress. Many patients have incorporated regular exercise and adopted healthier dietary practices to improve their condition. One participant noted using a mixture of besin (gram flour) and shahad (honey) as a topical treatment for acne.

Additionally, some patients integrate religious practices into their treatment regimen. For example, one individual recited Surah Al-Fatehah seven times over water and consumed it, believing it would aid in her recovery. Another patient mentioned reciting Surah Yaseen and Manzil, expressing her faith in Allah's ability to cure her. Delay in seeking treatment connects the patients with unqualified practitioners and Pirs (saints) who provide them amulets or special waters, often further complicating the management of PCOS.

These findings suggest that alongside medical treatments, ethno-medicinal approaches, including home remedies, exercise, balanced diet, and religious recitations, play a significant role in managing PCOS. Such integrative practices appear to complement conventional therapies and contribute positively to the overall treatment strategy for PCOS.

Conclusions

Socio-culture encompasses the interplay of social and cultural factors that shape human behavior, beliefs, and interactions within a community. Present research focused on how cultural, social, influence health, illness, and healthcare practices surround women with PCOS by specifically addressing social stigmas associated with PCOS. Societal criticism contributes to heightened stress among patients, exacerbating their condition. Particularly, individuals with low socio-economic status and low education were severely affected by the problem. Moreover, these condition presents numerous societal challenges that affect both personal identity and relationships of women and their experiences remain untapped. Married women often face societal judgment regarding infertility, while unmarried women grapple with fears of future infertility and concerns about beauty standards related to PCOS. Patients with PCOS frequently feel ashamed to discuss their condition openly which delays their consultation with healthcare professionals and leads to more severe complications. Cultural practices, including reliance on home remedies and treatments from unqualified practitioners, such as those providing amulets or special waters, often further complicate the management of PCOS. To reduce the burden of PCOS and its sensitization, education and public awareness programs are direly needed at all levels.

Abstract: Polycystic ovary syndrome (PCOS) is a complex endocrine disorder affecting the reproductive, metabolic and psychological health of women. Clinic-based studies indicate that sleep disturbances and disorders including obstructive sleep apnea and excessive daytime sleepiness occur more frequently among women with PCOS compared to comparison groups without the syndrome. Evidence from the few available population-based studies is supportive. Women with PCOS tend to be overweight/obese, but this only partly accounts for their sleep problems as associations are generally upheld after adjustment for body mass index; sleep problems also occur in women with PCOS of normal weight. There are several, possibly bidirectional, pathways through which PCOS is associated with sleep disturbances. The pathophysiology of PCOS involves hyperandrogenemia, a form of insulin resistance unique to affected women, and possible changes in cortisol and melatonin secretion, arguably reflecting altered hypothalamic–pituitary–adrenal function. Psychological and behavioral pathways are also likely to play a role, as anxiety and depression, smoking, alcohol use and lack of physical activity are also common among women with PCOS, partly in response to the distressing symptoms they experience. The specific impact of sleep disturbances on the health of women with PCOS is not yet clear; however, both PCOS and sleep disturbances are associated with deterioration in cardiometabolic health in the longer term and increased risk of type 2 diabetes. Both immediate quality of life and longer-term health of women with PCOS are likely to benefit from diagnosis and management of sleep disorders as part of interdisciplinary health care.

Keywords: polycystic ovary syndrome, sleep, sleep disturbance, hypothalamic-pituitary-adrenal, cardiometabolic health

Introduction

Polycystic ovary syndrome (PCOS) is a complex endocrine disorder with implications for reproductive, psychological and metabolic health. Despite first being identified in the 1930s, recognition of an association between PCOS and sleep disturbances is relatively recent. A search of the PubMed database indicates that the majority of research on this topic has been published after 2005 and the body of work remains quite small (Figure 1).

In this review, we first provide an overview of PCOS and summarize the clinical and epidemiological literature pertaining to sleep disturbances and disorders among women with the condition. The pathways through which PCOS may influence sleep are then described in detail, focusing on the endocrine, psychosocial and behavioral characteristics that are often present among women with PCOS, drawing attention to probable bidirectional relationships (Figure 2). Current knowledge about the long-term

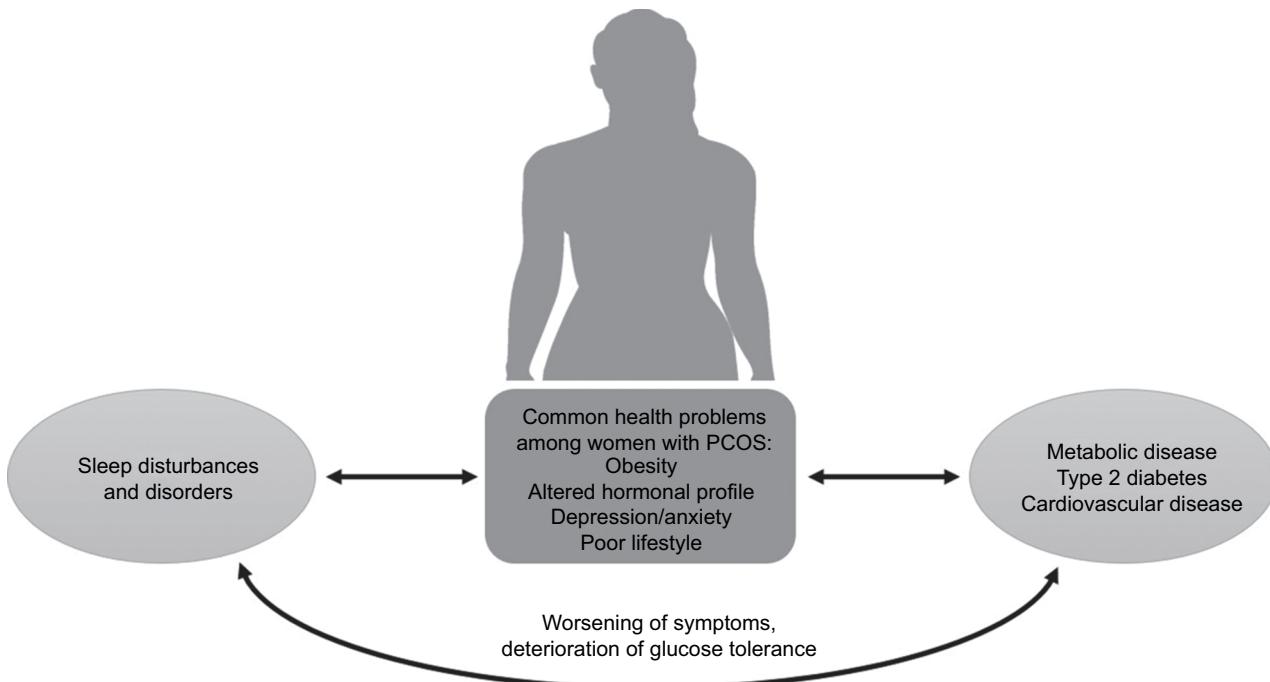

Figure 2 Summary of the bidirectional pathways through which PCOS interacts with sleep disturbances, with potentially detrimental effects on long-term cardiometabolic health.

Abbreviation: PCOS, polycystic ovary syndrome.

consequences of PCOS for cardiometabolic health is outlined as well as the potential contribution of impaired sleep to deterioration of health profiles.

Polycystic ovary syndrome

PCOS is an endocrine disorder that manifests in an array of symptoms that varies from one woman to another.¹ This

heterogeneity has hampered the definition of the syndrome, etiological research, recognition in clinical practice and appropriate treatment and support for women.

PCOS was first recognized as a clinical entity in the 1930s. At that time it was named Stein–Leventhal syndrome, after the two clinicians who first reported the disorder in seven women who presented with hirsutism, amenorrhea and

enlarged bilateral polycystic ovaries, along with obesity.^{2,3} Once considered a reproductive disorder acquired by adult women, it is now widely accepted that PCOS is a lifelong metabolic condition.⁴

Features of the syndrome classically emerge during puberty, but diagnosis can be difficult because irregular menstruation is common in normal development.^{1,5} Excess body hair accumulates gradually, reflecting increasing duration of androgen exposure. Some girls (and women) with PCOS have severe acne vulgaris (predominantly on the lower face, neck, chest and upper back).¹

Historically, recognition of PCOS by clinicians was erratic.^{6,7} In addition, reluctance to seek medical advice (e.g. due to embarrassment) meant that many women did not receive a diagnosis until they sought fertility treatment, or lifelong.⁸ Undiagnosed PCOS is still relatively common.⁹

Currently, there are three sets of criteria for diagnosing PCOS, summarized in Figure 3. Differences between the criteria reflect controversy about the pathogenesis of PCOS and the different forums in which experts' opinions were canvassed.³ In 1990, experts at a conference sponsored by the US National Institutes of Health (NIH) produced the first attempt at defining PCOS clinically. The NIH criteria specify (in order of importance) that clinical and/or biochemical signs of hyperandrogenism should be present as well as oligo- or anovulation (i.e. irregular or no periods).¹⁰ In 2003, the European Society of Human Reproduction and Embryology and the American Society for Reproductive Medicine produced a statement, known as the Rotterdam criteria, specifying that two out of the following three must

be met for a diagnosis of PCOS: clinical and/or biochemical hyperandrogenism, oligo- or anovulation and polycystic ovaries on ultrasound.¹¹ In 2006, the Androgen Excess Society (AES) Taskforce produced criteria specifying that hyperandrogenism must be present for diagnosis, in addition to either oligo- or anovulation or polycystic ovaries on ultrasound (or both).¹² There have been several attempts to subclassify the syndrome using clinical and metabolic criteria, without universal agreement.^{3,13}

All diagnostic criteria specify that diagnosis of PCOS should only be made after exclusion of other endocrine disorders including congenital adrenal hyperplasia, androgen-secreting tumors, Cushing's syndrome, thyroid dysfunction and hyperprolactinemia. Early studies of women with PCOS suggested they had elevated prolactin, and explored overlap in symptoms between hyperprolactinemia and PCOS, but these are now considered to be two distinct conditions.^{14–18}

Beyond the enlargement of ovaries originally noted by Stein and Leventhal,² ovaries with multiple cysts (follicles with arrested development) have other features, including a thickened covering capsule and greatly increased stromal tissue. The thecal and stromal layers produce excess androgen, and this led to the view that pathogenesis is primarily ovarian.¹⁹ While recognizing wider metabolic involvement, the AES takes the position that PCOS is primarily a disorder of hyperandrogenism.¹² Lack of consensus on this matter persists because hormone signaling has a major role in systems such as the hypothalamic–pituitary–adrenal (HPA) axis, so the disorder could have a central origin, and there are conflicting results from interventions in which androgens were

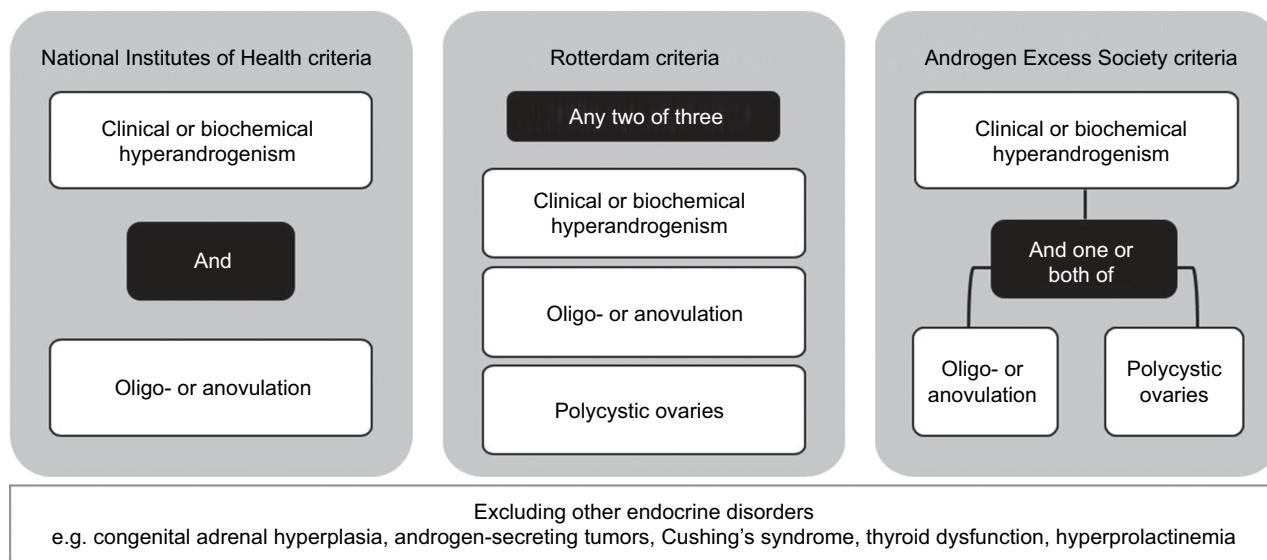

Figure 3 A summary of the three sets of criteria for the diagnosis of PCOS: the National Institutes of Health criteria (1990),¹⁰ the Rotterdam criteria (2003)¹¹ and the Androgen Excess Society criteria (2006).¹²

Abbreviation: PCOS, polycystic ovary syndrome.

reduced in women with PCOS.³ Additionally, constructive debate is impeded by lack of a reliable assay designed to measure androgens in the range relevant to women, approximately one-tenth that of men.^{20,21}

Research undertaken in the 1980s demonstrated insulin resistance in women with PCOS, underpinning the alternative view that this is the cardinal feature of the syndrome, with hyperinsulinemia causing hyperandrogenemia and anovulation.³ Even lean women with PCOS generally have insulin resistance of an intrinsic form,²² which appears to be the result of a defect in post-binding insulin signaling that disturbs metabolic but not mitogenic functions.²³ This abnormality appears unique to PCOS, as it has not been observed in other conditions of insulin resistance, including obesity and type 2 diabetes.²⁴ Thus, when women with PCOS have high body weight, they are affected by both intrinsic and extrinsic insulin resistance.³ PCOS has recently been conceptualized as a condition of severe metabolic stress,²⁵ a position that we support as it provides a way to account for the pervasive molecular and biochemical derangements that occur in PCOS and variation in symptom profiles.

Clustering of diagnosed PCOS and isolated hormonal and metabolic symptoms within families supports a genetic component to the etiology of PCOS;²⁶ however, phenotypic variation suggests that multiple genes are involved.²⁷ Familial and cohort studies have identified numerous gene loci as candidates for conferring susceptibility to PCOS. These include polymorphisms in loci associated with androgen receptors and with insulin signaling. For many of the candidate loci, it remains unclear as to how they relate to specific PCOS characteristics.²⁷

Support for fetal or early life origins of PCOS stems from animal models in which exposure to androgen excess, or growth restriction or acceleration, has produced symptoms of PCOS.^{3,28} It is unlikely that maternal androgens reach the fetus in human pregnancies, although fetal ovarian androgen production is possible.³ Birth phenotypes in humans have consistently been associated with insulin resistance, type 2 diabetes and the metabolic syndrome.^{29–32}

While we accept a genetic contribution, our research^{33,34} is premised on interactions with the fetal environment producing epigenetic changes that culminate in PCOS.³⁵ Hypothesized “programming” of metabolic function is not simply about growth of the fetus or size at birth, although these are overt signs of perturbed development in utero.³⁶ A range of conditions, including maternal under- and overnutrition and mental distress, can inhibit the activity of an enzyme in the placenta (11 beta-hydroxysteroid dehydrogenase) that is

critical to reducing fetal exposure to maternal glucocorticoids.³⁷ Through this process, it is proposed that overexposure of the fetus alters the set points and function of the HPA axis, with profound implications for metabolism.

Uncertainties about PCOS also persist because it is difficult to study in representative population-based samples of women. Obtaining self-reports of doctor-diagnosed PCOS will result in misclassification of a substantial proportion of women as unaffected. Some symptoms can be reported reliably but others require invasive tests, and the sensitive nature of symptoms may affect participation. Thus, few studies with community-based samples have been undertaken to date, although clinic-based samples have been reported on extensively.

We retrospectively established a birth cohort of Australian women using records from a large maternity hospital.⁹ We traced over 90% of 2199 female babies three decades after they were born. Around half of the young women who were eligible joined the study and completed an initial interview in which medical and reproductive history, including symptoms of PCOS, were reported. Women were asked to provide a blood sample for assessment of free testosterone. Those with evidence of both hyperandrogenism and oligo- or anovulation were classified as having PCOS as per the NIH criteria. Women with one or both of those two symptoms were referred to a clinic for ovarian ultrasound so that we could apply the Rotterdam criteria. The prevalence of PCOS was $8.7 \pm 2.0\%$ with NIH criteria, $11.9 \pm 2.4\%$ with Rotterdam criteria assuming those who did not consent to ultrasound did not have cystic ovaries and $17.8 \pm 2.8\%$ with Rotterdam criteria using multiple imputation for missing ultrasound data. Over two-thirds of those classified as having PCOS had not been diagnosed previously.

Sleep disturbances and disorders and PCOS

Sleep disturbances include altered sleep duration, delay of sleep onset, difficulty in maintaining sleep or awakening early.³⁸ Insomnia is defined as impairment in the ability to initiate or maintain sleep, including extended periods of wakefulness during the night. Chronic insomnia disorder is diagnosed when insomnia occurs at least three nights per week and for at least three months.³⁹ Obstructive sleep apnea (OSA) is characterized by frequent cessations of breathing during sleep and may occur along with other sleep disturbances.⁴⁰ Clinically, OSA is diagnosed by detecting the frequency of events that are apneic (no airflow for 10 seconds) and hypopneic (decreased airflow for 10 seconds

associated with either an oxyhemoglobin desaturation or an arousal detected by electroencephalography), as per the apnea–hypopnea index (AHI). A diagnosis of OSA is made when AHI is ≥ 15 or when AHI is ≥ 5 with symptoms such as daytime sleepiness, loud snoring and witnessed breathing interruptions.⁴¹

Sleep disturbances and disorders have repercussions for daytime mood, cognition and psychomotor functioning,⁴² which acutely affect well-being and daily activities, and can inhibit performance in roles such as that of parent or employee.^{43,44} Aspects of cognition that appear most affected are attention, executive function and working memory,^{42,45} with significant implications for productivity.⁴⁴ Fatigue, attention deficits and psychomotor impairment can affect safety, increasing the risk of workplace and motor vehicle accidents.⁴² Thus, poor sleep represents a serious health problem.

As mentioned, it is difficult to study PCOS in representative population-based samples; so evidence concerning the prevalence of sleep disturbances and disorders across the full spectrum of PCOS severity is limited. We identified only three such studies (Table 1), summarized here, each supporting an excess of sleep disturbances and disorders in women with PCOS that was not accounted for by obesity.

Two studies have drawn on the Taiwan National Health Insurance Research Database in which PCOS and sleep

disorders were recorded using International Classification of Diseases codes (and thus required recognition and formal diagnosis).⁴⁶ In a longitudinal design, data for women with PCOS ($n = 4595$) and a comparison group of women matched for age ($n = 4595$) were assembled over 2–8 years. Women with PCOS had greater incidence of OSA (1.71 vs 0.63 per 1000 person-years), a difference not due to obesity or demographic characteristics (adjusted hazard ratio [HR] = 2.6, 95% confidence interval [CI] 1.6–4.0). In the second study, sleep disorders excluding OSA were considered as part of an investigation of PCOS and psychiatric disorders.⁴⁷ Over a 10-year period, compared to an age-matched comparison group of women ($n = 21,724$), those with PCOS ($n = 5431$) were 50% more likely to be diagnosed with a sleep disorder (HR = 1.5, 95% CI 1.2–1.9).

In the community-based cohort of Australian women that we undertook, sleep disturbances were self-reported using a modified version of the Jenkins questionnaire,⁴⁸ by 87 women with PCOS (as per Rotterdam criteria) and 637 women of similar age.⁴⁸ Sleep disturbances, specifically difficulty falling asleep (odds ratio [OR] = 1.9, 95% CI 1.3–3.0) and difficulty maintaining sleep (OR = 1.9, 95% CI 1.1–3.3), were twice as common in women with PCOS compared to those without. The former association persisted after accounting for body mass index (BMI) and depressive symptoms, but

Table 1 Summary of population- and community-based studies of sleep disturbances and PCOS in women

Study, country	Study design	Study groups	Outcomes of interest	Key results
Hung et al, ⁴⁷ Taiwan	Retrospective cohort constructed from the National Health Insurance Database (98% coverage)	5431 with PCOS and 21,724 without PCOS matched for age	Diagnosis of new-onset sleep disorders: ICD-9 780.5 (insomnias) and 307.4 (difficulty initiating and maintaining sleep, excluding OSA)	<ul style="list-style-type: none"> Women with PCOS were more likely to be diagnosed with sleep disorders: HR = 1.495 (95% CI 1.176–1.899) Most developed in the first year since diagnosis of PCOS
Lin et al, ⁴⁶ Taiwan		4595 with PCOS and 4595 without PCOS matched for age and time of enrollment	Diagnosis of OSA during follow-up (2–13 years)	<ul style="list-style-type: none"> Women with PCOS had a greater incidence of OSA (1.71 vs 0.63 per 1000 person-years) HR = 2.63 (95% CI 1.57–4.04) adjusted for demographics (urbanization, income) and comorbidities (hypertension, dyslipidemia, diabetes, obesity)
Moran et al, ⁴⁸ Australia	Cross-sectional analysis of data from a cohort based on births (1973–1975) at a large maternity hospital	87 with PCOS and 637 without PCOS	Sleep disturbance assessed using modified Jenkins questionnaire	<ul style="list-style-type: none"> Any sleep disturbances two times higher in women with PCOS Difficulty falling asleep: OR = 1.94 (95% CI 1.28–2.95), attenuated but still significant after adjusting for BMI and depressive symptoms Difficulty maintaining sleep: OR = 1.92 (95% CI 1.12–3.31), mediated by BMI and depressive symptoms PCOS not associated with early awakening or daytime sleepiness

Abbreviations: BMI, body mass index; CI, confidence interval; HR, hazard ratio; ICD-9, International Classification of Diseases, Ninth Revision; OR, odds ratio; OSA, obstructive sleep apnea; PCOS, polycystic ovary syndrome.

not the latter. PCOS was not observed to be associated with unintended early morning waking or daytime sleepiness.⁴⁸

Clinic-based studies of sleep disturbances in women with PCOS

Polysomnographic assessments of clinical samples of women with PCOS have been undertaken, with OSA the focus in the majority (summarized in Table 2). Interpretation of the findings of these studies should be tempered with understanding of the limitations of this literature: clinic-based samples of women with PCOS are likely to comprise women with the most severe symptoms;⁴⁹ comparison groups are often convenience samples of women attending clinics for reasons other than PCOS; and sample sizes are often modest.

OSA is common in clinical samples of women with PCOS, affecting 17–75%, substantially higher than in other women of similar age and BMI, and thus is not attributable to the tendency of women with PCOS to be obese.^{50–54} One study has shown that OSA is elevated in women who have BMI in the normal range along with PCOS.⁵⁴ Women with PCOS have consistently been shown to have elevated AHI,

regardless of OSA diagnosis.^{50,51,53–55} Few differences in other polysomnographic variables, such as sleep latency, sleep efficiency and waking after sleep onset, have been found.^{50,51,54,55}

We have not systematically attended to studies of adolescents, given the difficulty in diagnosing PCOS at that stage of development and the likelihood that selection procedures (including factors involved in seeking an early diagnosis) contribute to inconsistent findings in polysomnographic studies.^{56–58} Of interest, however, one study demonstrated higher AHI and more OSA among obese girls with PCOS ($n = 28$) referred to a sleep clinic compared with a control group of girls ($n = 28$) matched for age and BMI, but no differences from a control group of boys ($n = 28$).⁵⁹

Excessive daytime sleepiness (EDS) is a hallmark of sleep disturbance in men, but may not be as relevant to women⁶⁰ who are more likely to report low mood or irritability or morning headaches following poor sleep.^{48,61} Nevertheless, EDS in women with PCOS has been investigated,^{50,51,54,55} usually using the Epworth Sleepiness Scale.^{50,51,55} Predominantly, the clinical studies have shown PCOS to be associated with EDS, often in the absence of OSA. For example, in one study

Table 2 Summary of clinic-based studies of sleep disturbances and PCOS in women

Study, country	Study design	Study groups	Outcomes of interest	Key results
Fogel et al, ⁵⁰ USA	Cross-sectional, PCOS and comparison group	18 with PCOS, all obese; and 18 without PCOS matched for age and weight	AHI, AHI (REM sleep), OSA (AHI >5 with EDS), ESS, sleep onset latency, sleep efficiency, % stages 3 and 4 and % REM sleep	<ul style="list-style-type: none"> • AHI: PCOS 22.5 ± 6.0 vs controls 6.7 ± 1.0, $p = 0.008$ • AHI (REM sleep): PCOS 41.3 ± 7.5 vs controls 13.5 ± 3.3, $p < 0.01$ • OSA: PCOS 44.4% vs controls 5.5%, $p = 0.008$ • ESS: PCOS 9.5 ± 0.9 vs non-PCOS 5.8 ± 0.8, $p < 0.01$ • No significant differences in other PSG variables • Clinically significant insomnia was higher in PCOS <ul style="list-style-type: none"> o AIS – 12.6% vs 3.2%, $p = 0.01$ o ISI – 10.5% vs 1.1%, $p = 0.004$ • No significant difference in ESS or PSQI

80% of women with PCOS ($n = 53$) complained of EDS but only 17% were diagnosed with OSA.⁵⁴

Insomnia in women with PCOS has received very little attention. Among a clinical sample of Polish women with PCOS ($n = 95$), 13% had insomnia according to the Athens Insomnia Scale and 10% according to the Insomnia Severity Index (ISI), with corresponding proportions among controls ($n = 130$) of 3% and 1%, respectively.⁶²

How pathophysiology of PCOS is linked to sleep disturbances

Since PCOS is characterized by metabolic disturbances, and as the endocrine system has an important role in governing the sleep–wake cycle, it is likely that PCOS interferes with arousal and sleep or that there is a more complex interrelationship.

The sleep–wake cycle in humans is driven by the interaction between two processes, Process S, which is sleep promoting, and Process C, which promotes wakefulness.⁶³ Process S represents the homeostatic need for sleep and accumulates over the time spent awake. Process C is regulated by the circadian system and ensures that sleep and wakefulness coincide with environmental light–dark stimuli.⁶⁴ The circadian system is coordinated centrally by the suprachiasmatic nucleus in the hypothalamus and is synchronized with environmental stimuli.⁶⁵ The suprachiasmatic nucleus relays circadian information to other areas of the brain, such as the pituitary and pineal pineal glands, and to peripheral tissues via the regulation of clock-gene expression and neuroendocrine signaling.⁶⁶

Melatonin and cortisol play important roles in regulating sleep and wakefulness. Melatonin, secreted by the pineal gland, is increased at night and decreased during the day, thus communicating light–dark information.^{64,67} Cortisol, which is secreted from the adrenal cortex and regulated by the HPA axis, also follows a circadian pattern, steadily increasing during sleep and peaking in the morning.^{67,68}

As illustrated in Figure 2, there are several pathways through which PCOS and sleep disturbances may be associated. The pathways outlined here have been identified based on the endocrine profiles of women with PCOS, the unique stressors they experience, and related psychological and behavioral factors.

Obesity

Obesity is common in women with PCOS and exacerbates the metabolic stress that we and others view as central to pathogenesis of the syndrome.²⁵ In a meta-analysis of mainly clinic-based samples ($n = 35$ studies),⁶⁹ 49% of women with PCOS were classified as obese (95% CI 42–55%) and 54%

had central adiposity (95% CI 43–62%). The proportions were around twofold higher than among comparison groups (obesity: relative risk [RR] = 2.8, 95% CI 1.9–4.1; central adiposity: RR = 1.7, 95% CI 1.3–2.3). These proportions should not be interpreted as prevalence estimates for all women with PCOS because obesity has been shown to be more common (and more extreme) in clinical samples than in community-based studies.⁴⁹ For example, in the Australian Longitudinal Study on Women's Health (overall $n = 9145$), at wave 4, 478 women reported having received a diagnosis of PCOS and, on average, had moderately higher BMI (mean difference 2.5 kg/m^2 , 95% CI 1.9–3.1) and moderately greater longitudinal weight gain over a 10-year period (mean difference 2.6 kg kg/m^2 , 95% CI 1.2–4.0) compared to their peers.⁷⁰

Variation in BMI among women with PCOS appears to be related to factors such as age and ethnicity and possibly to severity of the syndrome.⁶⁹ It is not clear why women with PCOS are predisposed to obesity, nor whether it reflects physiology or psychology. Some literature suggests that appetite and satiety are altered in PCOS, with affected women reporting higher postprandial hunger and lower satiety after a test meal compared to other women.⁷¹ Underlying postprandial suppression of gut hormones such as ghrelin, cholecystokinin, glucagon-like peptide 1 and peptide YY may occur in PCOS.^{71–74} Alternatively or additionally, obesity may reflect abnormalities in energy expenditure as women with PCOS have been found to have reduced resting metabolic rate (1659 kJ/day)⁷⁵ and reduced thermic effect of food (42 kJ/meal, equivalent to weight gain of 1.9 kg/year).⁷⁶ Psychological factors are consistent correlates of poor weight management;⁷⁷ as will be described presently, women with PCOS have relatively more anxiety and depression, and relatively poor self-esteem, body image and quality of life (QoL), compared to their peers.⁷⁸

Obesity is one of the strongest risk factors for OSA,⁷⁹ attributable to anatomical changes of the upper airways and thoracic region.⁸⁰ Longitudinal studies of men and women demonstrate that a 10% increase in body weight predicts a sixfold increase in risk of developing moderate-to-severe sleep-disordered breathing.⁸¹ When obesity is severe ($\text{BMI} > 40 \text{ kg/m}^2$), the prevalence of OSA in men and women is as great as 92%.⁸²

There is evidence that obesity contributes to sleep disturbances beyond OSA.⁸³ Several studies have shown that obesity is associated with objectively assessed daytime sleepiness and subjective reports of fatigue, independently of OSA.^{84,85} Vgontzas et al⁸³ have proposed two possible mechanisms through which obesity produces these sleep disturbances. In one pathway, shorter sleep duration and subjective fatigue in obese

individuals is related to psychological distress and upregulation of the HPA axis. In the second pathway, in which sleep duration is not altered, metabolic parameters such as insulin resistance as well as lack of physical activity are invoked, with normal- or downregulation of the HPA axis. Both pathways are proposed to be associated with hypercytokinemia.⁸³

There is some evidence that obesity directly contributes to OSA among women with PCOS, although, as highlighted previously, it does not fully account for findings from community- and clinic-based studies. For example, high BMI in women with PCOS ($n = 53$) has been associated with elevated risk of OSA and daytime sleepiness.⁵⁴ In a study of women with ($n = 44$) and without ($n = 34$) PCOS, obesity was the strongest predictor of sleep apnea risk (as measured by the Berlin questionnaire),⁸⁶ in contrast to another study of obese women with PCOS ($n = 23$), among whom there was no relationship between the degree of obesity and sleep apnea severity (as per AHI).⁸⁷

On balance, the evidence supports contributions to sleep disorders both of PCOS and obesity. From the perspective of stress, the former is metabolic while the latter is oxidative, which might aggravate sleep harmonically,²⁵ but studies that examine this are lacking.

Hyperandrogenemia

The prevalence of OSA differs by sex, with obese women having lower risk compared to males of similar BMI.⁸⁸ Men and women often have different clinical presentations for OSA. For example, when matched for age, BMI, AHI and EDS score, women were less likely than men to present with witnessed apnea but more likely to report insomnia.⁸⁹ Differences between men and women may be due to differences in the anatomy of the upper airway, sex hormones and/or central adiposity.^{90,91}

Women with PCOS commonly have increased testosterone (free and bound) and androstenedione, and hyperandrogenemia is a diagnostic criterion. Excess androgen is known to induce changes in body composition, including increased central adiposity. In women with PCOS, serum androgen levels are positively correlated with waist–hip ratio, independent of obesity.⁹² Androgen-induced changes to central adiposity, rather than increased weight overall, may contribute to OSA in these women.

This proposition is supported by work showing that among obese women with PCOS ($n = 18$), the severity of OSA was correlated with both the degree of androgen excess and waist–hip ratio.⁵⁰ Similarly, among nonobese women with ($n = 18$) and without ($n = 10$) PCOS, who did not have

OSA, AHI during non-rapid eye movement (NREM) sleep was correlated with total testosterone.⁵⁵ An inconsistent finding has been reported for a group of women with PCOS ($n = 44$) in whom risk of OSA was determined by the Berlin questionnaire.⁸⁶

Few studies have investigated the potential role of hyperandrogenemia in other forms of sleep disturbance in women. Mixed findings about androgens and sleep architecture have been reported from polysomnographic studies of adolescent girls with PCOS.^{56,93}

Insulin resistance

There is considerable evidence for a relationship between sleep disturbances and insulin resistance, with numerous studies demonstrating that sleep restriction and/or sleep disorders can exacerbate insulin resistance.^{94–96} Insulin resistance may also have a role in the development of sleep disturbances. For example, in a cross-sectional study of risk factors for EDS ($n = 1741$) undertaken in the US, diabetes (fasting glucose >126 mg/dL) was strongly associated with EDS.⁸⁴ Similarly, in a small study of men with OSA, those with EDS ($n = 22$) had higher plasma insulin levels and insulin resistance compared with those without EDS ($n = 22$) when matched for age, BMI, and AHI.⁹⁷ A prospective study of incident OSA in a population-based sample of French men and women ($n = 3565$) also demonstrated that fasting hyperinsulinemia predicted development of OSA, independently of BMI.⁹⁸

The mechanisms by which insulin resistance may lead to OSA or EDS are unknown. Evidence from animal and human studies has demonstrated that insulin increases sympathetic outflow,^{99,100} which may in turn affect sleep architecture and the risk of sleep-disordered breathing and daytime sleepiness.

In a polysomnographic study of women with ($n = 53$) and without ($n = 452$) PCOS, Vgontzas et al found that insulin resistance was the strongest risk factor for sleep apnea, before and after controlling for age, BMI, and free and total testosterone levels.⁵⁴ Similar findings were reported in another study of women with PCOS ($n = 40$), with higher fasting insulin levels observed among those with elevated risk of OSA (as per Berlin questionnaire).⁵²

If insulin resistance causes sleep disturbances, then treatment with insulin sensitizers should be mitigating. Adolescent girls with PCOS who received metformin treatment reported reduced sleep disturbances and daytime sleepiness, but it is not possible to distinguish between effects of improved insulin resistance and the concomitant reductions in BMI and hyperandrogenemia.¹⁰¹ In a recent pilot for a

randomized placebo-controlled trial, nondiabetic individuals with insulin resistance and OSA ($n = 45$) were allocated to receive either pioglitazone or placebo. Pioglitazone produced no improvement in OSA symptoms or other measures of sleep quality, despite significant improvements in insulin sensitivity.¹⁰² Thus, there is insufficient evidence to draw conclusions about this matter, and we recommend further research.

Cortisol

In a recent longitudinal study of obese girls aged 13–16 years with ($n = 20$) and without PCOS ($n = 20$), the role of the steroid metabolome was investigated. No difference in morning cortisol concentration was found between the two groups, although levels were twice as high as those reported in studies of girls of normal weight.¹⁰³ Furthermore, weight loss was associated with a decrease in cortisol whether or not the girls had PCOS. Together, this suggests that the adrenal stimulation was attributable to obesity rather than to PCOS.

Findings concerning women with PCOS are somewhat contradictory. In one study ($n = 21$ with PCOS, 11 overweight/obese; $n = 10$ without PCOS, none overweight/obese), 24-hour cortisol profiles were obtained. While there was no difference in mean 24-hour cortisol levels overall, women with PCOS had lower night-time cortisol levels compared to controls, and this was most pronounced for the women with PCOS who were not overweight/obese.¹⁰⁴ In another study, evening, but not morning, plasma cortisol levels were higher in women with PCOS ($n = 40$) compared to women of similar age and BMI without PCOS ($n = 55$).¹⁰⁵ It is possible that elevated cortisol levels among women with PCOS reflect high BMI, as one study showed that concentration and profiles of cortisol excretion were similar for obese women with ($n = 15$) and without ($n = 15$) PCOS.¹⁰⁶

Complete HPA function in women with PCOS has not been described. Any changes – whether due to PCOS or associated obesity – are relevant, as dysfunction of the HPA axis at any level impacts on sleep, including increased sleep fragmentation, decreased slow wave sleep, and shortened sleep time.¹⁰⁷

There is evidence that women with PCOS have a heightened physiological response to emotional stress. When exposed to an experimental stressor, women with PCOS ($n = 32$) had higher levels of adrenocorticotropic hormone immediately and 15 minutes post-stress, and higher serum cortisol level 15 minutes post-stress, compared to women without PCOS ($n = 32$), matched for age and BMI. This was despite the emotional response (state anxiety) reported by the two groups being similar.¹⁰⁸

Sleep deprivation is itself a stressor and is associated with elevated cortisol levels.¹⁰⁹ It is therefore possible that a bidirectional relationship exists between stress-related hyperactivity of the HPA axis and sleep disturbances in women with PCOS.¹¹⁰

Melatonin

A study of melatonin secretion over 24 hours in women with PCOS has not been undertaken. Melatonin from a single blood sample taken between midnight and 4 am was higher among women with PCOS ($n = 50$) compared to controls ($n = 50$).¹¹¹ Two studies have demonstrated elevated 24-hour urinary 6-sulphatoxymelatonin (the primary metabolite of melatonin) in women with PCOS ($n = 22$ in the first and $n = 24$ in the second study) compared to controls ($n = 35$ and $n = 26$, respectively).^{112,113}

However, the changes in melatonin described in women with PCOS are unlikely to result in the profound sleep disturbances that have been reported in this subpopulation, particularly given 6-sulphatoxymelatonin was not found to be correlated with sleep efficiency.¹¹³ A strong correlation between melatonin obtained from a single blood sample (as above) and testosterone was found in women with PCOS,¹¹¹ and melatonin was reduced after hyperandrogenemia was attenuated by cyproterone acetate-ethynodiol treatment.¹¹⁴ This suggests that elevated melatonin levels described in women with PCOS may be a result of androgen excess. Conversely, chronic administration of melatonin to women with PCOS (2 mg per day for six months) significantly decreased testosterone levels and reduced menstrual irregularities,¹¹⁵ suggesting that supraphysiological levels of melatonin can reduce androgen levels.

Psychosocial aspects of PCOS and association with sleep

A number of psychosocial aspects of PCOS are likely to contribute to sleep disorders and disturbances in affected women. These are summarized in Figure 4.

Mental health profiles of women with PCOS

Anxiety and depression are well recognized to be associated with sleep disorders.^{116–118} A systematic review of nine longitudinal studies found suggestive, though not definitive, evidence of a bidirectional relationship.¹¹⁹ A recent study of young women ($n = 171$) followed over two weeks found reciprocal dynamics between anhedonic depression and disrupted sleep to be especially potent.¹²⁰

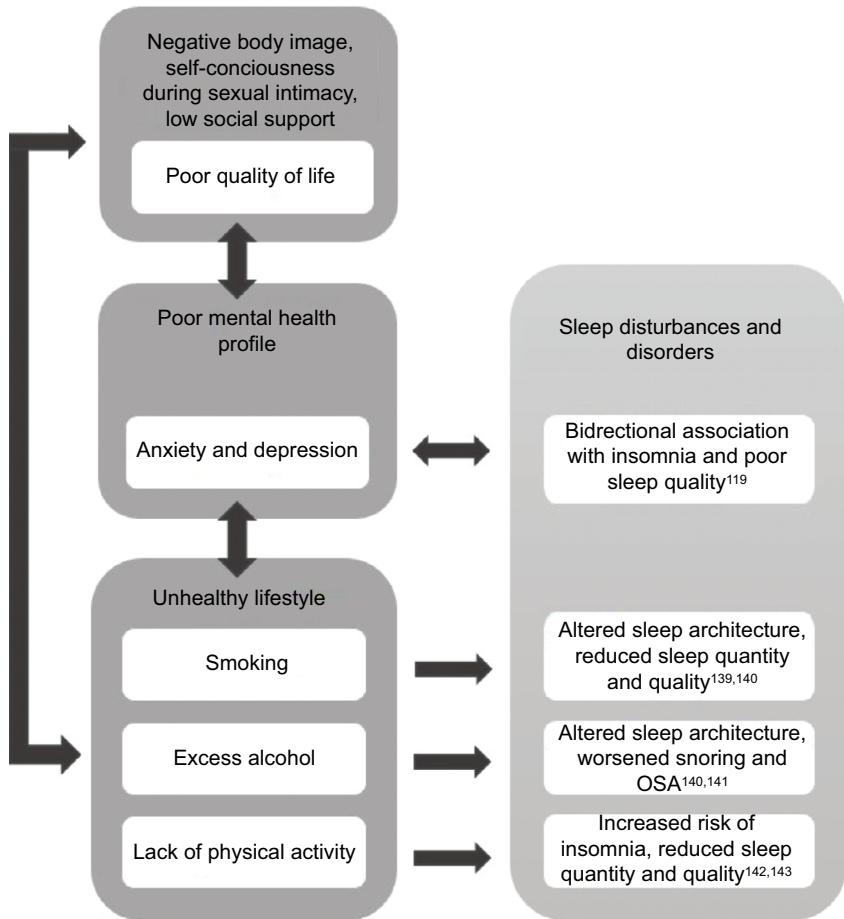

Figure 4 Summary of psychosocial and behavioral factors that are common among women with PCOS and their potential contribution to sleep disturbances and disorders.
Abbreviations: OSA, obstructive sleep apnea; PCOS, polycystic ovary syndrome.

Anxiety and depression are elevated in women with PCOS, with consistent evidence presented in several systematic reviews with meta-analysis.^{121–125} In our community-based sample, among women with PCOS (the majority of whom had not previously been diagnosed), 50% had symptoms consistent with clinical depression (Center for Epidemiologic Studies Depression Scale) compared with 30% of their peers.⁴⁸

In one of the above systematic reviews,¹²⁵ clinical symptoms, including hirsutism, obesity, and infertility, were shown to contribute to higher emotional distress in women with PCOS, but did not fully account for the disparity. Elevated androgens have been associated with negative affect and depressive symptoms in women with PCOS,^{78,126} but the relationship between androgens and mood disorders in women remains controversial.^{124,127} As discussed, women with PCOS may have hyperresponsivity of the HPA axis, which is associated with impaired mental health, including depression.¹²⁸

In the community-based cohort of Australian women that we undertook, as mentioned, difficulty falling asleep and difficulty maintaining sleep were twice as common in women with PCOS compared to peers of similar age.⁴⁸ Depressive symptoms mediated both associations, but to varying degrees.

In a clinical sample of women with PCOS ($n = 114$), those with a history of depression had a threefold increase in disturbed sleep (as per the Patient Health Questionnaire).¹²⁹ In another study, women with ($n = 30$) and without PCOS ($n = 30$), matched for age and BMI, were recruited by advertisement in a Swedish community.¹³⁰ Symptoms of anxiety and depression were self-reported (using subscales of the Comprehensive Psychopathological Rating Scale for Affective Syndromes). Over 60% of women with PCOS had anxiety symptoms above a cut-point corresponding to clinical relevance, compared to 13% of controls, with the specific symptom of reduced sleep prominent.

As with anxiety and depression, it is likely that a bidirectional relationship exists between sleep and

QoL.¹³¹ This may be especially so in people with medical conditions.¹³²

QoL for girls and women with PCOS appears to be poorer than for their peers, although less is known about this than about specific conditions such as depression and anxiety. A systematic review and meta-analysis of five studies showed that women with PCOS had lower scores than their counterparts on all domains assessed by the Short Form-36 Health Survey, including physical and social function.¹³³ A recent systematic review¹³⁴ of QoL in adolescents and young women with PCOS identified nine studies that were too diverse in approach for meta-analysis to be performed. However, all studies reported a negative association between PCOS and QoL, with body weight issues conspicuous.

Distressing symptoms of PCOS are likely to contribute to poor QoL. In women more broadly, a systematic review with meta-analysis has demonstrated the profound impact of infertility on QoL.¹³⁵ Other stressors experienced by women with PCOS – that have received less attention – may contribute, including negative body image, poor self-esteem, poor sexual relations, reduced social support and low social engagement.^{136–138}

Lifestyle and health behaviors

Lifestyle factors and health behaviors, including smoking, consumption of alcohol and lack of physical activity, can contribute to impaired sleep. Tobacco smoking has been associated with altered sleep architecture, short sleep duration and poor-quality sleep, based on both self-reports and polysomnography.^{139,140} In nonalcoholics, the effect of alcohol consumption on sleep varies during the night, at first decreasing sleep latency and increasing the quality and quantity of NREM sleep, then as alcohol is metabolized, reducing NREM and fragmenting sleep.^{140,141} Alcohol is also associated with exacerbation of snoring and OSA.¹⁴⁰ Physical inactivity has been associated with reduced self-reported hours of sleep¹⁴² and increased risk of clinically diagnosed insomnia.¹⁴³ Furthermore, there is evidence that increased physical activity improves sleep quality.^{144,145}

There is some evidence that lifestyles and behaviors of women with PCOS are less healthy than those of other women of similar age and socioeconomic status. For example, in a case series of women with PCOS presenting at a reproductive health clinic, around half smoked cigarettes, substantially more than expected based on their demographic profile.¹⁴⁶ Consistent with this, in the US 2002 National Health Interview Survey, women who reported menstrual-related problems

were shown to be more likely than others to smoke and drink heavily.¹⁴⁷

Women with PCOS are less physically active than other women and may have difficulty in sustaining engagement in physical activity over the long term.¹⁴⁸ When interventions to improve physical activity among women with PCOS have been trialed, attrition rates have been high.¹⁴⁹ Barriers contributing to low physical activity in women with PCOS include lack of confidence in the ability to maintain activity, fear of injury and physical limitations.¹⁴⁸ It is also possible that there are physiological reasons for impaired exercise capacity in women with PCOS. For example, it has been shown that sedentary normal-weight women with PCOS (n = 14) have impaired cardiorespiratory capacity (maximal oxygen consumption and submaximal ventilatory thresholds) compared to age- and BMI-matched sedentary women without PCOS (n = 14).¹⁵⁰

Long-term cardiometabolic consequences of sleep disturbances in PCOS

There are few long-term studies of women with PCOS, with information especially lacking after menopause. However, available evidence suggests that women with PCOS may have relatively early onset of type 2 diabetes and other cardiometabolic disorders. This is not accounted for by the higher prevalence of obesity among women with PCOS, as highlighted in the studies described here. Drawing on wider literature, it is possible that sleep disorders may contribute to deterioration in the health of women with PCOS, although this has not been studied directly.

Detailed cardiovascular profiles of around 1000 women were obtained across 20 years in the CARDIA (Coronary Artery Risk Development in Young Adults) study undertaken in the US, commencing when participants were aged 18–30 years. Information on PCOS symptoms obtained 16 years from baseline was combined with androgen data from year 2 to classify women as having PCOS or not. Using data from year 5, women with PCOS (n = 42) had higher left ventricular mass index and larger left arterial diameter.¹⁵¹ By year 16, when women were aged 34–46 years, PCOS was associated with a twofold increase in incident diabetes (with almost a quarter of women with PCOS affected) and a twofold increase in dyslipidemia. Among women with normal BMI, those with PCOS (n = 31) had three times the rate of diabetes compared to those without PCOS.¹⁵² At year 20, women with PCOS (n = 55) had increased coronary artery calcification and intima-media thickness.¹⁵³

Australian hospital admission data from 1980 to 2011 have been used to compare 2566 women with a recorded diagnosis of PCOS to 25,660 age-matched women (identified using the electoral roll); most women in this study were aged under 40 years. Women with a diagnosis of PCOS were two to three times more likely to be hospitalized for adult-onset diabetes, hypertensive disorders, ischemic heart disease and cerebrovascular disease compared to women without PCOS. These findings remained statistically significant after adjusting for obesity.¹⁵⁴

In a retrospective cohort study, women with PCOS ($n = 319$) identified through hospital records were compared with age-matched women ($n = 1060$) identified through general practice records. After an average follow-up of 31 years, when approximately 80% of women were postmenopausal, those with PCOS had elevated prevalence of diabetes, hypertension and high cholesterol.¹⁵⁵ Another study with a small sample size and substantial losses to follow-up over 21 years found more hypertension and higher triglycerides in women with PCOS ($n = 25$ of 35) compared to women of similar age and BMI ($n = 68$ of 120).¹⁵⁶

Turning to the wider literature, a recent meta-analysis of cohort studies showed that OSA was associated with increased risk of type 2 diabetes after adjustment for age, sex and BMI (RR = 1.49, 95% CI 1.27–1.75, eight studies, 63,647 participants).¹⁵⁷ Other types of sleep disturbance were also associated with type 2 diabetes, notably – in view of our findings on women with PCOS⁴⁸ – difficulty initiating sleep (RR = 1.55, 95% CI 1.23–1.95) and difficulty maintaining sleep (RR = 1.72, 95% CI 1.45–2.05).

Sleep restriction has been demonstrated to result in increased food intake due to increased appetite, exceeding the energy amount needed to meet the requirements of extended wakefulness, and thereby resulting in weight gain.^{158–160} It has also been shown to decrease the ability to lose body fat with dietary restriction,^{158,161} and to alter glucose metabolism, with decreases in glucose clearance, insulin sensitivity and acute insulin response documented.^{158,162,163}

OSA is likely to increase the risk of diabetes through intermittent hypoxia and arousals, which result in impaired glucose tolerance through increasing sympathetic nervous system activity, HPA axis dysregulation, altered cytokine release and oxidative stress.^{164–167} OSA is also independently associated with hypertension, premature atherosclerosis and arterial stiffness and an increased risk of future myocardial infarction, stroke and cardiovascular mortality.^{166,168,169} This may be due to the combination of sympathetic nervous

system stimulation and endothelial dysfunction that result from OSA.^{170,171}

In studies of short duration, insulin–glucose metabolism and lipids are worse in women with PCOS who have OSA than among women with PCOS but not OSA, independent of BMI.^{52,54,59,172} A link between sleep disturbances and poor long-term cardiometabolic health among women with PCOS remains speculative, as direct evidence is lacking.

Management of sleep disturbances in PCOS

Referral to a sleep specialist allows diagnosis of clinical conditions such as OSA and insomnia, and subsequent treatment. OSA is generally diagnosed using overnight polysomnography to generate AHI.⁴⁰ Insomnia diagnosis ideally requires assessment by a clinical psychologist.¹⁷³ However, many sleep medicine clinics do not currently have the resources necessary for adequate diagnosis, such as the ISI questionnaire, sleep diaries and measures of daytime fatigue without sleepiness. It is important to recognize that OSA and insomnia are frequently comorbid,¹⁷³ and also that women with PCOS may have other forms of sleep disturbance.

Weight loss is generally recommended for overweight and obese people with OSA,⁴⁰ although recent research has indicated that weight loss may only decrease the severity of OSA in a minority of patients.¹⁷⁴ As described above, weight loss may be particularly difficult to achieve in many women with PCOS due to hormonal abnormalities and other factors. Weight loss in women with PCOS would improve insulin sensitivity and symptom profiles, including fertility, so research is needed to understand the type and intensity of support required to achieve this. Avoidance of alcohol and sedative medications, which may predispose the upper airway to collapse, is also frequently recommended for OSA.⁴⁰ Again, this poses a particular difficulty for women with PCOS in view of their anxiety and use of alcohol, possibly as a coping mechanism.¹⁷⁵

In cases of mild OSA, oral appliances, commonly known as mandibular advancement splints, which are custom-made to increase upper airway size and reduce the likelihood of airway collapse during sleep, may be recommended.⁴⁰ However, efficacy and acceptability of oral appliances in women with PCOS is yet to be explored.

A small amount of research has been conducted in women with PCOS about the benefits of continuous positive airway pressure (CPAP) treatment, involving wearing a mask over the nose during sleep to maintain airway patency. CPAP has

been shown to be a promising treatment for OSA in young obese women with PCOS, with improvements in insulin sensitivity, daytime diastolic blood pressure, and cardiac sympathovagal balance after eight weeks of treatment.¹⁷⁶ These results indicate the need for a larger, well-designed randomized controlled trial to assess the clinically relevant effects of CPAP treatment on markers of future cardiovascular risk in women with PCOS.¹⁷⁷

For the general OSA subpopulation (mostly men), there is now evidence from systematic reviews with meta-analysis that CPAP reduces blood pressure¹⁷⁸ and endothelial dysfunction, which promote the development of atherosclerosis.^{179,180} Thus, CPAP could have a role in primary prevention of vascular disease, despite recent findings that CPAP is not effective in reducing coronary events in those with preexisting vascular disease.¹⁸¹ Systematic reviews with meta-analysis have also indicated that insulin resistance can be improved with CPAP use, thereby possibly reducing the risk of development of type 2 diabetes in nondiabetic and prediabetic individuals.¹⁸

Importantly for women with PCOS, a systematic review with meta-analysis has provided evidence that CPAP treatment reduces depressive symptoms.¹⁸² A subsequent large, randomized controlled trial of over 2000 individuals with moderate-to-severe OSA and coronary or cerebrovascular disease demonstrated that CPAP was effective in increasing QoL as well as decreasing symptoms of depression and anxiety.¹⁸³

The American College of Physicians now recommends cognitive behavior therapy (CBT) as the most appropriate treatment for all adults with insomnia.¹⁸⁴ This treatment is also recommended as a first-line treatment for insomnia by the British Association for Psychopharmacology.¹⁸⁵ The efficacy of CBT in treating insomnia symptoms has been demonstrated in multiple systematic reviews with meta-analyses,^{186–189} but most sleep clinics do not have clinical psychologists available to provide this treatment. In view of the widespread mental health and other problems reported among women with PCOS, there is a good case for referral to a clinical psychologist who can assess and address problems holistically.

In recent years, trials have been undertaken to assess the efficacy of online delivery of CBT for insomnia, using highly structured internet programs as a means of overcoming the barriers to face-to-face delivery of treatment.¹⁹⁰ A recent systematic review with meta-analysis of 15 randomized controlled trials of internet CBT for insomnia found evidence of clinically significant improvements in symptoms, of the order achieved in face-to-face CBT.¹⁹⁰ Importantly, the ISI score of patients was found to be reduced overall by 21%,¹⁹⁰ and by 15% in a similar systematic review with meta-analysis.¹⁹¹ This option may appeal to women with

PCOS as cost-effective, but they should still be encouraged to consult a clinical psychologist or other professional support services for wider problems.

There are well-recognized hazards in using pharmacotherapy for the primary treatment of insomnia. Depending on the type of drug used, negative effects include carry-over daytime sedation, slowed reactions and memory impairment, as well as the potential for intensification of symptoms upon cessation of treatment.¹⁷³ Pharmacotherapy is only recommended short term.¹⁹² This is particularly pertinent for women with PCOS whose insomnia and other sleep disturbances are unlikely to be short term and are related to underlying factors that need to be addressed directly.

Women who experience sleep disturbances, but do not meet the criteria for clinical diagnosis of a sleep disorder, may benefit from sleep hygiene approaches. This includes behavioral and environmental recommendations for promoting sleep.¹⁹³ Avoidance of smoking and alcohol and regular physical activity are aspects of sleep hygiene that have already been described. Other recommendations include avoidance of caffeine, adhering to regular sleep and wake times and stress management.¹⁹³ Stress management techniques, such as mindfulness, have been shown to reduce presleep arousal and worry,¹⁹⁴ which may be beneficial for women with PCOS. Clinical anxiety requires psychological expertise, however.

As has been highlighted throughout this review, it is common for women with PCOS to experience symptoms that span multiple medical specialties. The management of sleep disturbances among women with PCOS should form part of an interdisciplinary model of care (summarized in Figure 5) with effective communication between care providers.¹⁹⁵ It is important that interdisciplinary care is patient-centered¹⁹⁵ and emphasizes a holistic approach to health and well-being.

Conclusion

There is mounting evidence for an association between PCOS and sleep disturbances that is complex and possibly bidirectional. This is not simply due to the tendency of women with PCOS to be obese, as associations are seen in PCOS women of normal weight and most associations are upheld after adjustment for BMI. This suggests poor sleep is part of the pathophysiology of PCOS. We view PCOS as a condition of severe metabolic stress that cascades into oxidative and emotional stress. We suggest that multidimensional treatment, including treatment to improve sleep, may improve metabolic function and could potentially prevent long-term cardiometabolic sequelae for these women.

We have identified some important gaps in the literature, with further research recommended. These include a need

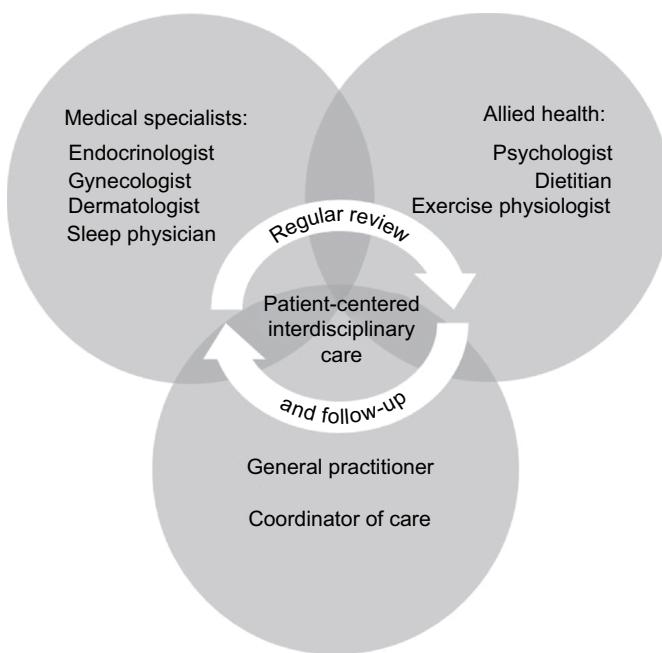

Figure 5 Model of interdisciplinary care recommended for management of sleep disturbances and disorders in women with PCOS.

Abbreviation: PCOS, polycystic ovary syndrome.

to fully describe HPA function in women with PCOS, and for further trials of insulin sensitizers and interventions designed to overcome the specific difficulties that women with PCOS have in sustaining physical activity. The implications for sleep deserve specific attention as well as the possibility that bidirectional processes can be harnessed so that improved sleep reduces metabolic stress in women with PCOS.

Abstract

Frequently may be seen that in communication with patients coming to radiological departments for medical examination or treatment radiologic staff is somehow frustrated and insufficiently skilled. Purpose of study is to analyze conditions influence in communication between pts. and radiologic co-workers. In total 75 pts. And 25 radiologists passed 95 targeted personal interviews. Different views of pts. as well as radiologic staff were registered. Recommendations for radiologic co-workers to achieve optimal communication with pts. is of decisive value.

1. Introduction

Frequently may be seen that in communication with the patients coming to department of radiology for medical examination and/or treatment interventions the radiologic staff is somehow frustrated and insufficiently skilled in its daily work. The purpose of our study is to analyze the situation and conditions influencing effective communication between the patients and radiologic co-workers by suitable interview methods and based on the results to optimize the communication skill of the radiologic staff (1,5).

2. Methods.

A special targeted questionnaire was developed by radiologist and clinical psychologist (with over 30, resp. 15 years of practical hospital experience on radiological departments) to interview: (1) patients referred for conventional X-ray studies, CT or MRI examinations or interventional procedures and (2) radiologic co-workers. In total 75 patients and 25 co-workers passed 95 targeted personal interviews (1).

3. Findings and recommendations for clinical practice.

Between general psychological aspects following specifics of communication on radiologic departments were identified:

3.1. Different views on clinical position of patients as well as radiologic staff.

The view of the patient: I am coming or was sent for an examination or treatment into a place I do not know ; the place seems to be unfriendly and overcrowded by strange sophisticated technical devices – it stresses me". "I feel not being sufficiently informed as to what will happen to me and what will be done with me; thus, my position causes a serious psychical burden for me" (2).

The view of radiologic staff: "A patient was referred to our department, without clear enough questions from referring physician". "He/she is like a number in a queue, just a migrant more or less anonymous to us". "He/she is going to leave for further treatment to other place".

In order to respect above mentioned situation it is necessary to keep in mind the reality: It is evident that rational and effective communication between patients and radiologic co-workers as well as referring physician plays the decisive role in patient's management.

Recommendations for radiologic staff: effort to achieve optimal communication level with the patients and fasten on an "alliance" ("condition sine qua non").(1).

3.2. Elements and premises for radiologic staff for creating rational communication with the patients:

- Introduce yourself and your position, listen to the patient, create feedback.
- Explain clearly the reasons and targets of diagnostic or treatment procedures planned (their character and course, patient's benefit, risk, other alternatives of medical care, etc.).
- Create mutual understanding and trust, be open, fair and honest.
- Respect patients' privacy and intimacy of their somatic and psychical problems ("patient is not a thing").
- Plug-up your ability of empathy and respect ethical memento: "The ill – not the illness – must be the focal point of medical staff, including radiologists and co-workers' interest.

Recommendation: to strengthen empathy which is basic condition of "mutual understanding" (2,4,8).

3.3. Requirements concerning main communication forms:

- Speech communication – eye-contact, clear wording, ensuring feedback.
- Paralinguistic means ("metacommunication") – intonation, mimics, gestures, "haptic", touch communication etc.(4).

Recommendations: respect the rules, concentrate and control yourself.

3.4. How to inform the patients on diagnosis and/or necessary interventional treatment?

Patients' need to know about their disease reveals as ethical problem. Presumptions:

- Inform the patient, first of all, about positive technical course of procedures being performed, about diagnostic value and/or treatment results of carried-out studies and interventions.
- Patient's psychical state should be "matured" for final diagnostic information (reaction: compensation versus decompensation).

- Ethical approach: to inform the patients after their compensation, in right time, at right place, by physician's personal handling, in professional form (fairness, dignity, enough time, calm environment, acceptance and encouraging of discussion, listen to).
- Extend psychological support (4,5,7,8).

Recommendations: Main goal for radiologic staff: to support patient's compliance and informed consent!!

3.5 Patients' laws (keep in mind)!:

- To refuse information on diagnosis in effort to save and support positive psychological condition (important immunological factor).
- Patient's agreement is necessary for diagnostic information of partners, family members and public (6).

Recommendations: to avoid mistakes and misunderstanding in communication with the patients, radiologic co-workers and interdisciplinary collaborators.

4. Conclusions

For radiologic co-workers it is essential to train their skills in rational communication with the patients to improve the duality of patients' care based on our common understanding of ethical and humanistic principles.

Abstract: Polycystic ovary syndrome (PCOS) is a common condition in reproductive-aged women. While lifestyle management is first-line treatment in PCOS, the dietary intake of women with PCOS is unclear and there is no research assessing dietary patterns of women with and without PCOS. The aim of this study was to examine dietary patterns in a large cohort of women with and without PCOS. Data were from 7569 participants in the 1973–1978 cohort of the Australian Longitudinal Study on Women’s Health population assessed at 2009 (Survey 5) ($n = 414$ PCOS, $n = 7155$ non-PCOS). Dietary patterns were evaluated using factor analysis and multiple logistic regressions assessed their associations with PCOS status. Three dietary patterns were identified that explained 27% of the variance in food intake between women with and without PCOS: Non-core foods; Meats and take-away and Mediterranean-style. The Mediterranean-style dietary pattern was independently associated with PCOS status. On adjusted analysis for each 1 SD increase in the Mediterranean-style dietary pattern, there was a 26% greater likelihood that women had PCOS. This may indicate an improvement in the quality of dietary intake following a diagnosis of PCOS. Future research should examine the contribution of dietary patterns to the incidence and severity of PCOS and the potential for modification of dietary patterns in the lifestyle management of PCOS.

Keywords: polycystic ovary syndrome; diet; dietary patterns; Australia

1. Introduction

Polycystic ovary syndrome (PCOS) is a common endocrine condition affecting 12%–18% of reproductive-aged women [1]. It is associated with reproductive (hyperandrogenism, anovulation, menstrual irregularity, infertility and pregnancy complications) [2], metabolic (increased risk factors for and prevalence of impaired glucose tolerance, type 2 diabetes and cardiovascular disease) [3–5] and psychological (worsened quality of life and increased risk factors for depression and anxiety) [6] features. There is a proposed bidirectional relationship between obesity and PCOS [7]. Women with PCOS have an elevated prevalence of obesity [8] and increased longitudinal weight gain [7]. Obesity also worsens the presentation and prevalence of PCOS [9]. Mechanisms include increasing the pathophysiological factor insulin resistance, which increases hyperandrogenism through augmenting ovarian androgen production and decreasing hepatic production of the androgen binding-protein sex hormone binding globulin [10,11]. Due to the key aetiological role of obesity

and insulin resistance in PCOS, weight management, defined as prevention of excess weight gain or achieving and maintaining a modest weight loss, is a key treatment strategy in PCOS. Evidence based guidelines recommend achieving this through a combination of diet, exercise or behavioural management [12].

The optimal dietary strategy as part of lifestyle management in PCOS remains controversial. We reported in a recent systematic review that the controlled clinical literature found no difference in the majority of anthropometric, reproductive, metabolic or psychological outcomes for a range of dietary approaches including higher protein, higher carbohydrate, lower glycaemic index or monounsaturated fat-enriched diets [13]. Despite this, a range of dietary approaches may be prescribed by health professionals [14]. While evidence-based National Health and Medical Council approved Australian guidelines outline the principles of dietary management for PCOS [12], the effect of these guidelines on actual dietary prescription by health professionals and subsequent dietary intake by women with PCOS is not known. In the absence of specific recommendations by health professionals, women with PCOS may also often seek non-evidence based sources of information on dietary management [15]. The effect of this on actual dietary intake is not known. We and others have reported subtle differences in dietary intake for women with PCOS compared to those without PCOS including a better dietary intake as indicated by elevated diet quality indices, fibre and micronutrient intake, lower glycaemic index and lower total fat or saturated fat intake or a poorer dietary intake indicated by poorer diet quality, increased fat, saturated fat and high glycaemic index food intake and decreased fibre intake compared to women without PCOS [16–21]. There however remains uncertainty as to the quality of dietary intake in women with PCOS.

Assessment of dietary patterns offers an additional way of comprehensively assessing dietary intake. Rather than assessing single nutrients in isolation, dietary pattern analysis identifies underlying dietary characteristics of the study population in which the consumption of foods that are eaten together can be derived. In particular, exploratory approaches or posteriori dietary pattern analyses such as principal components analysis, which are not hypothesis driven, groups correlated food groups into uncorrelated factors termed dietary patterns [22,23]. In pregnant populations, unhealthy dietary patterns in the pre-conception period were associated with increased risk for preterm birth [24] or gestational diabetes [25] and healthy, Mediterranean or prudent diet patterns were inversely associated with risk of developing hypertensive disorders during pregnancy [26] or gestational diabetes [27,28]. In non-pregnant populations, unhealthy/Western-type dietary patterns have been associated with increased risk of general and central obesity [29] and type 2 diabetes [30]; while a Mediterranean dietary pattern was associated with decreased prevalence of hypertension and metabolic syndrome [31] and a healthy dietary pattern containing vegetables, fruits and whole grains was associated with reduced risk for diabetes [30].

These findings are of potential relevance to PCOS given the increased prevalence of cardiometabolic conditions and pregnancy complications and the potential for clinical benefits with approaches such as the Mediterranean diet [32]. However, there has been limited research examining dietary patterns in women with and without PCOS. This could provide an understanding on both the association of dietary intake with the pathophysiology of PCOS as well as of the dietary changes that occur following a diagnosis of PCOS. The aim of this study was therefore to examine dietary patterns in a large cohort of women, with and without PCOS, participating in the Australian Longitudinal Study on Women's Health.

2. Experimental Section

2.1. Study Population

This study is based on data from the Australian Longitudinal Study on Women's Health (ALSWH), a longitudinal population-based study of three age cohorts of Australia women. Women were randomly selected from the national health insurance scheme (Medicare) database,

which includes almost all people who are permanent residents of Australia, with national recruitment and intentional over-sampling from rural and remote areas [33]. Further details of the methods and characteristics of the sample have been reported elsewhere [34–36]. The Human Research Ethics Committees of the University of Newcastle and the University of Queensland approved the study methods and informed written consent was obtained from each participant.

The current study uses data from the cohort of younger women (born 1973–1978) ($n = 14,779$ at Survey 1) who first completed a mailed survey in 1996 [37]. For this analysis, data are from Survey 5 (2009, $n = 8200$, 58% retention of baseline participants and 84% retention of those who completed the second survey). The greatest drop out was from Survey 1 to Survey 2. However, the impact of attrition on associations between variables has been found to be minimal [36].

As with our prior publications on health outcomes in PCOS, we analysed data from $n = 7569$ women who completed Survey 5 and responded to the question on PCOS diagnosis (“In the last 3 years have you been diagnosed with or treated for Polycystic Ovary Syndrome”) of which $n = 414$ were classified as PCOS and $n = 7155$ as non-PCOS [7]. The analyses in this study are based on cross-sectional analysis of dietary patterns in women with and without PCOS. No specific inclusion or exclusion criteria were applied to this cohort and all women were included irrespective of pregnancy, medication, country of birth and language spoken.

2.2. Anthropometric, Demographic and Physical Activity Variables

Self-reported height, weight and BMI were reported with overweight and obesity defined by the World Health Organization criteria ($\text{BMI} \geq 25 \text{ kg/m}^2$ for overweight and obesity, $\text{BMI} \geq 30 \text{ kg/m}^2$ for obesity) [38]. Demographic variables including parity, education, occupation and income were collected at Survey 5 and area of residence was measured at Survey 1. Physical activity was calculated as the sum of the products of total weekly minutes in categories of walking, moderate-intensity or vigorous-intensity physical activity and the metabolic equivalent value (MET) was assigned to each category: (walking minutes \times 3.0 METs) + (moderate-intensity physical activity minutes \times 4.0 METs) + (vigorous intensity physical activity minutes \times 7.5 METs). Outliers were truncated at 28 h/day for total physical activity.

2.3. Food Group Consumption

At Survey 5, self-reported dietary intake data were collected from the Dietary Questionnaire for Epidemiological Studies (DQES) Version 2, a FFQ developed by The Cancer Council of Victoria previously validated in young Australian women [39] as previously reported [19]. One hundred different foods (grams per day) were obtained from the FFQ and were assigned into 33 food groups (grams per day) based on a previous Australian study [24,40] for use in the dietary pattern analysis.

2.4. Dietary Pattern Analysis

Dietary patterns were derived using factor analysis with factor loadings extracted using the principal component method and varimax/orthogonal rotation. The number of dietary patterns identified was based on eigenvalues >1.5 , on identification of a break point in the scree plot, and on interpretability [41]. Using these criteria, a 3-factor solution was chosen and rerun with the resulting factor scores saved and converted to Z-scores for analysis. Items with factor loadings ≥ 0.25 were considered as the items of relevance for the identified factor. These items represent the foods most highly related to the identified factor [42]. Foods that cross-loaded on several factors were retained.

2.5. Statistical Analyses

All statistical procedures were performed using SPSS version 22. Frequencies and descriptive statistics were expressed as n (%) and as means (SD), respectively. All reported P values were 2-tailed, and a p -value < 0.05 was considered to be statistically significant. Before hypothesis testing, data were examined for normality, in which all independent variables were normally distributed.

Data were analysed by independent *t*-test to compare continuous variables and chi-square test to compare categorical variables between women with and without PCOS. Binary logistic regression analyses were used to test the association between PCOS (yes/no) and the independent variables for each dietary pattern (Z-score), with values presented as OR (95% CI). All logistic regression analyses were undertaken adjusting for potential confounders identified a priori, including maternal age, BMI, currently breastfeeding, number of children and waist circumference, or statistically, from association with PCOS on univariate analysis ($p < 0.05$). Multicollinearity was tested with binary regression analysis using the variance inflation factor (<5); no multicollinearity was observed between any of the independent variables. All model assumptions were validated with residual plots. Analyses were conducted using survey commands for analysing data weighted by area of residence to adjust for the deliberate over sampling in rural and remote areas.

3. Results

3.1. Participant Characteristics

Participant characteristics are reported in Table 1. The women with PCOS were around two months younger, were more likely to not have children and had a lower prevalence of currently breastfeeding compared to women without PCOS. As reported previously, women with PCOS also reported a higher BMI, weight and waist circumference than women without PCOS [7]. As previously reported [19], women with PCOS had an elevated energy and fibre intake and lower glycaemic index and percent energy intake from saturated fat compared to women without PCOS (data not reported). As previously reported [19], women with and without PCOS had similar physical activity levels (814 ± 874 vs. 820 ± 895 MET/min, $p = 0.75$).

Table 1. Characteristics for women with and without polycystic ovary syndrome.

* Values represent mean (SD); † Values represent n (%); Data were analysed by independent t-test to compare continuous variables and chi-square test to compare categorical variables between women with and without PCOS; BMI: Body mass index.

3.2. Dietary Patterns

The dietary pattern analysis revealed three distinct patterns explaining a total 27% variance (Table 2). The first pattern was labelled *Non-core foods* as there were high factor loadings for cakes, biscuits, sweet pastries; confectionary; refined grains and also take-away foods and crisps. The second pattern was labelled *High meat and take-away* as fish (fried, processed, canned and cooked), processed meat, red meat, but also take-away food highly correlated in this pattern. The final pattern was labelled *Mediterranean-style* as Mediterranean type foods highly correlated to this pattern including a variety of vegetables, fruit and nuts, small correlations with fish, while crisps were inversely correlated. Participant characteristics across the quartiles of dietary pattern score are presented in Supplemental Table 1.

Table 2. Factor loadings for each of the identified pre-conception dietary patterns for women with and without PCOS.

Food Group	Non-Core Foods	High Meat and Take-Away	Mediterranean-Style
Cakes, biscuits, sweet pastries	0.661	0.010	0.020
Confectionary	0.629	0.089	0.020
Refined grains	0.483	0.239	0.146
Vegemite	0.483	0.106	0.068
Takeaway	0.467	0.402	-0.138
Crisps	0.466	0.199	-0.262

<i>Percentage variance explained</i>	13%	8%	6%

Dietary patterns obtained using factor analysis with factor loadings extracted using the principal component method and varimax/orthogonal rotation. Food groups with factor loadings <0.25 for all factors are not included in the table (cruciferous vegetables; yellow or red vegetables; low fat dairy; full fat dairy; and canned fruit).

3.3. Dietary Patterns and PCOS

Table 3 reports the results from logistic regression. In the crude analysis, for each 1 SD increase in the *High meat, fish, poultry and take-away* pattern, there was a 9% greater likelihood for women to have PCOS, however this association did not remain in the adjusted analysis. In the crude analysis, for each 1 SD increase in the *Mediterranean-style* dietary pattern, there was a 15% greater likelihood for women to have PCOS. This association was strengthened after adjusting for maternal age, maternal BMI, current breastfeeding, number of children, such that for each 1 SD increase in the *Mediterranean-style* dietary pattern, there was a 26% greater likelihood that the women reported had PCOS. There were no associations between the *Unhealthy, non-core foods* pattern and PCOS.

Table 3. Odds ratios for likelihood of PCOS according to the dietary patterns identified.

	OR *	95% CI	p	Adjusted OR * †	95% CI	p
PCOS						
Unhealthy, non-core foods	1.06	0.97, 1.16	0.22	1.03	0.94, 1.13	0.55
High meat, fish, poultry and take-away	1.09	1.00, 1.17	0.03	1.04	0.95, 1.13	0.43
Mediterranean-style	1.15	1.05, 1.26	0.02	1.26	1.15, 1.39	<0.001
Maternal age	-			0.92	0.85, 0.98	0.014
Maternal BMI	-			1.09	1.07, 1.10	<0.001
Current breastfeeding	-			1.00	0.96, 1.05	0.97
Number of children	-			0.88	0.75, 1.04	0.13

Associations between PCOS and dietary patterns (Z-scores) in crude and adjusted analyses carried out using binary logistic regression analyses; Referent category is not having PCOS; * Indicates change in risk per 1 SD increase in factor score; † Adjusted for maternal age, maternal BMI, current breastfeeding, number of children.

4. Discussion

We report here for the first time that women with PCOS have different dietary patterns compared to women without PCOS, in a large population-based cohort of women. Women with PCOS were more likely to consume a dietary pattern consistent with the Mediterranean diet; however there were

no differences in the other commonly consumed dietary patterns of unhealthy non-core foods or a pattern higher in meat.

The Mediterranean-style dietary pattern contains a number of foods similar to a Mediterranean diet which consists of fish, monounsaturated fats from olive oil, fruits, vegetables, wholegrains, legumes and nuts and moderate alcohol consumption [43]. It is also consistent with previously defined “Mediterranean” patterns in prior research comprising vegetables, fish, fruits, poultry, low-fat dairy products, and olive oil [44,45]. Surprisingly however, we found an inverse factor loading for poultry which is typically consumed in higher intakes in the Australian population compared to fish [46], which loaded on this pattern in moderate amounts for both processed (*i.e.*, tinned fish) and other fish (*i.e.*, cooked fish), while fried fish was inversely associated. It is to be noted that intake of olive oil is not collected in the food frequency questionnaire used in this study. Another surprising finding was that both low fat and high fat dairy foods did not correlate to any pattern. This might reflect the overall low consumption of dairy in men and women in the adult Australian population; yet this is consistent with a previous study in pregnant women where low fat dairy did not load on any of the three dietary patterns, and high fat dairy only moderately correlated with the vegetarian-type dietary pattern [24]. Nevertheless, non-core foods inversely loaded on this pattern such as take-away foods and crisps, as well as added sugar, which supports an overall healthier dietary pattern consisting of a number of Mediterranean foods. As we are the first to report that a Mediterranean-style dietary pattern was independently associated with increased likelihood of having PCOS, this discrepant finding may indicate the possible high level of women with PCOS seeking dietary knowledge with a subsequent adoption of healthy dietary patterns.

To date, there are few other studies reporting on the relationship between dietary patterns and other conditions co-existing with PCOS. In literature assessing infertile women, a large proportion of whom will likely have PCOS, a Mediterranean diet is associated with a higher chance of natural or assisted reproduction conception [44,47]. The adoption of a Mediterranean-style diet in PCOS may therefore have positive implications for the appropriate lifestyle management of chronic diseases associated with PCOS. Further studies are needed to expand on our findings on the association of dietary changes in those with a diagnosis of PCOS, the optimal means of conveying dietary education at diagnosis and the long-term maintenance of positive dietary changes.

We observed here that the two other identified dietary patterns, namely those consisting predominantly of non-core foods or a higher meat intake from either take-away/processed or non-processed sources explained a moderate proportion of variability in food intake in all participants (13% and 8% respectively). However, neither pattern was associated with PCOS status in the adjusted analysis. In association with higher weight and BMI in PCOS, this is a positive finding that is also consistent with the diagnosis of PCOS contributing to an improvement of dietary habits in keeping with population-based dietary guidelines of minimising discretionary or non-core food intake, reducing processed meats and consuming a moderate intake of protein [48].

While a Mediterranean diet is not a specifically recommended dietary intake for PCOS, emerging research suggests beneficial effects of certain components of this diet, such as elevated omega-3 fatty acids which are generally found in high amounts of oily fish. Although the specific types of fish consumed in our Mediterranean style dietary pattern cannot be extracted, both processed fish and cooked fish varieties contain some omega-3 fatty acids, likely contributing to a reasonable intake of omega-3 fatty acids in this population. The literature in PCOS focuses predominantly on omega-3 fatty acid supplementation studies which report improvements in outcomes including reductions in bioavailable androgens, triglycerides, blood pressure, glucose and surrogate markers of insulin resistance [49–52]. One recent study found that a Mediterranean diet pre-pregnancy was associated with a 42% reduced likelihood of developing hypertensive related disorders during pregnancy [26]; while higher consumption of sweets and seafood [25] or high intake of red meat, processed meat, refined grain products and sweets [27] during pregnancy was associated with a 23% and 63% increased risk of gestational diabetes. A Mediterranean dietary pattern has also been reported to be

associated with improved health outcomes including decreased inflammation [53] and prevalence of the metabolic syndrome [54], abnormal glucose tolerance [55] or depression [45]. As adverse health outcomes are commonly associated with PCOS [3,4,6], this dietary pattern may therefore result in health benefits. However, we have previously reported in this cohort that this improved diet quality occurred in conjunction with a modest increase in energy intake (+215 kJ/day) which could contribute to additional longitudinal weight gain [19]. The potential benefits of an improved dietary pattern may not outweigh the effects of increased energy intake and consequent weight gain with regards to effects on reproductive, and potentially metabolic and psychological, parameters.

Strengths to our study include the large population of women with and without PCOS from a community-based population in contrast to the majority of the existing research assessing diet and PCOS. This minimises selection bias. This is also more likely to capture a lower proportion of women with PCOS with a more severe clinical phenotype and a higher BMI who typically present to clinical services and are captured in research studies [56]. While the use of self-report PCOS is a limitation, the nature of this research means that it is not feasible to clinically verify PCOS or control status. It is also not possible to determine the PCOS phenotype or which diagnostic criteria were used in diagnosis. However, given that the Rotterdam criteria were first published in 2004 [57], it is also most likely that the majority of women self-reporting diagnosed PCOS in Survey 4, conducted in 2006, would have been diagnosed based on NIH criteria. There are also some other limitations to our study. We report here 58% participant retention compared to baseline levels 13 years prior which may indicate bias and limit generalisability. However, no differences between completors and non-completors has previously been reported indicating a likely minimal effect of attrition on outcomes [36]. Although the FFQ is a validated measure of assessing nutritional intake, we are not able to assess the contribution of dietary patterns to the development or severity of PCOS due to the study design and report here only associations between dietary patterns and PCOS status. Further, the total variance explained by each factor was intermediate compared with previous factor analyses conducted in different age groups [29,58,59]; however, the Kaiser-Meyer-Olkin measure of sampling adequacy was 0.78, exceeding the recommended value of 0.6; and Bartlett's test of Sphericity achieved statistical significance indicating the correlations in the data set are appropriate for factor analysis. Moreover, the food groups loading on the factors were varied and many were greater than the 0.25 cut-off value suggesting that our population had a varied diet that was, nevertheless, still specific to the identified factors. As the present study is the first of its kind in this population, further studies are required to refute or support our findings and future work is warranted assessing the contribution of dietary pattern intake to the severity or incidence of PCOS.

5. Conclusions

In conclusion, we report for the first time the independent association of PCOS status with self-reported dietary patterns, specifically a Mediterranean diet pattern. This may indicate an improvement in the quality of dietary intake following a diagnosis of PCOS. We also report no increase in dietary patterns high in non-core, meat or take-away foods despite a higher body weight. Combined with our prior research showing healthier intake but higher caloric consumption, it appears that women with PCOS may have a greater appetite and are more overweight, despite a healthier diet. Future research should examine the contribution of dietary patterns to the incidence and severity of PCOS and the potential for modification of dietary patterns in the lifestyle management of PCOS.

Acknowledgments: The research on which this paper is based was conducted as part of the Australian Longitudinal Study on Women's Health, which was conceived and developed by groups of inter-disciplinary researchers at The University of Newcastle and The University of Queensland. We are grateful to the Australian Government Department of Health for funding and to the women who provided the survey data. The authors thank Professor Graham Giles of the Cancer Epidemiology Centre of The Cancer Council Victoria for permission to use the Dietary Questionnaire for Epidemiological Studies (version 2), Melbourne: The Cancer Council Victoria, 1996. We also thank all the participants for their valuable contribution to this project. L.J.M. is supported

by a South Australian Cardiovascular Research Development Program Fellowship (ID AC11S374); a program collaboratively funded by the National Heart Foundation, the South Australian Department of Health and the South Australian Health and Medical Research Institute. J.A.G. is funded by a Robinson Research Institute Post-Doctoral Fellowship, G.D.M. is funded by the ARC Future fellowship (FT120100812) and H.J.T. is funded by an NHMRC fellowship (ID 545888).

Author Contributions: L.J.M., G.D.M.: Substantial contributions to conception and design, or acquisition of data; L.J.M., J.A.G.: Analysis and interpretation of data; L.J.M., J.A.G., G.D.M., H.J.T.: Drafting the article or revising it critically for important intellectual content; L.J.M., J.A.G., G.D.M., H.J.T.: Final approval of the version to be published.

Conflicts of Interest: The authors declare no conflict of interest.

ABSTRACT

Introduction: Polycystic Ovarian Syndrome (PCOS) affects 18-22% women of reproductive age. We conducted a systematic review and meta-analysis to quantify expected benefits of lifestyle (exercise and dietary) interventions on various clinical outcomes in PCOS. **Methods:** Potential studies were identified by conducting systematic search of Pub Med, CINAHL and Cochrane controlled trials registry (1966 to April 2013) using key concepts of PCOS, exercise, dietary and lifestyle interventions. **Results:** Significant improvements were seen in women who received lifestyle intervention versus usual care, in body composition parameters of body mass index (BMI), mean difference (MD) -1.12 kg.m⁻² (95%CI -0.22 to -0.03, P=0.009), body weight MD -3.42 kg (95%CI -4.86 to -1.99, P<0.00001), waist circumference MD -1.64 cm (95%CI -2.09 to -1.19, P<0.00001), waist hip ratio MD -0.03 (95%CI -0.05 to -0.01, P=0.0002) and body fat % MD -1.71% (95%CI -3.10 to -0.32, P=0.02). Insulin improved significantly, MD -1.10 pmol/L (95%CI -2.05 to -0.16, P=0.02). Lipid profile improved, total cholesterol MD -0.09 mmol/L (95%CI -0.14 to -0.04, P=0.0007) and low density lipoprotein (LDL) MD -0.15 mmol/L (95%CI -0.23 to -0.07, P=0.0003). C-reactive protein (CRP) was significantly lower, MD -0.47 mmol/L (95%CI -0.80 to -0.15, P=0.004). Significant improvements were also observed in cardio-respiratory fitness with resting heart rate MD -1.89 beats.min⁻¹ (95%CI -2.90 to -0.88, p=0.0002) and peak VO₂ MD 5.09 ml.kg⁻¹.min⁻¹ (95% CI 3.13 to 7.05, P<0.00001). **Conclusions:** Our analyses suggest lifestyle intervention is optimal for improving body composition parameters, insulin, total and LDL-cholesterol, CRP and cardio-respiratory fitness in women with PCOS.

INTRODUCTION

Polycystic Ovarian Syndrome (PCOS) was first reported in the 1930s by Stein and Leventhal [1]. This is the most common endocrine disorder affecting up to 18-22% of reproductive age women [2]. PCOS is characterised by clinical or biochemical hyperandrogenism [excess androgens which lead to acne, scalp hair loss, excessive facial and body hair (hirsutism)], insulin resistance, oligo/amenorrhea (infrequent or no menstruation), polycystic ovaries and infertility or reduced fertility [3, 4]. Physical inactivity and obesity work together with the genetic post receptor defects and lead to insulin resistance and hyperinsulinaemia [5, 6]. Insulin resistance and increased insulin levels aggravate the symptoms of PCOS in relation to biochemical and clinical hyperandrogenism. It is not the entire body weight but the distribution of that weight as fat in android (abdominal, central or visceral) pattern that increases health risks and worsens PCOS symptoms. Visceral adipose tissues produce adipocyte related hormones – Adiponectin and Leptin, which are insulin antagonists and contribute towards insulin resistance [7]. Insulin resistance and obesity increase the risk of glucose intolerance, dyslipidemia and diabetes mellitus (DM) considerably, which in turn increases cardiovascular risks [8].

Elevated levels of androgens (testosterone, dehydroepiandrosterone and androstenedione) are not uncommon, and occasionally hyperprolactinaemia or hypothyroidism are present [9]. Most women with PCOS have elevated luteinizing hormone (LH) levels with normal oestrogen and follicle-stimulating hormone (FSH) production [10]. Increased insulin levels, obesity and hyperandrogenism contribute to the vicious cycle of anovulation which makes it hard for these women to conceive, often leading to depression and anxiety [11].

"The Effect of Lifestyle Intervention on Body Composition, Glycaemic Control and Cardio-Respiratory Fitness in Women With Polycystic Ovarian Syndrome: A Systematic Review and Meta-Analysis"

Hyperinsulinaemia leads to excess androgen production, so lowering insulin levels by exercise training and weight loss (even as little as 5% of body mass) may reduce free testosterone levels and restore ovulatory cycles, resulting in improved menstrual regularity, ovulation, and pregnancy rates in many women with the disorder [12].

A systematic review was completed in 2009 by Harrison et al. [13] but these authors did not conduct data pooling. In 2011 a systematic review and subsequent meta-analyses was conducted by Moran et al.[14], but this analysis only included 6 published studies. Six more recent lifestyle studies for PCOS mean that the volume of pooled data has doubled and the number of outcome measures has been extended. We therefore conducted a systematic review and meta-analysis; the primary aim was to quantify the expected benefits of exercise training and dietary interventions on a range of clinical outcomes in women with PCOS.

METHODS

Search strategy

Potential studies were identified by conducting a systematic search using Pub Med, www.ncbi.nlm.nih.gov/pubmed (1966 to April 2013). A search strategy can be seen in the supplementary files. CINAHL and the Cochrane controlled trials registry were also searched (1966 to April 2013). The search strategy included the key concepts of PCOS, dietary therapy, lifestyle therapy and exercise training. These were combined with a sensitive search strategy to identify randomized controlled trials. Reference lists of papers found were scrutinized for new references. All identified papers were assessed independently by two reviewers (NS and LH). Searches of published papers were also conducted up until April 2013.

Inclusions

Randomized, controlled trials of exercise alone or lifestyle (exercise and diet) intervention in people with PCOS were included. There were no language restrictions.

Exclusions

Animal studies, review papers and non-randomized controlled trials were excluded. Studies that did not have desired outcome measures or participants who were non-polycystic ovary syndrome patients in either exercise, lifestyle (exercise and diet) or usual care groups were excluded. Several authors were contacted and provided missing data, these data were used in the analyses. Incomplete data or data from an already included study was excluded. Studies using interventions other than lifestyle (e.g. electro acupuncture, ultrasound) were excluded.

Studies included in the review

Our initial search identified 201 manuscripts, examination of the latest editions of relevant journals yielded a further 32 manuscripts. Out of 233 studies, 28 were excluded at first inspection as duplicates, 182 were removed after reading titles or abstracts, 13 of these studies were not trials of lifestyle therapy in PCOS women, leaving 23 studies; 11 studies were excluded for various reasons (see Supplementary Table 3), 12 studies were included for analysis (see consort statement, Figure 1).

Data synthesis and Outcome Measures

Our lifestyle intervention groups were defined as exercise alone or exercise plus diet. Our definition of usual care (comparator) groups could include sedentary control, placebo, diet only or metformin. Analyses were only conducted on intervention versus comparator 1, see Table 1. Data on all outcomes measures were archived in a database. Outcome measures following interventions included body mass index (BMI), body weight, waist circumference

"The Effect of Lifestyle Intervention on Body Composition, Glycaemic Control and Cardio-Respiratory Fitness in Women With Polycystic Ovarian Syndrome: A Systematic Review and Meta-Analysis"

(WC), percentage body fat, waist hip ratio, glycaemic parameters (insulin, glucose and homeostatic model assessment (HOMA) which quantifies insulin resistance), lipids, C-reactive protein (CRP) and cardio-respiratory fitness (peak oxygen consumption (peak VO₂) and heart rate).

Statistical analysis

Meta-analyses were completed for continuous data by using the change in the mean and standard deviation of outcome measures as we did not wish to assume randomization would adjust for baseline imbalance. Change in post-intervention mean was calculated by subtracting baseline from post-intervention values. Change in the standard deviation of post-intervention outcomes was calculated by using Revman 5.0 (Nordic Cochrane Centre Denmark). Data required was either (i) 95% confidence interval data for pre-post intervention change for each group or when this was unavailable (ii) actual P values for pre-post intervention change for each group or if only the level of statistical significance was available (iii) we used default P values (e.g. P<0.05 becomes P=0.049, P<0.01 becomes P=0.0099 and P = not significant becomes P=0.05). A random effects inverse variance was used with the effects measure of mean difference. Heterogeneity was quantified using Cochrane Q test [15]. Sensitivity analyses were conducted by removing studies of exercise and diet, leaving exercise only studies, for the outcomes BMI, WC and peak VO₂. The purpose of sensitivity analyses was to compare effect sizes of exercise alone with exercise and diet. Egger plots [16] were provided to assess the risk of publication bias (see supplementary files). Study quality was assessed by using a modified PEDro [17] score (out of 9 maximum score) as blinding participants difficult in lifestyle studies. We used a 5% level of significance and 95% confidence intervals, figures were produced using Revman 5.

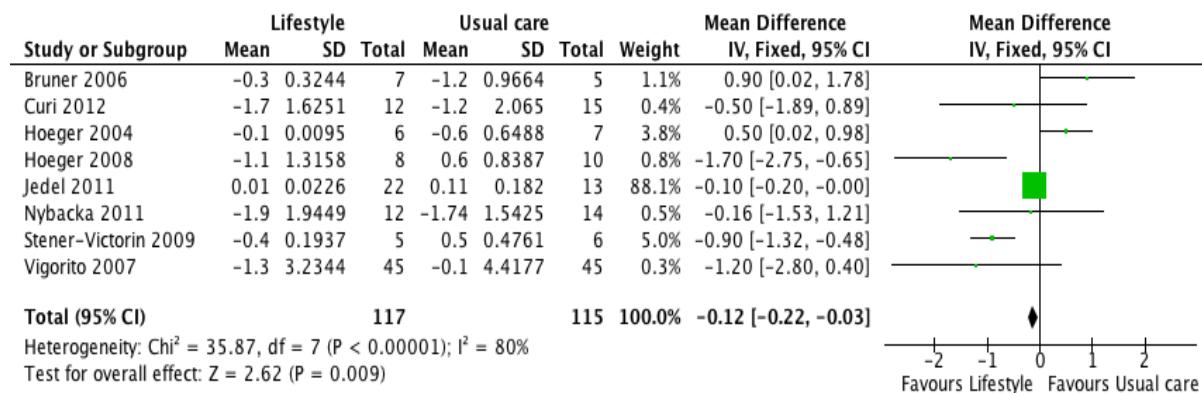

RESULTS

Our analyses included data from 12 studies [3, 4, 18-27], which yielded data on 668 women with PCOS. In seven studies the mean BMI indicated the participants were obese, three studies indicated women were overweight and in two studies it was unclear. Mean age of participants in all but one study was 21-32 years of age. Details of number of participants, duration of studies and withdrawals for included studies can be seen in Table 1. Supplementary Table 1 contains detailed descriptions of all interventions and comparator groups. Details of baseline characteristics of participants in included studies can be seen in supplementary files, Table 2. Details of the excluded randomized, controlled, trials [28-38] can be seen in supplementary file, Table 3.

Body Composition Parameters

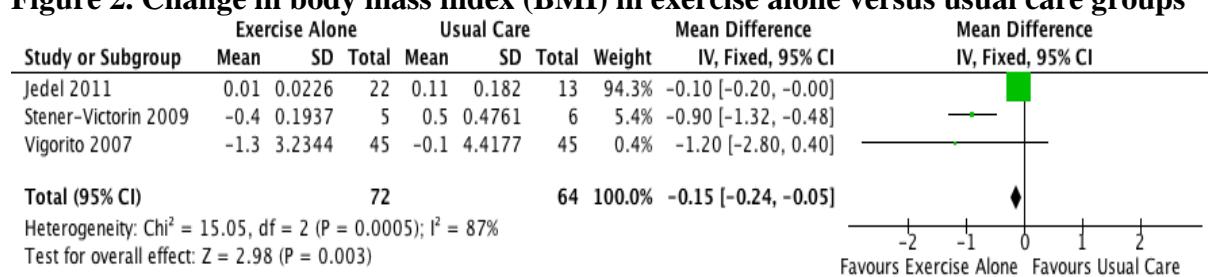

Analysis of change in BMI showed significant improvement in lifestyle versus usual care groups, mean difference (MD) -1.12 kg.m^{-2} (95%CI -0.22 to -0.03 , $P=0.009$), see Figure 1.

Figure 1. Change in body mass index (BMI) in lifestyle versus usual care groups

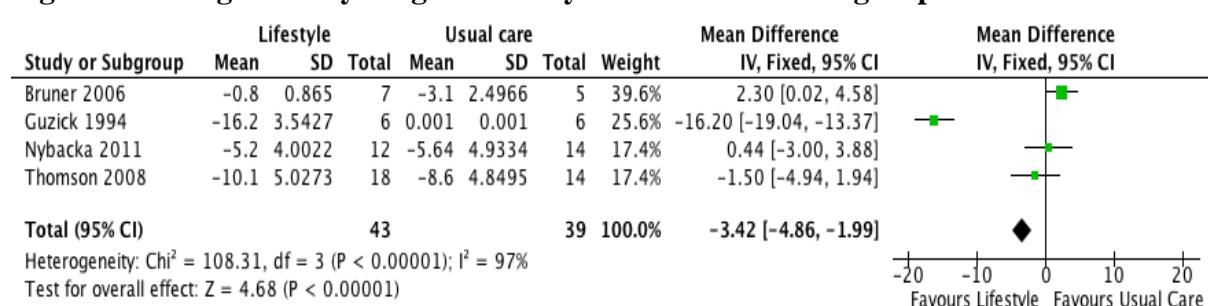

When studies using exercise plus diet were removed to distinguish between exercise alone and exercise plus diet groups, MD was -0.15 kg.m^{-2} (95% CI -0.24 to -0.05 , $P=0.003$), see Figure 2. Note the 95% CI's in figures 1 and 2 overlap considerably.

Figure 2. Change in body mass index (BMI) in exercise alone versus usual care groups

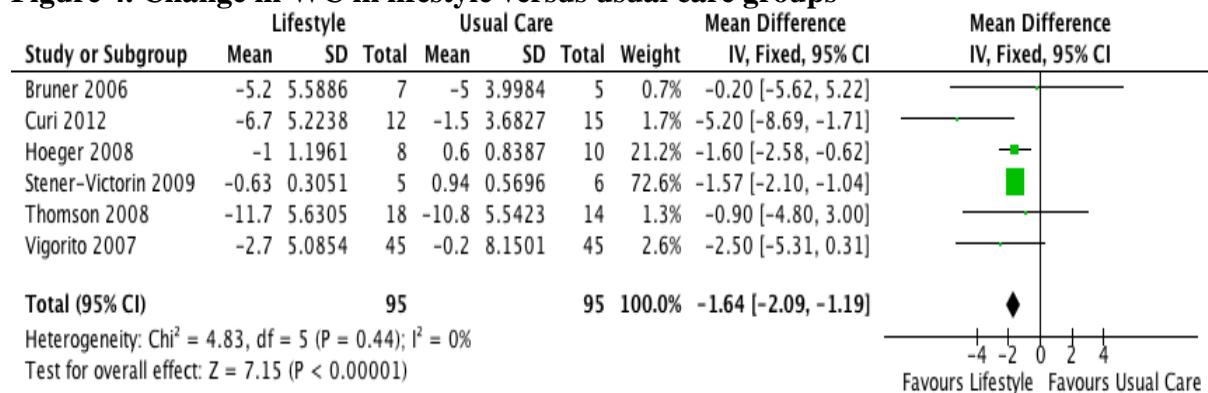

Analysis of change in body weight showed significant improvement in lifestyle versus usual care groups, MD -3.42 (95%CI -4.86 to -1.99, $P < 0.00001$), see Figure 3.

Figure 3. Change in body weight in lifestyle versus usual care groups

Waist circumference (WC) was significantly reduced for lifestyle versus usual care groups, MD -1.64 cm (95%CI -2.09 to -1.19, $P < 0.00001$), see Figure 4.

Figure 4. Change in WC in lifestyle versus usual care groups

When studies using exercise plus diet were removed to distinguish between exercise alone and exercise plus diet groups, MD was -0.51(95% CI -0.67 to -0.34, $P < 0.00001$), see Figure 5.

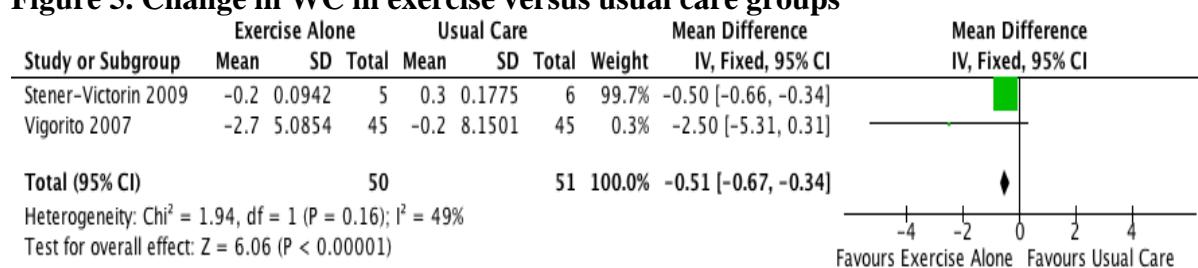

"The Effect of Lifestyle Intervention on Body Composition, Glycaemic Control and Cardio-Respiratory Fitness in Women With Polycystic Ovarian Syndrome: A Systematic Review and Meta-Analysis"

by Haqq L, McFarlane J, Dieberg G, Smart N

International Journal of Sport Nutrition and Exercise Metabolism

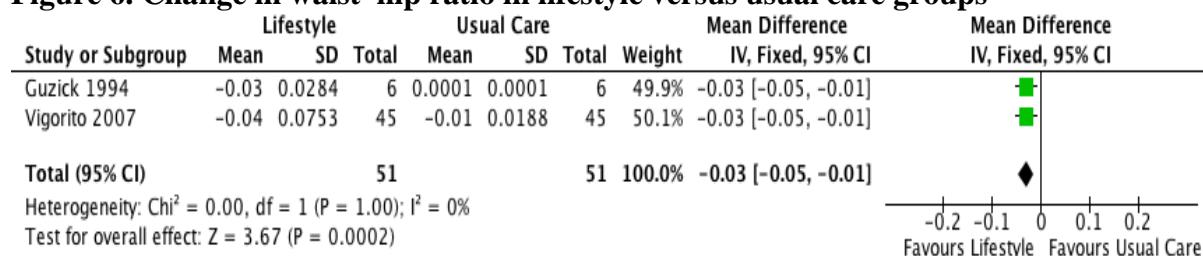

© 2014 Human Kinetics, Inc.

Figure 5. Change in WC in exercise versus usual care groups

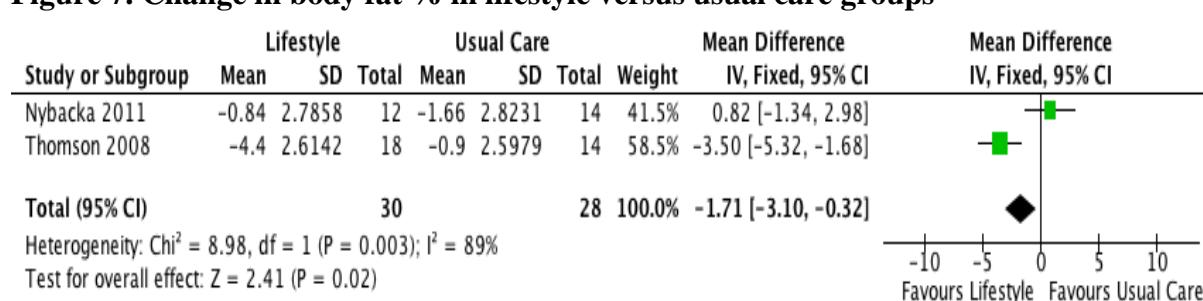

Waist-Hip ratio was significantly lower for lifestyle versus usual care groups, MD -0.03 (95%CI -0.05 to -0.01, $P=0.0002$), see Figure 6.

Figure 6. Change in waist–hip ratio in lifestyle versus usual care groups

Body Fat % was significantly lower for lifestyle versus usual care groups, MD -1.71% (95%CI -3.10 to -0.32, $P=0.02$), see Figure 7.

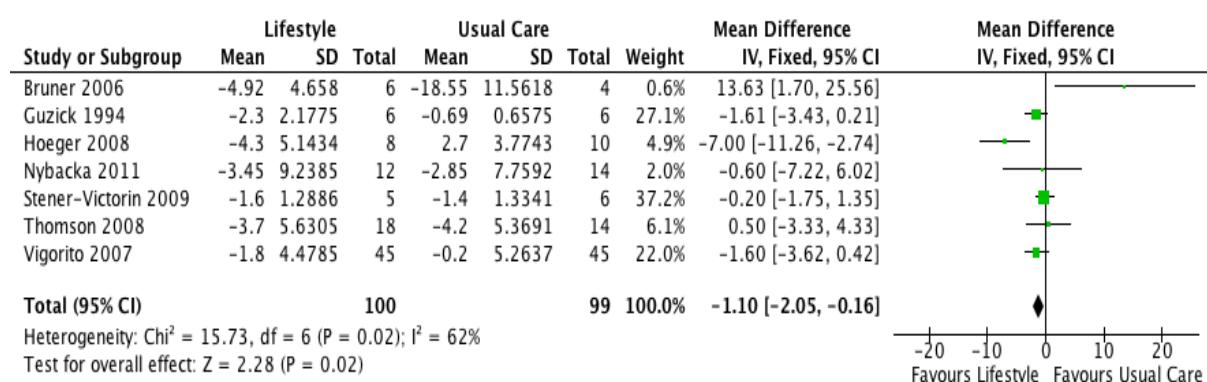

Figure 7. Change in body fat % in lifestyle versus usual care groups

Glycaemic Parameters

Insulin levels were significantly lower for lifestyle versus usual care groups, MD -1.10 pmol/L (95%CI -2.05 to -0.16, $P=0.02$), see Figure 8.

Figure 8. Change in insulin in lifestyle versus usual care groups

Glucose levels were not significantly lower for lifestyle versus usual care groups, MD

-0.02 mmol/L (95%CI -0.04 to 0.00, P=0.06), see supplementary file, Figure S1.

HOMA was not significantly different for lifestyle versus usual care groups, MD 0.10

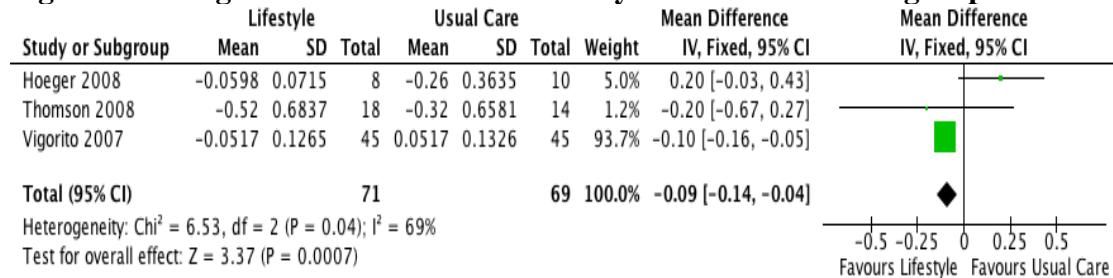

(95%CI -0.22 to 0.42, P=0.56), see supplementary file, Figure S2.

Lipid Profile

There was no significant difference in triglycerides between lifestyle versus usual care groups, MD 0.19 mmol/L (95%CI -0.04 to 0.42, P=0.11), see supplementary Figure S3.

Total cholesterol was significantly lower in lifestyle versus usual care groups, MD -0.09 mmol/L (95%CI -0.14 to -0.04, P=0.0007), see Figure 9.

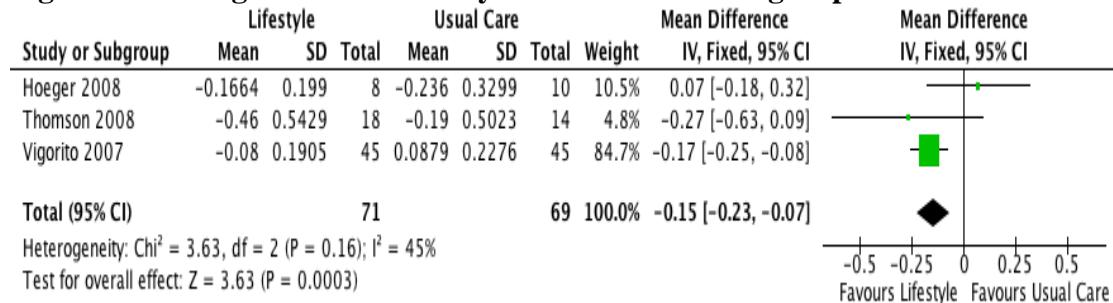

Figure 9. Change in total cholesterol in lifestyle versus usual care groups

LDL cholesterol was significantly lower in lifestyle versus usual care groups, MD -

0.15 mmol/L (95%CI -0.23 to -0.07, P=0.0003), see Figure 10.

Figure 10. Change in LDL in lifestyle versus usual care groups

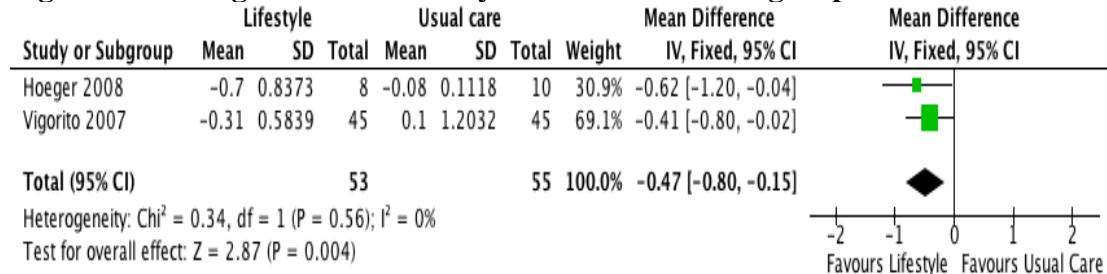

HDL was not significantly different in lifestyle versus usual care groups, MD -0.01

mmol/L (95%CI -0.04 to 0.02, P=0.51), see supplementary Figure S4.

C-Reactive protein (CRP)

Inflammatory marker CRP was significantly lower in lifestyle versus usual care groups, MD --0.47 mmol/L (95%CI -0.80 to -0.15, P=0.004), see Figure 11.

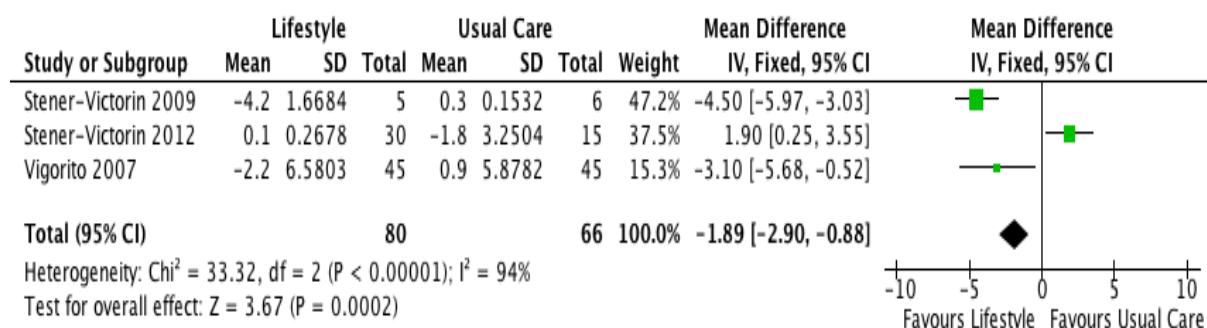

Figure 11. Change in CRP in lifestyle versus usual care groups

Cardio-respiratory Fitness

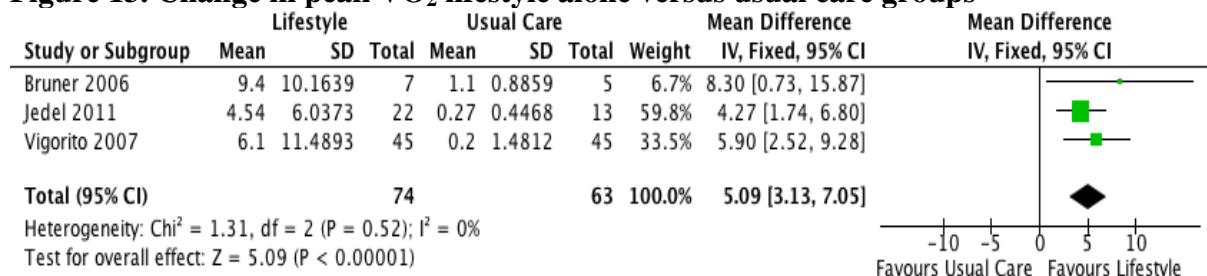

Resting heart rate was significantly lower in exercise alone versus usual care groups, MD -1.89 beats. min^{-1} (95%CI -2.90 to -0.88, P=0.0002), see Figure 12.

Figure 12. Change in resting heart rate in exercise alone versus usual care groups

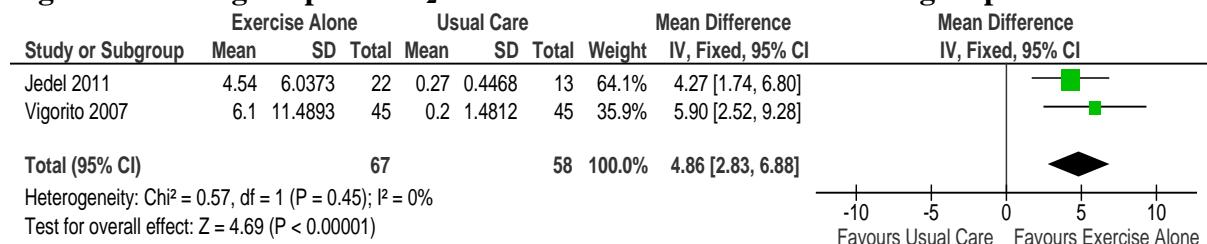

Peak VO_2 improved significantly for lifestyle versus usual care groups, MD 5.09 $\text{ml} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$ (95% CI 3.13 to 7.05, $P < 0.00001$), see Figure 13.

Figure 13. Change in peak VO_2 lifestyle alone versus usual care groups

When studies using exercise plus diet were removed to distinguish between exercise alone and exercise plus diet groups MD was 4.86 (95% CI 2.83 to 6.88, $P < 0.00001$), see Figure 14.

Figure 14. Change in peak VO_2 in exercise alone versus usual care groups

STUDY QUALITY

In terms of study quality, median score was 7, with four studies scoring 6, four studies scoring 7, three studies scoring 8 and one study scoring 9, using a modified PEDro scale (out of 9). Details of the scores and PEDro scale are given in the supplementary file, Table 4. Egger plots showed little or no evidence of publication bias (see supplementary Files, Figures S5-S9).

DISCUSSION

This work presents a meta-analysis of the effectiveness of lifestyle (exercise and diet) intervention for polycystic ovarian syndrome (PCOS). These analyses were conducted using

"The Effect of Lifestyle Intervention on Body Composition, Glycaemic Control and Cardio-Respiratory Fitness in Women With Polycystic Ovarian Syndrome: A Systematic Review and Meta-Analysis"

by Haqq L, McFarlane J, Dieberg G, Smart N

International Journal of Sport Nutrition and Exercise Metabolism

© 2014 Human Kinetics, Inc.

a range of prognostic markers of PCOS as outcome measures. There was a significant improvement in body composition parameters (BMI, body weight, waist circumference, waist-hip ratio and body fat %), total- and LDL-cholesterol, C-reactive protein, insulin and cardio-respiratory parameters (resting heart rate and peak VO₂). These data have clinical implications for improving reproductive function in overweight/obese women with PCOS using non-pharmacological methods.

Lifestyle with or without dietary intervention produced favourable changes in body composition measures; WC, waist-hip ratio, percentage body fat and BMI, suggesting that a large proportion of weight lost was adipose tissue. Previously, combined diet and exercise interventions for PCOS participants reported reductions in body fat but also muscle mass [23]. Previous work has suggested it is exercise, not dietary, intervention that provides the greatest changes in body composition and glycaemic control in women with PCOS [23]. Previous work also suggests modest weight reduction of about 5-10% might play the most significant role in restoration of ovulation and fertility in obese women with PCOS [21, 39]. The mean study duration of this analysis was 20 weeks; this duration may not be sufficient to achieve 5-10% weight loss.

Exercise alone has been shown to improve fertility [23, 40] and this is most likely mediated by improved insulin resistance [40]. Our analyses lend weight to the theory that insulin sensitivity is improved with regular exercise training in women with PCOS, although blood glucose was actually better in control groups. Our results suggest that optimal reductions in measures related to central obesity (waist circumference and waist-hip-ratio) require both exercise and dietary intervention. These reductions in central obesity are accompanied by improvements in measures of glycaemic control. Previous work has suggested that improved insulin sensitivity is closely related to improved waist circumference

and waist-hip ratio, which in turn is related to android (central) body fat morphology [41].

Previous work has hypothesized that either through exercise alone, or in combination with appropriate dietary intervention, enhancements in insulin sensitivity is possible in women with PCOS.

Our analyses demonstrated improved peak VO₂ and reduced resting heart rate after completion of lifestyle therapy in women with PCOS. Vigorito et al. have previously shown that in overweight women with PCOS insulin sensitivity and peak VO₂ are positively correlated [27]. Moreover a 2006 review suggested: (i) Exercise may prevent reproductive complications associated with maternal obesity. (ii) Obesity increases the risk of infertility and miscarriage. (iii) Weight loss programs that incorporate diet and exercise are a cost-effective fertility treatment that may also reduce the probability of obesity-related complications during pregnancy. (iv) Regular exercise following conception may prevent excessive gestational weight gain and reduce post-partum weight retention [42]. Our measurements support the argument that higher levels of cardio-respiratory fitness are associated with better fertility. The magnitude of change in peak VO₂ demonstrated here would be noticeable to the participants and also clinically meaningful.

With respect to lipid profile, our analyses showed improvements in only Total- and LDL-cholesterol. Previous work has suggested that exercise induced changes in lipid profiles require a sustained lifestyle adherence program [43]. It may be that the included studies were not of sufficient duration to induce lipid improvements [14, 44], although reduced CRP levels indicate reduced systemic inflammation.

The sensitivity analyses for exercise only for the BMI, WC and peak VO₂ yielded very similar effect sizes and statistical significance as combined diet and exercise

interventions. This suggests that exercise will improve these outcomes either in isolation or in combination with dietary intervention.

In summary, previous work has suggested that exercise is superior to dietary intervention for improving glycaemic control and body composition in women PCOS, our data support this, although intuitively a combined exercise and dietary intervention approach may yield superior results in trials lasting more than 20 weeks. We suspect there are currently insufficient published data to separate the effects of exercise or dietary intervention.

The limitations of this study are that exercise prescriptions vary slightly, and several studies used additional dietary interventions, although we conducted sub-analyses for BMI, WC and peak VO₂ to account for this. Meta-analysis of continuous data is problematic; we took the approach of adjusting for baseline difference in primary outcomes between allocation groups by measuring pre-versus post-intervention change. In many cases we were accurately able to calculate change in standard deviation, but in some cases where exact P-values were not provided in included study reports we had to use default values e.g. P<0.05 or P<0.001 in our calculations which may have introduced errors. Moreover these errors may have increased the measures of heterogeneity in our analyses which in some cases were high. Finally, we acknowledge that other factors, especially those related to volume of exercise (e.g. program duration) may explain some of the outcomes reported.

Conclusions

Our analyses suggest lifestyle intervention involving exercise are optimal for improving body composition parameters, insulin, lipid profile (especially total and LDL-cholesterol), CRP and cardio-respiratory fitness in women with PCOS.

Abstract

Background: This paper reports the findings of an exploratory study about the information women diagnosed with Polycystic Ovarian Syndrome (PCOS) want to know about their condition and the consequences of this information for future treatment and health outcomes.

Methods: In-depth qualitative interviews regarding their information needs were undertaken with ten South Australian women diagnosed with PCOS. These women were aged 28–38 years and at differing stages of their fertility experience. The time since diagnosis ranged from 1–17 years. The main outcome measures sought were the identification of the information needs of women diagnosed with Polycystic Ovarian Syndrome (PCOS) during different periods of their lives; how and where they obtain this information, and the consequences of this information for future treatment and health outcomes.

Results: The women with PCOS in this study preferentially used the Internet for their information needs, as it had the advantages of convenience, privacy and accessibility, when compared with traditional mechanisms of information provision.

Conclusion: Giving a name to a collection of symptoms may bring relief and provide recognition that there really is a problem. However, with a diagnosis comes the need to have questions answered. A diagnosis of a chronic condition such as PCOS necessitates decision-making regarding possible treatment strategies and lifestyle choices. Information is needed in order to participate in shared decision making. The Internet proved to be a most versatile and beneficial source of information source for women with PCOS, if its limitations are taken into consideration.

Background

Polycystic Ovarian Syndrome (PCOS), the most common endocrine disorder in women [1], generates numerous health problems, usually commencing at puberty. PCOS affects approximately 5 to 10% of women of reproductive age in Australia [2].

The aetiology of PCOS is unclear: however, genetic inheritance may be implicated [3], and both insulin and androgen production are affected. Women diagnosed with PCOS have an increased risk of menstrual disorders, hirsutism, infertility, miscarriage, obesity, cardiovascular complications, endometrial cancer, and a seven fold greater risk of Type II diabetes [4].

The symptoms of PCOS may appear at any age during the reproductive life, and manifest in some groups of women differently to others. Women with PCOS may not seek assistance until they attempt to conceive, as this may be the first time they have not been under the influence of contraception, which may have masked the symptoms [5]. Symptoms such as obesity and hirsutism which were previously just annoying may get worse, and infertility may be a problem. Studies suggest symptoms vary by ethnicity. A 1999 study of Greek Caucasian women aged 17 to 45 years with PCOS (6.8% overall prevalence, n = 192), reported the prevalence of obesity at 38%, 29% experienced hirsutism with no menstrual disorders and 9.2% had menstrual disorders with moderate to severe hirsutism [6]. In Spanish Caucasian pre-menopausal women aged 18 and over, a study undertaken in 2000 found those with PCOS (6.5% overall prevalence, n = 154) had a prevalence of obesity of 36%, 40% had hirsutism, and 100% had menstrual disorders [7]. However, another 2000 study concerning women in the USA aged 18 to 45 years, white and black with PCOS (overall prevalence of 6.6%, n = 400) had a prevalence of 66% with menstrual disorders only, 19% with hirsutism only, and 14.7% experiencing both [8]. In Iranian girls aged 14 to 18 years, there was an overall prevalence of 3% with PCOS, and of these 6% had hirsutism, 7.4% had menstrual dysfunction, and 4.7% had severe acne [9].

In order to manage its impact, women with PCOS have a great need for information [10]. The physical and psychological problems associated with obesity and infertility, in particular, significantly affect quality of life [11]. Despite the huge increase in the availability of health information concerning PCOS, such as PCOS related books and websites, there has been little research in this area, particularly qualitative research. One of the few studies concerned with general health status of PCOS women examined questions important to women with PCOS. This 1998 study developed a tool to assess the quality of life of women with PCOS, in order to evaluate treatment outcomes [12]. Kitzinger & Willmott concentrated on women's own experience of PCOS within a feminist framework [13]. They found PCOS to be deeply stigmatising, and associated with considerable stress.

There is much consumer information available for many different aspects of health and disease, including PCOS. This information includes that developed by health professionals, advertising disguised as education, and also resources developed by support groups and individuals. The amount of information has increased and has recently become far more accessible with the advent of the Internet. The 1999 South Australian Health Omnibus Survey (n = 3013), a representative survey of people age fifteen years and above [14], found that the sources used to

answer health related question in the last twelve months included mostly Doctors (83.6%), with Internet (12.3%) ranked seventh out of ten categories. The same survey found that 77.5% of respondents only sought health information when they had a problem.

Another group specialising in research considering how people use the internet for health research, found that the users appreciated the convenience of being able to seek information at any hour, that they could get a wealth of information online, and that they could do research anonymously.[15]

However, this paucity of research around specific conditions is disappointing. Women with PCOS often deal with their symptoms for a long time, without a specific diagnosis [13]. Many of these women do not know where to look for information. Such women have both a right to more information about their condition and are likely to benefit considerably if information is available. Given questions regarding the reliability, adequacy and agenda behind various sources of potential health information, our hopes are that guidelines can be formulated which assist health care providers in assuring the highest quality of information for the greatest benefit to health consumers.

Methods

This study used in-depth qualitative interviews to explore the complexity and in-process nature of meanings, attached to PCOS [16]. Women were recruited for the study from two major sources. Initially, seven women were recruited from a previous nutritional study of PCOS, undertaken jointly by the Commonwealth Scientific Industrial Research Organisation's Division of Health Sciences and Nutrition (CSIRO HSN), and the University of Adelaide's Department of Obstetrics and Gynaecology [17]. These women had previously been diagnosed in accordance with the National Institute of Health (NIH) consensus criteria for clinical diagnosis of PCOS [18]. A second group of women were recruited from the Polycystic Ovarian Syndrome Association of Australia (POSAA), a support group for women with PCOS. All women recruited to the study had previously obtained a diagnosis, which provided them with a reference point in their life from which to build their stories.

Intensity sampling, a sampling technique aiming to select cases that manifest the experience being examined intensely, was used to identify potential recruits [19] The characteristics of participants are discussed below.

Women with PCOS were recruited into the study until no new themes were identified during the interviews. Recruitment took place from May to August 2002. Informed writ-

ten consent was obtained from all participants. Ethics approval was obtained from both the University of Adelaide and CSIRO HSN. Inclusion and exclusion criteria are described in Table 1.

Ten Australian women aged 28–38 years (mean age 32.4) were interviewed. The narrow age group of the participants in this study reflect the time at which fertility is of most concern in a woman's life, as many of the symptoms of PCOS are directly related to fertility, and this is often when women seek diagnosis. The women in this study were at differing stages of their fertility experience. A profile of these women is given in Table 2.

The interviews were carried out by the first author. The first author had previously been involved with a nutrition study, as both a subject and a study coordinator [17] and many of the women were recruited from this same study. Thus, the subjects knew that the author had PCOS, and camaraderie had been established prior to interview. The interviews were reflexive; as the first author had her own experience of the condition, she had been part of the experience of the women in the past, and this experience was the basis of the relationship formed through the interviews such that the subjects and the interviewer were willing to openly exchange their experiences. This also provided the first author with insights during the analysis that may have not otherwise occurred [16].

Interviews were carried out in the women's own homes. The original interview schedule was developed from a review of the literature surrounding PCOS, patient information and education. Questions were developed relating to when the subjects received information, where they obtained it, whether it was helpful, and in what form it came. Other questions were asked regarding the women's own particular experience of the condition, their health status, treatments they had embarked upon, and their own rationale and interpretation regarding the aetiology of the condition. After the piloting, the schedule was modified and, consistent with a grounded approach, it was further developed during the interviews as concepts, categories and themes were identified [16]. The full inter-

view schedule is provided in Table 3. A number of themes from the study are reported on, as they represent stages in the information collection process. These include Information and Diagnosis of PCOS, Information Sources, and Preferences for Information Provision. The time taken for the interviews was between 45 to 90 minutes, and all interviews were tape-recorded.

Each of the interviews was transcribed and reviewed by the first author, which enabled further familiarity with the emerging themes of the interviews. 'Framework' content analysis, an analytical process involving a number of distinct yet highly interconnected stages [20], was used to categorise themes for discussion. This method was chosen because of its ability to facilitate systematic analysis. After transcription, data was managed using QSR N6 Student software [21].

Results and discussion

Information and diagnosis of PCOS

The participants in this study often began their search for information in an environment of uncertainty.

I think one of the difficult things about it was because the symptoms are so diverse and I didn't feel like I had some of them. But I definitely had others of them so it was hard to actually work out whether it applied to me or not. And because no one gave me a definite "Yes, you have it", I still was saying well I don't know have I got it, no I haven't, you know, I don't know, this person says I haven't, this person says I have. So what was probably the most important thing was to find out, "Did I have it?" and what constituted the fact that I had it – so that was probably the most pressing thing. (Portia).

In order to "have an illness", there needs to be a recognition that problems being experienced are abnormal, and part of a greater disorder. In the case of PCOS, symptoms can be explained by other causes, such as stress, diet, lack of exercise and hormones. The path to diagnosis of an underlying cause is delayed, creating further problems with illness, fertility, state of mind and quality of life. Kitzinger and Wilmott refer to the frustration and anger PCOS

Table 2: Profile of Participants

Pseudonym ^a	Age (Years)	Diagnosis (Years)	Marital Status	Education	Fertility Status
Cynthia	28	2	Single	Post school	Trying to conceive (TTC)
Martha	28	2	De facto	University	1 girl
Portia	35	1	Married	University	TTC
Holly	29	4	Married	University	2 boys
Michelle	29	3	Married	Pre matric	TTC, 2 miscarriages
Petra	36	12	Single	Post school	Not tried
Miranda	36	6	Married	Post school	4 miscarriages, adopting
Rebecca	38	4	Relationship	Pre matric	Starting to TTC
Jemima	30	7	Married	Post school	1 girl, 1 boy
Christine	35	17	Married	Post school	TTC, 1 miscarriage

^aPseudonyms are used to conceal the identity and preserve the confidentiality of the thoughts and experiences of the participants of this study.

women felt about delays in diagnosis, lack of information and an unwillingness of health professionals to take their symptoms seriously [13]. These findings demonstrate the dominant themes that women with PCOS face in their path to diagnosis.

Women suffering from PCOS present their initial problem, with differing symptoms that alone may not be cause for major concern. When associated with other symptoms, the effect is compounded and medical advice may be sought.

I had irregular periods as a teenager. My mother, finally after going from GP to GP, the GP just saying "Teenagers have irregular periods", found another GP who referred me to a gynaecologist, who did some tests, different blood tests, didn't do an ultrasound or anything. When I went back to see him he said, "Bit of a hormonal imbalance, come back and see me if you ever have trouble having children". As an 18 year old I thought "yeah right," and didn't think much more about it. (Jemima)

It was important to the women that someone recognised that they did have a problem. Radley talks about resolving the worry caused by uncertainty about signs and symptoms, by having others establish that one is really ill [22]. This social comparison provides a mechanism for the evaluation of one's symptoms. A medical confirmation of an illness can further reassure suspicions of an illness. In this sense, recognition of a problem validated the women's concerns.

Upset, I was upset when I found out. Relieved at the same time because finally I had a name for something that was wrong with me. (Cynthia)

Prior to obtaining verification of their symptoms, and due to their frustration at the delay in diagnosis, some of participants in this study approached the search for relevant information in a different way. Through past knowledge,

gathering of information, and sometimes coincidentally via acquaintances, some of the women suspected that their symptoms did in fact reflect something called Poly-cystic Ovarian Syndrome, and presented this idea to their doctors.

I was probably self-diagnosed in the end... In between seeing the gynaecologists, doing loads of blood tests, an ultrasound, I was in a bargain basement bookshop, they had a one-dollar book on infertility. I opened it up and looked up irregular periods, read through the thing it said PCOS and I said "Hey I've got that, I've got that, I've got that!" So I went along for my follow up appointment, and he said, "You've got a bit of a hormone imbalance." I said "Have I got PCOS?" and he said, "Yes". (Jemima)

Considering the prevalence of PCOS, surprisingly few participants had knowledge of the condition. Once they were given a name, some completely identified with the condition, after doing some initial research.

I didn't know anything,, never heard of PCOS. When I went to the first endocrinologist I said I'd been putting on weight, noticed hair growth, no periods, skin tags and skin discolouration and after I'd done all the reading, they were all the symptoms for PCOS. So I didn't know anything at first. (Holly)

Sources of information are presented in different ways. The women with PCOS in this study identified a range of sources, and these varied in terms of the women's levels of satisfaction, in terms of quality, their expectations, access and availability.

Information sources

Most women were diagnosed by general practitioners, gynaecologists or endocrinologists. Their expectation was that they would receive information about their condition through this initial source. Experience of the initial information that doctors gave them was varied. It has been

Table 3: Interview Schedule

Diagnosis of PCOS
Think back to when you first found out you had PCOS. Tell me about how you were diagnosed? <ul style="list-style-type: none"> • When did you find out? • Who told you? • Why do you think there was a problem/seek help in the first place? • What did they tell you? • How do you feel about what you found out? • What happened next?
Could you tell me what you knew about PCOS when you were told that you had it? <ul style="list-style-type: none"> • Where did you get that information? • Who told you where to look for information? • Were you interested then in finding out more information? • Have you sought information since then? • At the time, what kind of information did you want to know?
Information about PCOS
What do you understand now about PCOS? <ul style="list-style-type: none"> • What do you think causes PCOS? • What are the symptoms and long term effects? • What kinds of treatments are there? • How do you feel about having PCOS now?
What information have you collected about PCOS? <ul style="list-style-type: none"> • What have you learnt from this information? • What did you do with this information • What did you like/dislike about this information? • What is the best way of obtaining information? • What format would you like information presented?
Outcomes/Lifestyle
Do you think that the information you've had about PCOS has helped you take better care of yourself? How? <ul style="list-style-type: none"> • How do you think your general health will be affected in the future? • What information have you had about how PCOS affects getting pregnant? • From this information how do you think PCOS will affect your chance of getting pregnant?
Are there things you would like to know about PCOS for the future? Considering your life experiences, do you think you look for information in the same way as others? If you could start over again: <ul style="list-style-type: none"> • Who do you think is best to give you information about PCOS? • Where would you go to look first for information if you had no guidance? • Why do you think that is a good source? • What would you do differently about getting your information about PCOS?
Is there anything else you think may be important in order to understand your experience with information about PCOS that we should discuss?

shown that there are marked differences between the different specialties in the diagnosis and management of PCOS [23]. The women considered that some doctors did not know very much about PCOS and most were not satisfied with this information.

"Some of them have got no idea. I think we know more than them" (Michelle).

Kitzinger and Wilmott reported a similar finding, as women who have sought information about their condi-

tion upset the doctor-patient relationship balance, complain that they are more informed than the doctors in general, and do not receive positive responses when they suggest treatment options [13]. This finding has been reflected in other similar studies [24,25].

I went to my GP and he sent me on to an endocrinologist, and he told me that with the symptoms that I was telling him that I had, that I probably had PCOS and to go home and lose weight... When I went back to my doctor, he didn't actually know a lot about it. He didn't know a lot about

treatments for PCOS. He was very supportive, in our wishes to have children... I'm sure there are doctors out there now who know a lot more about PCOS, I don't know about GPs, I never got a lot of information about it from GPs, but I'm sure it's well known. (Holly)

Doctors focused on fertility issues as the main problems for those with PCOS, often with the worst-case scenario being emphasised. This was evident in both the women who were trying to conceive, and those where this was not yet an issue. The baseline health risks of the syndrome were not emphasised. Some women were left feeling as though they were powerless to do anything about their condition until they wanted children.

I think it's important to ensure that the medical profession are fully aware, both male and female doctors, and have that information on hand, that first port of call for people who need more information and then to have something on hand to make it easier for people to find out information. I felt like the doctor just did not explain it to me properly and I think doctors need to, I mean they do it with everything. If she'd sat there and told me what my major risks were or whatever, I probably would have taken some steps to do things differently. But from this there doesn't apparently to be anything much you can do until you start having children, then it becomes an issue but as far as the doctors are concerned, unless you've got worse symptoms with the hair and those other things, but if you don't have many symptoms, its all just a matter of just wait and see. (Rebecca)

Some of the participants realised that, at diagnosis, the main issues of PCOS were not of great concern to them. This meant that they might only have retained the information that was important to them.

I really can't begrudge the information my doctor gave me, my local GP. I mean, I'm sure that if I had wanted to take it further, she would have been happy to get other references and things for me. Like I said, it wasn't relevant. It was just I had a name. (Martha)

Those that did have positive experiences with their doctors thought that they were fortunate and this kind of experience was rare.

My local GP is very well up on it... The thing I enjoyed about talking to that doctor was that he seemed to know what I was talking about. The symptoms and things like that. He was the one who said to me this is how you feel, this is what's happening and he was spot on. And he didn't make me feel like I was an idiot. That it was all in my head. He was really, really good. (Michelle)

Information at initial diagnosis was sometimes provided in a take home format, such as a photocopied page out of a medical textbook.

All she basically did was give me the name of the condition and a couple of handouts describing what it was. That was it really. (Martha)

Those who hadn't receive pamphlets wanted some written information to aid in their understanding, after the initial information had been taken in. However, pamphlets were also seen as just part of a whole resource package. Pamphlets had a number of advantages, such as being short, portable, local, and providing information on how to find further information.

That little flyer was really good. I liked it because it was Australian. I found out since then that lots of the stuff differs between America and Australia. But also because it was simple and easy and it was something I could give my parents and family, which is really important. It's hard to explain it. (Portia)

Often looking for information might involve a trip to the library, where books and resources can be found. Local libraries however, did not seem to be helpful, and one participant even felt uncomfortable with the idea. In this study, using a library was associated with level of education. The two women who considered the library, or used it, both had a university education. The woman who did not consider this resource had left school before matriculation.

I don't actually go to the library and say "Hello, can you give me PCOS stuff." Not that I should be ashamed of it but if I don't know stuff then I feel a bit embarrassed asking. (Portia)

The information found in books was scarce, outdated or not at a suitable level for the consumer. Occasionally, information could be found in generalist women's health books, but this often referred to PCOS as a condition of "too many male hormones" [26], which may encourage the stigma of this condition. Sometimes the information provided in books was regarded as paternalistic [27], not providing the information needed for shared decision-making.

I never found a book totally on PCOS... Most of the books that were written by the male doctor type, books I thought were quite clinical and didn't tell the whole truth. This is on reflection because at the time you don't know these things. (Jemima)

Dedicated support groups for PCOS are fairly new in Australia. However, one of the participants had sought out information from an American support group via the Internet prior to the establishment of the Australian network. Three of the women interviewed were involved in the Polycystic Ovarian Syndrome Society of Australia (POSAA), established in 1998. Seven of the women had been involved in a clinical trial regarding PCOS, and this provided contact with other sufferers, as well as information and exercise sessions, designed by a fertility clinic [17]. These groups provided the participants with a very positive experience as it was the first time that they had met with other women who had PCOS. This provided the women with opportunities to share experiences with other sufferers, and for finding information regarding their condition on both an individual and a more general level.

It wasn't until I started doing the diet study that I started communicating with other people that had it and all of a sudden you know I came to accept that I had it, and wanted to know a lot more about it... I think the thing that I did that was really good was that I did the CSIRO study, because doors opened and the information I found. (Cynthia)

It was important for the women to be able to compare themselves with other sufferers. This gave them a frame of reference to rate their own symptoms. Some women came to believe that they were better off than other women with PCOS, which reassured them. The women found that networking with other women provided them with an opportunity to validate their experience, as well as supply them with practical information at their level, from other women with PCOS, and concerned their interests at the time.

I guess I've learnt the most from chatting with other women who've got it, and learning different things like maybe that is related to PCOS when before I thought it wasn't. I thought it was a different problem or whatever... Talking to other people is a huge thing. (Miranda)

Even taking all of the above sources into account, the Internet was the medium of choice for the participants to obtain their information about PCOS, as it had the advantages of other methods as a well as further benefits. However, while the Internet was considered the best way of obtaining information, it was not ideal for everyone. Nonetheless, the women who did not have easy access to the Internet thought that it would be the best way to obtain information, and were keen to use it. Seven of the participants had access to the Internet at home, two at work, and only one did not have any easy access. Five of

the participants used the Internet on a regular basis, and four only used it sporadically.

Finally when the Internet was connected in late 1997, that was the explosion when I connected up to the Internet and thought "My God! – look what we've discovered!"... I've got that many bookmarks on the Internet. Tried to just become informed... Online is good., but I understand that so many people it's not for them. (Jemima)

Although the participants were keen to use the Internet, they had variable responses to the information they found there. Some women found much valuable information, but some were disappointed with the quality, and others were not able to access the information they wanted. Often women found information on the Internet that they would not normally have received, and they shared this with their doctor. The Internet provided the women with evidence that they could present to their doctors, to which they would not otherwise have had access.

I did a lot of research on the Internet and found out a lot about different treatments for women with PCOS. But the treatments were mainly used in the United States, so I had to convince the gynaecologist that I could give it a go. (Holly)

The Internet had enabled communication via chat groups and email lists for some women. This interaction was similar to that found via support groups, yet it could remain anonymous. The participants found these very helpful.

That's the first thing I did was find out all the information and join a few email groups in Australia. I discovered there was a few PCOS groups, so I joined them... I've participated in some chat groups. (Holly)

Using the Internet did, however, require a degree of skill, and the women who were most proficient were more highly educated. In general, the participants were aware that much of the information on the Internet needed to be critically assessed.

I know how to sift through online material... It's a worry when some people present all sorts of witchcraft, heaps of the stuff and a lot of young naïve people do. (Jemima)

Some women also used the Internet in specific ways; obtaining information from support groups that provided email lists, newsletters and question and answer sessions. Information on the Internet was found to be available at different levels of understanding, and this was appreciated.

I think the thing about the Internet is that you don't have to read huge amounts at one time. You can have a little bit and absorb it and then have a little bit more of it. I don't know how you could do that any other way. So you can sort of go at a level when you're ready to. (Portia)

Preferences for information provision

There are likely to be a number of reasons for the participants' preference for the Internet as an information source. Firstly, frustration at the paucity of information available via traditional mechanisms to women with PCOS, may be one motivating factor for why these women preferred to obtain information via the Internet. Established health and medical information sources may be inadequate for the information that women want about PCOS. Women with PCOS need time to understand the complexities of their chronic condition. The average length of a medical consultation in Australia is 14.8 minutes [28], which may be inadequate for a condition such as PCOS. In addition, women diagnosed some while ago may not want to retell their story and going through tests again every time they change doctors for other opinions, or just to get new information. Many women have also had unpleasant prior experiences, which undermined their confidence in talking to doctors.

Secondly, many of the participants preferred the Internet because it is private and accessible from one's own home, rather than having to make contact with a library or with medical practitioners. Broom (2005) found that men with prostate cancer, had similar experiences, preferring to be anonymous in their pursuit of information. Women with PCOS find it an embarrassing disease and consequently they may seek anonymity when they look for information. They prefer not to discuss their hairiness, obesity and failure to become pregnant with others who would not understand or empathise with their experience. The women realised that they had many choices of information available to them through the Internet, and this did not seem to be daunting.

I like the way I can access the information, that I can do it all of the time, night and day...Because it's accessible, because there's lots of stuff on there, look up more than one thing. Because it's easy for me to use... I can do it privately as well. At least this way I can explore by myself. (Portia)

Finally, women with PCOS used the Internet because it provided them with a sense of control. This included control over the information that they received, the time they received it, the level of the information, and the amount of information. This finding was also reflected in men with prostate cancer by Broom (2005). This continues to upset the power balance between medicine and health consumers, as the women in this study were obtaining

their information outside the usual medical sphere, and on their own terms.

Information about PCOS has grown recently. Women with PCOS want the most up to date information at their fingertips, and the Internet makes this information accessible. Women can become familiar with this area of knowledge, and learn exactly where to look, depending on their information needs.

Because there's a lot on there, there's a lot of different groups and different opinions, and you can compare it. Different studies, its not just one person's opinion. (Michelle)

Women's information needs about PCOS evolve as different parts of their lives are emphasised. Frank (1995) refers to people with illnesses telling stories to work out their changing identities, and women with PCOS need to do this at many different points in their life [29].

I came across some real life stories, which weren't really good because all of them had unsuccessful rates of fertility, so it just upset me... I learnt, I'm not alone, its good to know people around you have it. It's also good to hear that there are some people that aren't doing so well and that there's also good to hear the people who are doing well, because you can sort of rate yourself between that and where you're at. (Cynthia)

Many of the women in this study also had a high level of education, which allowed them to make use of more specialized information resources such as electronic databases, and enabled them to venture into unfamiliar areas such as medicine in their search for information. Much of this information was designed for people with medical training, so was sometimes inappropriate for the average woman with PCOS. However, the women in this group were discerning, and were happy that this information was available to them. The women with the least education in this group made the least use of the Internet, and information resources in general, such as reading material. These women preferred talking with a doctor.

As PCOS is a hidden disease, women with PCOS often have no contact with other sufferers. Other recent studies regarding chronic disease information seekers have illustrated a preference for sources other than the Internet [30], such as social networks. Perhaps this is why women with PCOS seem to make use of Internet for their health information, as well as to network with other sufferers. The Internet provides an initial anonymity, an arena to discuss sensitive issues, and a reciprocal support network, that can be further developed once trust is gained.

Conclusion

Women with PCOS in this study, in addition to routinely using other information sources, preferred using the Internet. The Internet had the advantages that other sources provided, and a number of extra strengths. The Internet opened a world of information to these women, not just that which the doctor provided. It was convenient, private and highly accessible to most, and the information was available at a number of different levels. The women were also aware of the problems with the Internet. They knew that there was some skill involved in searching for and critically assessing information. Often the women would share the information with their doctors, in order to become involved with managing their health. They began to ask the "right" questions, that led to appropriate and efficient answers [31]. The age group of the women in this study reflects the beginning of the Internet literate generation; these women often had training and access to the Internet via their post school education, or at work. However, similar findings have been reported in other health information seeking groups such as older men with prostate cancer, now embracing the Internet also, such that online information provided empowerment, anonymity, but may upset the doctor-patient relationship [24].

There are some limitations to this study. The participants in this study present a group of women with PCOS who were already relatively confident with taking charge of their health care, via being involved in a clinical trial, and/or being involved in a PCOS support group. Other women, not in this environment, or even unaware of the implications of PCOS on their future health, may not be so assured in seeking information. The women in this group also represent a narrow age group, reflecting the age where fertility, rather than the other symptoms of PCOS, may be a major focus. The finding may not be representative of younger women, closer to their primary diagnosis, who may be even more Internet literate. These limitations to the study, particularly the characteristics of the participant group, mean that when discussing information needs, we can only generalise to a similar group of women. Other limitations of this study include the small sample size, and that only one form of data collection was used. The study could be strengthened using triangulation methods, extending to perhaps a questionnaire, and including the women in further discussions of the themes through focus groups. The results of the have also been reported back to participants and members of a PCOS support group.

How then should information be provided to women with PCOS? The medical practitioners may need to be provided with a "sample bag" of information to give to PCOS women at their diagnosis, and follow this information with a review session where the women can ask con-

sidered questions about their syndrome. The "sample bag" would need to have pamphlets for a quick run down of the condition and terminology, lifestyle information, support group contact information and a list of reputable web sites; so that further research can be carried out by the woman as her lifestyle and information needs changes over time.

Women with PCOS need to be consulted and involved with creating the design, and assessment of quality of information about their condition, so that this is relevant to their lifestyle. PCOS provides an ideal opportunity for directed health promotion, particularly in terms of diabetes and cardiovascular illnesses, as well as an opportunity for consumer involvement in decision-making, and development of clinical guidelines. The most important treatment that we know of for PCOS is promoting healthy lifestyle as early as possible. Women with PCOS need information and guidance about how to do this to enable them to take control of their own health.

The Molecular-Genetic Basis of Functional Hyperandrogenism and the Polycystic Ovary Syndrome

Héctor F. Escobar-Morreale, Manuel Luque-Ramírez, and José L. San Millán

Departments of Endocrinology (H.F.E.-M., M.L.-R.) and Molecular Genetics (J.L.S.M.), Hospital Ramón y Cajal, Madrid, Spain E-28034

The genetic mechanisms underlying functional hyperandrogenism and the polycystic ovary syndrome (PCOS) remain largely unknown. Given the large number of genetic variants found in association with these disorders, the emerging picture is that of a complex multigenic trait in which environmental influences play an important role in the expression of the hyperandrogenic phenotype.

Among others, genomic variants in genes related to the regulation of androgen biosynthesis and function, insulin resistance, and the metabolic syndrome, and proinflammatory genotypes may be involved in the genetic predisposition to functional hyperandrogenism and PCOS.

The elucidation of the molecular genetic basis of these disorders has been burdened by the heterogeneity in the diagnostic criteria used to define PCOS, the limited sample size of the studies conducted to date, and the lack of precision in the

identification of ethnic and environmental factors that trigger the development of hyperandrogenic disorders. Progress in this area requires adequately sized multicenter collaborative studies after standardization of the diagnostic criteria used to classify hyperandrogenic patients, in whom modifying environmental factors such as ethnicity, diet, and lifestyle are identified with precision.

In addition to classic molecular genetic techniques such as linkage analysis in the form of a whole-genome scan and large case-control studies, promising genomic and proteomic approaches will be paramount to our understanding of the pathogenesis of functional hyperandrogenism and PCOS, allowing a more precise prevention, diagnosis, and treatment of these prevalent disorders. I. Introduction

POLYCYSTIC OVARY SYNDROME (PCOS) is one of the most common endocrinopathies in women of childbearing age (1). PCOS is characterized by increased ovarian and adrenal androgen secretion (2); hyperandrogenic symptoms such as hirsutism, acne, and/or alopecia; menstrual irregularity; and, in a significant proportion of patients, insulin resistance (3).

The presence of male sexual secondary characteristics in women has been recognized from ancient times, but it was not until 1921 when Achard and Thyers (4) reported the association of hyperandrogenic symptoms with abnormalities in glucose metabolism, highlighting the presence of polycystic ovaries in some of their patients. However, only after the description of seven cases of amenorrhea and bilateral polycystic ovaries by Stein and Leventhal in 1935 (5) was PCOS considered a separate entity that interested clinicians and researchers worldwide.

Although for many years the interest in PCOS has been

focused on the cutaneous and reproductive manifestations of this disorder, the recent evidence suggests that metabolic and cardiovascular risk factors cluster in these patients (6–8). This evidence has renewed research efforts on hyperandrogenism and PCOS, including those directed toward the identification of the genetic and environmental factors involved in the pathogenesis of these prevalent conditions.

At present, there is no consensus on the criteria for the diagnosis of PCOS (Table 1). Most clinicians and researchers from the United States and from southern Europe use the criteria derived from the conference held at the National Institute of Child Health and Human Development (NICHD) in 1990: clinical and/or biochemical hyperandrogenism, menstrual dysfunction, and exclusion of specific etiologies (9). According to these criteria, the presence of polycystic ovaries on ultrasound examination is not needed for the diagnosis. On the contrary, most specialists from the other European countries, Asia, and Oceania rely mostly on the presence of polycystic ovaries on ultrasound examination for this diagnosis, whereas menstrual dysfunction is not required (10). A recent consensus workshop held in The Netherlands in 2003 under the auspices of the European Society for Human Reproduction and Embryology and the American Society for Reproductive Medicine proposed a revision of the criteria for the diagnosis of PCOS, of which two of the following three would be needed: 1) oligo- and/or anovulation; 2) clinical and/or biochemical signs of hyperandrogenism; and 3) polycystic ovaries, together with the exclusion of other etiologies such as congenital adrenal hyperplasia, androgen-secreting tumors, or Cushing's syndrome (11, 12).

However, the term PCOS as used in the literature is not specific and has been applied to a wide range of hyperandrogenic women, including women with or without menstrual dysfunction or polycystic ovaries. For that reason, in the present review, we will use the more general term functional hyperandrogenism to define these patients presenting with androgen excess, including those diagnosed with PCOS according to any of the current definitions of the syndrome, in whom a specific etiology such as congenital adrenal hyperplasia or androgen-secreting tumors cannot be identified, and, whenever possible, we will describe the particular characteristics of the patients included in the different studies. Of note, we will not include idiopathic hirsutism in this definition, because this infrequent disorder, in which hyperandrogenemia, menstrual dysfunction, and ultrasonographic polycystic ovaries are not present, appears to be a separate entity in which increased skin activity of 5 α -reductase (resulting in increased conversion of testosterone into the more

potent androgen dihydrotestosterone), androgen receptor (AR) polymorphisms, and altered local androgen metabolism contribute to the development of hirsutism (13).

Functional hyperandrogenism and PCOS cluster in first-degree relatives of patients (14) and are inherited together with insulin resistance and metabolic disorders (15, 16). During the past decades, the inheritance of these disorders has been the subject of intense research (17–19), but many questions remain unanswered.

The pattern of inheritance is still unknown. Initially, an autosomal dominant model, including premature balding as the male phenotype, was proposed (20, 21), but later studies did not confirm this hypothesis. The heterogeneity of the populations, the large number of candidate genes studied to date (22), and the difficulty inherent to identifying the molecular genetic mechanism leading to a complex metabolic disorder such as PCOS, in which environmental factors play a major role (23, 24), provide an explanation for the fact that the molecular genetic basis of functional hyperandrogenism and PCOS remains largely unknown despite significant efforts.

The purpose of this review is to provide a systematic evaluation of the studies conducted to date in functional hyperandrogenism and PCOS and to suggest priorities and new strategies that may contribute to understanding the pathogenesis of these disorders.

II. Evidence Suggesting a Genetic Origin for Functional Hyperandrogenism and PCOS

A. Familial aggregation (Table 2)

The familial aggregation of PCOS, hyperandrogenemia, and associated metabolic abnormalities suggests a genetic origin for functional hyperandrogenism and PCOS. Back in 1968, Cooper *et al.* (25) studied the families of 18 Caucasian women with polycystic ovaries and clinical and biochemical traits associated with PCOS, and the families of 18 paired control women. The incidence of oligomenorrhea and polycystic ovaries was increased in first-degree relatives of PCOS patients compared with controls, and males in these families had increased hairiness according to a questionnaire, suggesting an autosomal dominant pattern of inheritance (25). Givens and colleagues (26–28) published a series of family-based studies in patients presenting with hirsutism, oligomenorrhea, and increased ovarian size, and they found familial aggregation of hyperandrogenic symptoms (hirsutism and oligomenorrhea) and of metabolic disorders (diabetes mellitus, dyslipidemia, arterial hypertension, and athero-

TABLE 1. Diagnostic criteria for the diagnosis of PCOS

NICHD criteria (9)	Ultrasonographic criteria (10)	Rotterdam criteria (11, 12)
1) Oligoovulation	1) Ultrasonographic polycystic ovaries	1) Oligo- and/or anovulation
2) Clinical and/or biochemical hyperandrogenism	2) Clinical and/or biochemical hyperandrogenism	2) Clinical and/or biochemical hyperandrogenism
Exclusion of secondary etiologies such as congenital adrenal hyperplasia, androgen-secreting tumors, and hyperprolactinemia.		
Criteria 1 and 2 must be present for the diagnosis of PCOS according to NICHD and ultrasonographic criteria. The Rotterdam criteria require the presence of two of the three individual criteria. All definitions require exclusion of secondary etiologies.		

TABLE 2. Studies of familial aggregation in functional hyperandrogenism and PCOS

Authors ^a	Phenotype in first-degree relatives	Suggested inheritance
Cooper et al. (25)	Women: oligomenorrhea and PCO	Autosomal dominant with variable penetrance
Wilroy et al. (26), Givens (27, 28)	Men: increased hairiness Women: hyperandrogenism and metabolic disorders	X-linked

Azziz et al. (14), Kahsar-Miller et al. (32)	Men: increased DHEA-S Women: PCOS (NICHD)	Not determined
Mao et al. (37)	Men: premature baldness	Not determined
Yildiz et al. (35)	Women: PCOS (NICHD) and insulin resistance Men: insulin resistance	Not determined

^a Authors are cited in chronological order. PCO, Polycystic ovaries on ultrasound examination; DHEA-S, dehydroepiandrosterone sulfate.

sclerosis). These authors suggested both a maternal and paternal pattern of inheritance, in which the latter showed higher penetrance and expression (26–28). Of note, in some of these male subjects, oligospermia and increased LH secretion were found pointing to an X-linked pattern of inheritance.

Ferriman and Purdie (29) studied first-degree relatives of hirsute women presenting with or without enlarged ovaries in gynecography. Compared with a control group, patients had an increased prevalence of oligomenorrhea and infertility, and the prevalence of hirsutism was increased in their female first-degree relatives. Hague et al. (30) studied the families of 61 patients with ultrasonographic polycystic ovaries and hyperandrogenic symptoms and found that 67% of the mothers and 87% of the sisters of probands were affected. Lunde et al. (31) studied the families of 132 Norwegian women with polycystic ovaries previously treated by ovarian wedge resection, who also had two or more of the following symptoms: menstrual irregularity, hirsutism, infertility, and/or obesity. A control group of 71 women and their families was used for comparison (31). Clinical manifestations of hyperandrogenism were found in 31.4% of the female relatives of the patients compared with only 3.2% of the female relatives of the controls (31). Among male relatives, premature balding and increased hairiness were found in 19.7% of the relatives of the patients, but only in 6.5% of the relatives of the controls (31). Azziz and colleagues (14, 32), using NICHD criteria for the diagnosis of PCOS, found that PCOS was present in 35% of the mothers and 40% of the sisters of PCOS patients.

In addition to hyperandrogenism, insulin resistance clusters in the families of hyperandrogenic women. Legro et al. (33), also using also NICHD criteria for the definition of PCOS, found that 22% of the sisters of patients actually had PCOS, whereas a further 24% of the sisters of these patients presented with hyperandrogenemia and regular menstrual cycles. This bimodal pattern suggested a monogenic defect

for hyperandrogenism (33). Additional studies from Legro et al. (34) recently demonstrated that in these families, insulin resistance is associated with hyperandrogenemia rather than with menstrual dysfunction. This suggests that insulin resistance and hyperandrogenemia share the same pathogenic mechanisms, whereas the presence of menstrual dysfunction needed for the diagnosis of PCOS may be only a matter of degree. Therefore, of PCOS sisters, those with PCOS and those presenting with hyperandrogenemia and regular menstrual cycles may actually have functional hyperandrogenism.

The finding of an increased prevalence of insulin resistance in families of PCOS patients has been replicated in the Turkish population. Yildiz et al. (35) recently studied 102 relatives of 52 PCOS patients defined by NICHD criteria and found that, compared with different population-based control groups matched for sex, age, and pre- or postmenopausal status with the relatives of PCOS patients, insulin resistance and disorders of carbohydrate metabolism were more frequent in the mothers, sisters, and brothers of PCOS patients, and that the mothers and sisters of PCOS women had increased serum androgen levels compared with the controls.

B. Male phenotype

The lack of a clearly defined male phenotype in families of PCOS patients has burdened the progress in the search for the genetic origin of functional hyperandrogenism and PCOS. Although initial studies suggested that male pattern premature balding was the male equivalent for PCOS (20, 29, 31, 36, 37), these findings have not been universally confirmed (38). More recently, increased serum dehydroepiandrosterone sulfate concentrations in the brothers of PCOS patients described above (39) and insulin resistance in the fathers and brothers of PCOS women (35) have been proposed as the male phenotype in PCOS families. However, there was a considerable overlap between male PCOS relatives and controls in serum dehydroepiandrosterone sulfate

levels and indexes of insulin resistance, and additional studies are needed to establish the actual usefulness of these abnormalities as markers of the syndrome in male relatives of PCOS patients.

C. Twin studies

There are very few data regarding PCOS in twins. Jahanfar *et al.* (40) studied 34 (19 monozygotic and 15 dizygotic) twin pairs, in which PCOS diagnosis was based on ultrasonographic and biochemical findings. Although 11 pairs were discordant for the presence of polycystic ovaries, model-fitting analysis suggested that fasting insulin level, serum androstenediol glucuronide, and body mass index were significantly influenced by genetic factors (40). A later report of this study suggested a genetic origin for an unfavorable lipid profile, especially for increased circulating concentrations of

lipoprotein (a), but only in twin pairs concordant for polycystic ovaries (41). These data point to a genetic component in the metabolic abnormalities associated with PCOS but suggest a polygenic etiology in which environmental influences play a significant role.

D. Environmental and other confounding factors

Familial aggregation of hyperandrogenism and PCOS strongly suggest a genetic origin for these disorders, but another possibility is that clustering of PCOS within families results from nongenetic inheritance related to certain environmental factors that are present in the affected families, and not in the families of unaffected women.

As exemplified in Fig. 1, insults during pregnancy may induce intrauterine growth retardation, which has been proposed to induce a thrifty phenotype in small for gestational

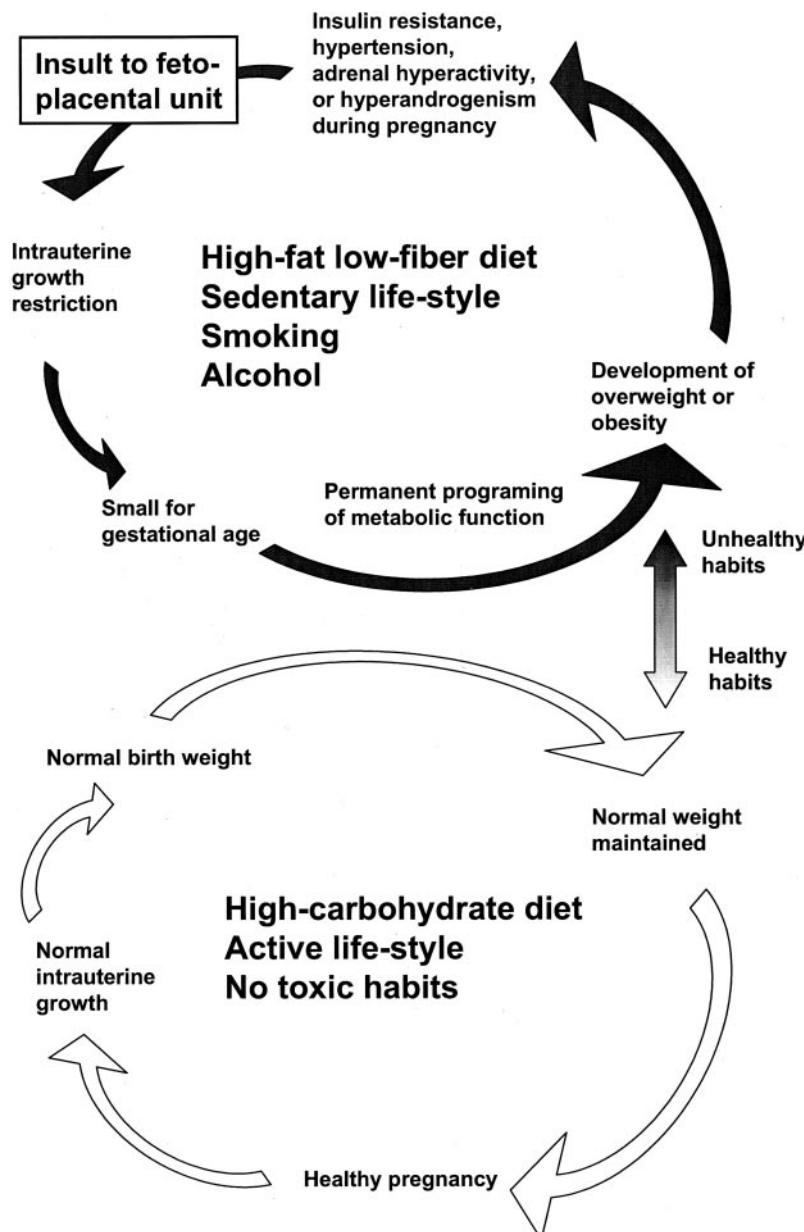

FIG. 1. Intrauterine growth retardation and insulin resistance as an example of nongenetic inheritance, markedly influenced by environmental factors. Insults during pregnancy may result in intrauterine growth retardation, inducing a thrifty phenotype in small for gestational age babies. These women are predisposed to suffer from insulin resistance and may develop hypertension, glucose intolerance, adrenal axis hyperactivity with relative cortisol excess, functional hyperandrogenism, and PCOS later in life, especially when these individuals are exposed to environmental factors such as sedentary lifestyle and a diet rich in saturated fat. These environmental factors may also cluster in certain families because exercising and diet are heavily influenced by parental habits. The metabolic abnormalities associated with the thrifty phenotype can induce further insult to the pregnancies of small for gestational age women, and the defect might be transmitted to another generation without the participation of any genetic abnormality. However, if small for gestational age babies maintain healthy habits, insulin resistance and its consequences might be avoided and, at least in theory, their fetuses will not be exposed to an unfavorable metabolic milieu during pregnancy, preventing nongenetic inheritance of these conditions.

age babies. These babies are predisposed to suffer from insulin resistance, which may result in hypertension, glucose intolerance, adrenal axis hyperactivity with relative cortisol excess, functional hyperandrogenism, and PCOS (42) later in life, especially when these individuals are exposed to environmental factors such as a sedentary lifestyle and a diet rich in saturated fat. These environmental factors may cluster in certain families because exercising and dieting are heavily influenced by parental habits.

The metabolic abnormalities associated with the thrifty phenotype can induce additional insult to the pregnancies of small for gestational age women, and the defect might be transmitted to another generation without the participation of any genetic abnormality. Therefore, the presence of more than one small for gestational age baby in a family may result from exposure of the mothers and their fetuses to the same unfavorable environmental conditions, rather than being related to genetic factors.

Yet it is important to highlight, as shown in Fig. 1, that if small for gestational age babies have healthy habits, insulin resistance and its consequences might be ameliorated, and, at least in theory, their fetuses will not be exposed to an unfavorable metabolic milieu during pregnancy, preventing nongenetic inheritance of these conditions. Nevertheless, intrauterine growth retardation may also be influenced by genetic variants, and the most probable scenario is that of an interaction between predisposing genetic abnormalities with unfavorable environmental conditions. Of note, even the influence of intrauterine growth restriction on the development of PCOS is debatable (43–45), considering that the presence of polycystic ovaries also has been related to above-average birth weight in babies born from obese, androgenized mothers (43–45).

There are very few data on the influence of environmental factors on the development of hyperandrogenism and PCOS, other than the triggering role for obesity on the development of these disorders (46). Although the prevalence of PCOS is similar in different countries, ethnic factors influence the clinical manifestations of the syndrome. In Caucasian premenopausal women, the reported prevalences of PCOS defined by NICHD criteria ranged from 4.7% in Alabama (47) to 6.5% in Spain (48) and 6.8% in the Greek island of Lesbos (49). Moreover, the prevalence in African-American women from Alabama (3.4%) was comparable with that in Caucasian women (47).

However, ethnicity influences the manifestations of PCOS. Carmina *et al.* (50) compared the clinical histories, physical examinations, ovarian morphology by ultrasound, insulin sensitivity, serum gonadotropin, and steroid profiles in 25 Japanese, 25 Italian, and 25 Hispanic-American women with PCOS. The three groups were homogeneous in terms of serum testosterone and adrenal androgen concentrations, insulin resistance, and polycystic ovaries, but Japanese women were less obese and did not present with hirsutism (50).

Dunaif *et al.* (51) found that insulin resistance is higher in Hispanic-Caribbean women with PCOS defined by NICHD criteria compared with Caucasian patients and with control women paired for age, weight, body composition, and ethnicity. Williamson *et al.* (52) recently reported a higher in-

cidence of obesity, dyslipidemia, and infertility, as well as a higher degree of insulin resistance in Maori and Pacific Islander PCOS patients, defined by ultrasonography and clinical symptoms, compared with European patients. In the United Kingdom, the prevalence of polycystic ovaries and type 2 diabetes is increased in Indian subcontinent Asian women (53). Compared with Caucasian women, PCOS patients of southeastern Asian origin presented with oligomenorrhea and were diagnosed at younger ages; hirsutism, acne, acanthosis nigricans, and subfertility were more prevalent, and patients were more insulin resistant (54).

These ethnic differences in the clinical presentation of PCOS may be related to environmental factors such as diet, exercise, and lifestyle. Of note, even the content of polyunsaturated or monounsaturated fatty acids in the diet may influence the metabolic manifestations of the syndrome (55). Thus, because of differences in the environmental factors triggering the development of PCOS, the genes contributing to PCOS patients may also be different, depending on the population studied. These considerations may also apply to the discrepant results of previous studies regarding the association of genomic variants with PCOS.

III. Classic Techniques Used in Molecular Genetic Studies

Before reviewing the molecular genetic studies conducted to date in functional hyperandrogenism and PCOS, we will provide a brief description of the techniques usually used for molecular genetic studies, focusing on the particular advantages and disadvantages of each technique.

A. Linkage analysis

Linkage analysis is a family-based molecular genetic technique that has permitted the identification of the genetic abnormalities leading to many monogenic Mendelian disorders (56). However, most complex metabolic disorders result from the interaction between multiple genes and environmental factors, making their identification much more difficult than in disorders with a Mendelian pattern of inheritance (57–63).

In linkage analysis, markers frequently located at intergenic regions of DNA are studied in multiple members of affected families. The cosegregation of alleles with a disease phenotype is studied, and the linkage of the disease with any marker focuses the search for genomic abnormalities to the DNA regions close to the polymorphic marker segregating with the disorder.

Linkage analysis is based on the meiotic recombination that occurs during ovogenesis and spermatogenesis. The closer two genomic markers are, the more seldom these markers are separated during meiotic recombination. The probability of recombination between two markers is an estimation of the distance between them, and is expressed in centimorgans (cM). Two markers are defined to be 1 cM apart if they become separated by recombination in 1% of meioses. One centimorgan is equivalent on average to 10^6 bp of physical distance. The markers usually studied in linkage studies

include microsatellites and single nucleotide polymorphisms (SNPs).

Classical or parametric linkage analysis requires the specification of a model for the disease or trait *a priori*, in terms of allelic frequencies, penetrance, and pattern of inheritance, and the result is expressed by the LOD score (64). The LOD score is the base 10 logarithm of the odds that two markers (one being the disease-causing or disease-associated genomic variant) are truly linked, divided by the odds that the observed set of data may result from chance if the markers are unlinked. Usually, significant positive proof of genetic linkage requires a LOD score of 3.0 or greater, corresponding to odds favoring linkage of at least 1000:1 at a given specified recombination frequency. Because the pattern of inheritance of functional hyperandrogenism and PCOS is complex and uncertain, nonparametric or model-free linkage analysis is required to ensure the power to detect linkage (22). In nonparametric linkage analysis, multiple DNA markers are obtained from siblings and, if possible, from their parents, and allele sharing between relatives is investigated (64). Allele sharing is defined as identity-by-state (having the same DNA sequence) or as identity-by-descent (when two alleles come from the same ancestral allele) (64). Nonparametric linkage scores use a similarity statistic defined by the average of the possibilities that relatives are identity-by-state (64). However, the number of meioses assessed, disease penetrance, knowledge of the marker coupling phase, and other relevant variables must be considered before reaching a clinically significant conclusion (65).

There are several factors that may limit the usefulness of linkage studies including, among others, the uncertainty about the pattern of inheritance, a variable penetrance of the genetic defect, the delay in the debut of the disease, possible errors in clinical diagnosis, gene to gene interactions, interaction with environmental factors, and the limited resolution of these techniques. The sample size needed to detect a particular effect varies inversely with the square of the effect (62), and therefore genes that contribute modestly to the phenotype may be missed because of the extremely large sample size needed to demonstrate the association. This is especially important given that PCOS affects women in reproductive age and is associated with reduced fertility, limiting the pedigrees and the generations studied to two (mothers and daughters) in most of the linkage analyses performed to date, resulting in small sample sizes within families (66, 67).

The resolution of linkage analysis may be improved using tests such as affected sibling-pair identity by descent analysis or the transmission disequilibrium test (68), allowing the detection of genes of modest effects that might be otherwise missed by linkage analysis. The transmission disequilibrium test involves genotyping the parents of the proband and the proband, and it determines whether or not the parent heterozygous for the putative allele transmits it more often to their affected children than other allele(s). These tests are frequently used to confirm the linkage already established but may also be useful when used without previous evidence for linkage (69).

Linkage with a polymorphic marker only serves to focus the search of the genomic abnormality associated with the

disorder to an area of approximately 1–2 cM, and locating the precise genetic defect may involve studying as many as 30–100 genes in the linked area. After obtaining linkage with a genomic region, the search of the particular genomic abnormality involved can be accomplished by fine-mapping of that region using additional markers, and by a candidate gene approach searching for variants in biologically appealing genes located there. This approach has been facilitated by the growing number of genes identified all across the genome, but frequently the demonstration that a gene has a causative role in a disease requires direct sequencing of the whole gene in affected and nonaffected individuals (70).

B. Case-control studies

These studies look for specific genetic markers or alleles that are more frequent in affected individuals (cases) compared with unaffected subjects from the same population (controls). These studies are focused on association of a genetic variant with a disease in a population and not on the mode of inheritance of a trait (71, 72). Association studies are preferable for finding "susceptibility" loci, low-risk alleles that are often found in relatively high frequencies in the general population, and do not result in robust signals in family-based studies (73). A positive association indicates an increased risk for the disease in subjects carrying the at-risk allele, which may have a causative role in the disorder or be in linkage disequilibrium with the gene actually causing the disease. Population stratification is a major problem in case-control studies, because the higher prevalence of particular alleles in different ethnic groups might bias the results and lead to false-positive associations. Moreover, case-control studies are especially prone to type II errors, that is, ruling out an association that is actually present in the population because of the small sample sizes often used in these studies.

In summary, linkage studies and case-control studies are both valid approaches for the study of the genetics of functional hyperandrogenism and PCOS, provided that the sample sizes of these studies are sufficiently large, the diagnostic criteria used to define affected and nonaffected subjects are clearly defined, and both ethnicity and differences in environmental factors are carefully considered.

IV. Studies in Pediatric and Adolescent Hyperandrogenism

Functional hyperandrogenism and hyperinsulinism may be detected early in life in affected women, even before pubertal development. As stated above, the presence of low birth weight in small for gestational age newborns, resulting from an unfavorable environment during intrauterine life and/or to defective maternal nutrition, has been related to the development of insulin resistance (74), disorders of glucose tolerance (75), hypertension, and cardiovascular disease (76–79) later in life.

The association of low birth weight with the development of hyperinsulinism and type 2 diabetes mellitus has been confirmed in different populations (80, 81), and these children present with an accelerated growth and increased body mass index during adolescence.

Although environmental factors may be an important contributor to the restriction of fetal growth in small for gestational age newborns, genetic factors may also be involved in this association (82). According to this hypothesis, affected fetuses might suffer insulin resistance because of the influence of several unknown genes or genomic variants. Insulin resistance would lead to restriction of intrauterine growth and abnormal fetal vascular development, ultimately leading during adult life to increased vascular resistance and endothelial dysfunction. The compensatory increase in circulating insulin concentrations would contribute to the abdominal deposition of fat, and inflammatory cytokines and other mediators secreted by abdominal adipocytes would perpetuate insulin resistance and endothelial dysfunction, leading to abnormal glucose tolerance, atherosclerosis, and cardiovascular disease (82).

However, the analysis of the influence of genomic variants on the association of birth weight and insulin resistance has yielded conflicting results. Dunger *et al.* (83) analyzed a variable number of tandem repeats (VNTR) polymorphism in the insulin gene (*INS*) at 11p15.5. This VNTR polymorphism consists of a repeated sequence of 14 to 15 bp (ACAGGGGT-GTGGGG), and is located at -596 bp of the start of transcription site (84). Among Caucasians, these alleles have been typed as class I (small, with 28–44 repeats, frequency approximately 70%), class II (intermediate, rare), and class III (large, with 138–159 repeats, frequency approximately 30%). The VNTR polymorphism in the *INS* promoter regulates the transcriptional rate of the gene (85) and probably that of the gene encoding IGF-II (84–89). Newborns homozygous for class III alleles, which are those associated with increased transcription of the *INS*, presented with increased head circumference, length, and weight at birth as compared with babies homozygous for class I alleles, possibly favoring newborn survival. On the contrary, data from the same researchers suggested that the maternally inherited 16,189 mitochondrial DNA variant, which increases the risk for type 2 diabetes mellitus, was associated with restrained fetal growth, thereby favoring maternal survival by decreasing birth-related morbidity and mortality (90). Therefore, other genetic and environmental factors are possibly involved in the relationship between birth weight and the development of insulin resistance and type 2 diabetes mellitus in adulthood.

Given the association of insulin resistance with functional hyperandrogenism, Ibáñez *et al.* (91) have proposed that low birth weight is related to the development of premature pubarche, and of functional hyperandrogenism during adolescence, insulin resistance being the underlying disorder common to both conditions. Retrospective analysis of a cohort of patients presenting with premature pubarche showed, especially in those girls who developed hyperinsulinemia and functional ovarian hyperandrogenism at adolescence, a lower birth weight compared with a control group, suggesting that low birth weight, premature pubarche, and functional hyperandrogenism are different manifestations of a unique disorder originating during prenatal life (92–95), but becoming clinically apparent peripubertally (42).

Additional analysis of this cohort showed that adolescent

girls who had anovulation and higher androgen levels were those with lower birth weight (96) and also confirmed the association of adrenal androgen excess, low birth weight, premature pubarche, and hyperinsulinemia (97).

In conceptual agreement, an exaggerated adrenal response to adrenocorticotropin stimulation, similar to that described in women with functional hyperandrogenism and PCOS, has been found in girls with premature pubarche, suggesting that this disorder can be considered an early manifestation of the syndrome (98). However, the relationship of low birth weight with hyperandrogenism and PCOS has not been universally confirmed. Jaquet *et al.* (99) compared a large population of young women born with intrauterine growth retardation with age-matched healthy controls, and although low birth weight was associated with insulin resistance, androgen levels were similar in both groups of women. Moreover, birth weight had no influence on the presence of hyperandrogenic symptoms suggestive of PCOS in a large cohort of Finnish women recently reported (100).

Given the association of functional hyperandrogenism and insulin resistance in children and adolescents, several genomic variants related to insulin resistance and the metabolic syndrome have been studied in these patients, mostly by the group of Ibáñez in Spain and the group of Witchel in Pittsburgh.

The VNTR locus at the *INS* has been studied in girls with a history of premature pubarche (101). Although class I and class III alleles were equally distributed in patients and controls, patients carrying class I alleles presented with lower birth weight and lower insulin sensitivity compared with patients homozygous for class III alleles (101).

The common Gly⁹⁷²Arg variant in the gene encoding the insulin receptor substrate 1 (*IRS-1*), which has been shown to influence insulin resistance and glucose tolerance in adult PCOS patients (102, 103), has also been studied in adolescents (104). The frequencies of heterozygosity for the Gly972 allele were 31% among girls with a history of premature pubarche, 40% among girls with hyperinsulinemic ovarian hyperandrogenism, and only 19% among healthy control subjects. Carriers of Gly972 alleles presented with decreased sex hormone-binding levels (104).

The human homolog for the sorbin and SH3-domain-containing-1 gene (*SORBS1*), which encodes for an important signaling molecule in insulin-stimulated glucose uptake in the mouse, might play a role in human disorders with insulin resistance. The Ala228 allele of the Thr²²⁸Ala polymorphism of *SORBS1* is a protective factor for both obesity and diabetes (105). However, alleles of the Thr²²⁸Ala polymorphism of *SORBS1* were equally distributed in a multiethnic group of healthy adolescents compared with those presenting with premature pubarche and/or functional hyperandrogenism (106).

The Arg64 allele of the Trp⁶⁴Arg polymorphism in the β_3 -adrenergic receptor gene is associated with abdominal obesity and resistance to insulin and may contribute to the early onset of type 2 diabetes mellitus (107). However, Witchel *et al.* (108) found no differences in the distribution of Trp⁶⁴Arg alleles in the girls presenting with premature pubarche and/or functional hyperandrogenism described above compared with healthy adults, and neither was an

influence of this polymorphism on the body mass index of these girls. Similarly, the study of the common Pro¹²Ala polymorphism in the gene encoding the peroxisome proliferator-activated receptor- γ 2 (*PPAR*- γ 2), which influences insulin sensitivity in Caucasians (109), has been studied in children with premature pubarche and in adolescent hyperandrogenic girls, but no association was found with any of the *PPAR*- γ 2 alleles and hyperandrogenism (110).

In addition to genes related to insulin resistance, those encoding for the steroidogenic enzymes involved in androgen biosynthesis and the genes encoding several molecules involved in androgen metabolism and action have been considered candidate genes to explain premature pubarche and adolescent hyperandrogenism.

Witchel and colleagues from Pittsburgh conducted a series of studies focused on the steroidogenic enzymes involved in androgen synthesis, which are shared by the adrenal and the ovaries. These authors have found that children with premature pubarche and adolescent girls with hyperandrogenism were heterozygous for mutations in *CYP21*, the gene encoding for 21-hydroxylase, and in the gene encoding 3 β -hydroxysteroid-dehydrogenase (*HSD3B2*), more frequently than nonhyperandrogenic controls (111–113). In these patients, *CYP17* mutations were ruled out as the cause of androgen excess (114). However, because congenital adrenal hyperplasia is an autosomal recessive disease requiring mutations in both alleles—in homozygosity or double heterozygosity—of *CYP21* or of *HSD3B2*, it is unclear how carrying only one defective allele of these genes in these clinically symptomatic heterozygotes contributes to the hyperandrogenic phenotype (113). Moreover, defective *CYP21* and *HSD3B2* alleles were found only in a minority of these patients, and the authors concluded that other genomic variants were also involved in the pathogenesis of these disorders (111–113).

To further explore this possibility, Witchel et al. (115) evaluated the prevalence of the common variants and mutations in *CYP21*, *HSD3B2*, *IRS-1*, β_3 -adrenergic receptor gene described above, and the glucocorticoid receptor gene within their series of children with premature pubarche and adolescent hyperandrogenism. They found that the prevalence of these variants and mutations was clearly increased when

compared with 15 healthy controls, suggesting that the occurrence of multiple sequence variants in these genes might contribute to the development of hyperandrogenism.

Finally, the AR and uridine diphosphate-glucuronyltransferase 2B15, an enzyme involved in androgen inactivation, have been considered candidate genes for premature pubarche and adolescent hyperandrogenism. The study of the AR gene CAG repeat polymorphism suggested that shorter AR gene CAG numbers, indicative of increased androgen sensitivity, were associated with premature pubarche (116), whereas the allele frequencies of the D85Y polymorphism in uridine diphosphate-glucuronyltransferase 2B15 gene were similar in patients and in controls (117).

In summary, studies conducted to date in girls with premature pubarche and adolescent hyperandrogenism suggest a polygenic etiology for these disorders, which can be considered predictors of functional hyperandrogenism and PCOS later in life.

V. Studies in Hyperandrogenic Adults

Most if not all the studies conducted to date to elucidate the genetics of functional hyperandrogenism and PCOS have used a candidate gene approach, because no genome-wide scan has been conducted comparable with those done for other complex metabolic disorders, such as type 2 diabetes mellitus. Although many genes have been considered candidates to explain PCOS inheritance, most studies have included genes related to androgen biosynthesis and action and their regulation, genes involved in insulin resistance and associated disorders, and lately genes involved in chronic inflammation and atherosclerosis.

A. Genes involved in androgen biosynthesis, transport, and action, and their regulation (Table 3)

1. *CYP17*. The limiting step in androgen biosynthesis in the ovary and adrenal gland is an enzyme termed P450c17 α , which possesses both 17 α -hydroxylase and 17,20-lyase activities. Therefore, P450c17 α may catalyze the conversion of pregnenolone and progesterone into 17-hydroxypreg-

nenolone and 17-hydroxyprogesterone, respectively, and of these steroids into dehydroepiandrosterone and androstenedione, although in humans only the conversion of Δ^5 steroids has been demonstrated (118).

Rosenfield *et al.* (2, 119, 120) proposed several years ago that women with functional hyperandrogenism and PCOS had an exaggerated adrenal and ovarian responsiveness, and that increased activity of P450c17 α was responsible for the enhanced androgen synthesis and secretion. They proposed the increase in serum 17-hydroxyprogesterone in response to the GnRH analog nafarelin as the marker of functional ovarian hyperandrogenism (119). Studies using adrenal stimulation with ACTH and ovarian stimulation and suppression with the long-acting GnRH triptorelin also suggested that most hyperandrogenic women have increased P450c17 α activity in the adrenal and ovary (121–123), and that the increased adrenal P450c17 α activity was not influenced by ovarian function (122). Moreover, P450c17 α expression and activity are increased in ovarian theca cells from PCOS women, defined by NICHD criteria, compared with those from nonhyperandrogenic controls (124).

Given these findings, the gene encoding the P450c17 α enzyme, *CYP17*, was considered a candidate gene in early studies. *CYP17* is located in chromosome 10q24.3 (125, 126), and its promoter contains a T/C SNP at –34 bp from the start of transcription site that might modulate enzyme activity. Some studies suggested that this polymorphism was associated with the presence of polycystic ovaries on ultrasound (125), and PCOS patients homozygous for C alleles of this polymorphism presented with increased serum testosterone levels (127, 128). Other studies failed to confirm these observations, suggesting that this base change is a polymorphism without functional consequences for the development of polycystic ovaries and hyperandrogenism (129–131). Also, no evidence for linkage or association was found between PCOS, defined by NICHD criteria, and the *CYP17* locus in a family-based study that included mostly families of European ancestry from the United States (132). Moreover, no abnormalities were found after single-strand conformational polymorphism analysis of the entire coding region of *CYP17* in a small sample of PCOS patients with or without exaggerated 17-hydroxyprogesterone response to a GnRH analog (133), ruling out *CYP17* as a major candidate gene for the pathogenesis of PCOS and functional hyperandrogenism. However, posttranscriptional hyperphosphorylation of the serine residues of P450c17 α by a defective serine kinase might increase the 17,20-lyase activity of this enzyme, contributing to hyperandrogenism (118, 134). Confirmation of this hypothesis is still pending (135).

2. *CYP11A*. Ovarian theca cells from women with PCOS defined by NICHD criteria overexpress all the steroidogenic enzymes involved in androgen biosynthesis (136, 137), and these cells secrete increased amounts of progesterone, 17-hydroxyprogesterone, testosterone, and androstenedione compared with theca cells from nonhyperandrogenic women (136, 138).

The initial step in adrenal and ovarian steroidogenesis is the conversion of cholesterol into progesterone, which is catalyzed by the cholesterol side chain cleavage enzyme. The

CYP11A gene, located at 15q24, encodes the cholesterol side chain cleavage enzyme and has therefore been considered a candidate gene for functional hyperandrogenism and PCOS (139). It has been proposed that a VNTR polymorphism, consisting in repeats of a (ttta)n pentanucleotide at –528 bp from the ATG start of translation site in the *CYP11A* promoter, plays a role in the pathogenesis of PCOS (140). Evidence for linkage with the *CYP11A* locus was found in 20 pedigrees presenting with PCOS, based mostly on the presence of polycystic ovaries or male pattern premature balding, and the absence of the more common four-repeats allele (this VNTR appears with four, six, eight, and nine repeats in Caucasians) was associated with hirsute PCOS patients and with higher serum testosterone levels (140). Diamanti-Kandarakis *et al.* (141), using NICHD criteria for the definition of PCOS, confirmed its association with absence of four-repeat alleles in Greek patients. In women from the United States, nine-repeat alleles were more frequent in PCOS patients, defined by oligomenorrhea and polycystic ovaries, and four- and six-repeat alleles were more frequent in controls, but these allelic differences did not influence *CYP11A* expression in theca cells (142).

Other studies failed to demonstrate linkage with the *CYP11A* locus in PCOS patients defined by NICHD criteria (132) or association of *CYP11A* VNTR alleles with functional hyperandrogenism (143). Moreover, in a small sample of hirsute hyperandrogenic patients from Spain (144), no consistent genomic abnormalities have been found in the entire *CYP11A* coding region, nor in the genes encoding the steroidogenic acute regulatory protein, steroidogenic factor-1, and dosage-sensitive sex reversal-adrenal hypoplasia gene on the X chromosome gene-1 (DAX-1), which are also involved in the first step of steroidogenesis and its regulation. The family-based study cited above failed also to demonstrate linkage or association with the steroidogenic acute regulatory protein (132). Finally, Gaasenbeek *et al.* (145) recently failed to confirm any influence of *CYP11A* VNTR alleles on polycystic ovaries and on serum testosterone levels in a series of experiments involving a large number of subjects, concluding that the existence of associations between *CYP11A* promoter variation and androgen-related phenotypes had been substantially overestimated in previous studies, including their own preliminary report cited above (140).

3. *CYP21*. An exaggerated serum 17-hydroxyprogesterone response to ACTH stimulation is a common finding in women with PCOS or functional hyperandrogenism (121, 146). This finding prompted several groups to study *CYP21*, which encodes the 21-hydroxylase enzyme catalyzing the conversion of 17-hydroxyprogesterone into 11-deoxycortisol; increased serum 17-hydroxyprogesterone levels are the biochemical marker for 21-hydroxylase deficiency. This type of congenital adrenal hyperplasia is an autosomal recessive disease resulting from homozygosity or double heterozygosity for missense or nonsense mutations in *CYP21* and is characterized by hyperandrogenism with or without mineralocorticoid deficiency.

However, whether or not heterozygous *CYP21* mutations influence functional hyperandrogenism and PCOS is still matter of debate. As stated above, girls presenting with pre-

mature adrenarche and adolescent hyperandrogenism carry *CYP21* mutations more frequently than nonhyperandrogenic controls (112). Clinically symptomatic heterozygotes for *CYP21* mutations present with a phenotype that resembles that of PCOS (113), but it is unclear whether all carriers of *CYP21* mutations have an increased risk of having PCOS. Moreover, in hyperandrogenic women carrying *CYP21* mutations there is no clear concordance between the *CYP21* genotype and the functional origin of androgen excess (147).

Finally, the presence of polycystic ovaries in ultrasound scans has been associated with increased frequency of DRW6 and decreased DR7 human leukocyte antigen haplotypes, whereas 21-hydroxylase deficiency is associated with the Bw47, B14, or DR1 haplotypes (148). Moreover, in families of patients with 21-hydroxylase deficiency, polycystic ovaries segregate independently from adrenal dysfunction (149).

4. *HSD3B2*. This enzyme catalyzes the conversion of Δ^5 steroids into Δ^4 steroids in the adrenal and in the ovary. Mutations in *HSD3B2* result in a rare form of classic congenital adrenal hyperplasia, causing various degrees of salt wasting in both sexes and incomplete masculinization of the external genitalia in genetic males because both adrenal and ovarian steroidogenesis are severely impaired (150). Biochemically, this disorder is characterized by a marked increase in serum 17-hydroxypregnенolone and dehydroepiandrosterone concentrations (150).

Mild increases in these steroid precursors, and in the ratio of Δ^5 to Δ^4 steroids, are not infrequent in hyperandrogenic patients, and hyperandrogenic patients presenting with increased 17-hydroxypregnенolone concentrations and/or increased Δ^5 to Δ^4 ratios after adrenal stimulation with cosyntropin were initially considered to have a nonclassic form of *HSD3B2* deficiency (151–153). However, these mild increases in serum 17-hydroxypregnенolone concentrations and in the Δ^5 to Δ^4 ratios were interpreted by others as an exaggerated adrenal response to cosyntropin stimulation without a genetic origin (154). Molecular analysis of *HSD3B2* of hyperandrogenic patients presenting with increased Δ^5 steroids and increased Δ^5 to Δ^4 ratios revealed no abnormalities (155, 156), ruling out the existence of a nonclassic form of *HSD3B2* deficiency in these women. In conceptual agreement, a marker close to the *HSD3B2* locus was not in linkage or association with PCOS, defined by NICHD criteria, in the American family-based study cited above (132).

5. *17 β -Hydroxysteroid dehydrogenases.* 17 β -Hydroxysteroid dehydrogenase type III is also known as 17-ketosteroid reductase. This enzyme catalyzes the conversion of androstanedione into testosterone in the testis. Up to 20 mutations in *HSD17B3* have been identified as the cause of male pseudohermaphroditism because of testosterone deficiency (157). Pang et al. (158) hypothesized that genetic females with ovarian 17-ketosteroid reductase deficiency would probably have a normal female phenotype at birth and normal pubertal breast development but would present at puberty with virilization and menstrual disorders because of the sudden increase of the ovarian secretion of androstanedione. However, no mutations have been identified in *HSD17B3* in Caucasian and African-American women presenting with PCOS

defined by NICHD criteria (159). Also, no evidence for linkage or association with the type 1, type 2, and type 3 17 β -hydroxysteroid dehydrogenase loci was found in the American family-based study cited previously (132).

6. *Aromatase.* This enzyme, encoded by *CYP19*, is responsible for the conversion of C19 steroids (androgens) into C18 steroids (estrogens). Aromatase activity may be decreased in granulosa cells and follicles from women with PCOS, and the possible androgen excess resulting from this decreased activity might contribute to abnormal follicle development (160, 161). Although mutations in *CYP19* have been associated with multicystic ovaries in a case report, the clinical picture was that of hypergonadotropic hypogonadism (162). Moreover, no evidence for linkage of *CYP19* with PCOS was found in studies conducted in the United Kingdom (140) and in the United States (132).

7. *11 β -Hydroxysteroid dehydrogenase type 1 and hexose-6-phosphate dehydrogenase.* These enzymes regulate the inactivation of cortisol into cortisone at the tissue level. 11 β -Hydroxysteroid dehydrogenase type 1 converts cortisol into cortisone directly, and endoluminal hexose-6-phosphate dehydrogenase regenerates reduced nicotinamide adenine dinucleotide phosphate in the endoplasmic reticulum, thereby influencing the directionality of 11 β -hydroxysteroid dehydrogenase type 1 activity. Mutations in the genes encoding 11 β -hydroxysteroid dehydrogenase type 1 and hexose-6-phosphate dehydrogenase have been recently shown to cause cortisone reductase deficiency (163), and because the phenotypic features of affected women resemble those of PCOS, these genes should be considered candidates to explain the pathogenesis of PCOS. However, this possibility has not been explored in any series of patients with functional hyperandrogenism and PCOS to date.

8. *Gonadotropins.* In as many as 40% of PCOS patients, LH hypersecretion is present (164). The gene encoding the β -subunit of LH (*LH β*), which is responsible for LH specificity, has been explored in PCOS and hyperandrogenic women. Initially, two point mutations, Trp⁸Arg and Ile¹⁵Thr, were identified as the cause of an immunologically abnormal *LH β* molecule (165). These mutations induce structural changes in the mutant *LH β* molecule (166) and have a 15% prevalence worldwide, although with significant differences depending on the population studied (167). The resulting *LH β* molecule has an increased *in vitro* activity and a decreased *in vivo* half-life compared with the wild-type molecule (168).

This *LH β* variant has been associated with increased serum testosterone, estrogen, and SHBG levels in healthy women, but not in PCOS patients (169). Furthermore, the prevalence of this *LH β* variant is reduced in obese women with PCOS, suggesting a protective role against the development of hyperandrogenic symptoms in these women and a possible usefulness in determining the risk for PCOS in obese women (170, 171). However, no association with PCOS, hyperandrogenism, or serum androgen or estrogen concentrations has been found in other studies (172, 173).

Other variants in the *LH β* gene might influence hyperandrogenism and PCOS. A Gly¹⁰²Ser mutation in exon 3 has been related to menstrual disorders in Chinese women (172,

174). Finally, in Japanese patients with ovulatory disorders, several SNPs in the promoter of the LH β gene (-894C/T , -1018G/C , -1036C/A , -1098C/T , and -1423C/T) are more frequent than in normal ovulatory women (175).

Polymorphisms in the FSH β -subunit gene have also been reported to influence PCOS. In Chinese women, homozygosity for a thymine-cytosine substitution in exon 3 (codon 76, TAT to TAC) has been found more frequently in PCOS patients, as defined by oligomenorrhea and polycystic ovaries, compared with nonhyperandrogenic women, especially in obese patients, and correlating with higher serum androgen concentrations (176). In these women, two SNPs in the gene encoding the FSH receptor, Thr³⁰⁷Ala and Ser⁶⁸⁰Asn, showed similar allele distribution among PCOS patients and controls (177). Moreover, the search for mutations in exons 6, 7, 9, and 10 of the FSH receptor gene, which have been shown previously to inactivate the receptor, yielded negative results in Japanese patients with oligomenorrhea and polycystic ovaries (178). This locus was not in linkage or association with PCOS in a family-based study conducted in the United States (132). Finally, mutations in the gene encoding the GnRH receptor have not been found in PCOS patients, defined by NICHD criteria (179).

9. Dopamine receptor. Given that dopamine is involved in the hypothalamic control of gonadotropin secretion, the association between polymorphisms in the dopamine receptor and disorders of ovulation and fertility has been studied. Legro *et al.* (180) reported that SNPs in exons 5 and 6 of the gene encoding the type 2 dopamine receptor influenced serum gonadotropin and prolactin levels, as well as parity and prevalence of miscarriage in women of Hispanic ancestry. In these women, a genomic variant in the type 3 dopamine receptor was associated with hyperandrogenic chronic anovulation and resistance to clomiphene citrate (181), but this association was not confirmed in a large series of non-Hispanic women (182).

10. SHBG. SHBG regulates the access of testosterone and estradiol to target tissues. Decreased SHBG concentrations are characteristic of hyperandrogenic women, contributing to increased tissue androgen availability (183). Despite the fact that evidence for linkage or association was not found between a marker close to the SHBG locus and PCOS in a family-based study conducted in the United States (132), a missense Pro¹⁵⁶Leu mutation in the SHBG gene, resulting in abnormal glycosylation and secretion of a SHGB mutant that retains binding capacity (184), has been detected in a women presenting with severe hyperandrogenism during pregnancy. However, it is seldom found in unselected hyperandrogenic women (184).

Recently, an association between a (TAAAA)n polymorphism in the promoter of the SHBG gene and PCOS has been reported (185). Longer alleles (more than eight repeats) were frequent in Greek PCOS patients, defined by NICHD criteria, whereas nonhyperandrogenic women presented with a higher frequency of shorter alleles (185). Furthermore, in the PCOS group, carriers of the longer allele genotypes had lower SHBG levels than in those with shorter alleles (185). Therefore, this polymorphism might be related to the low

SHBG levels characteristic of PCOS, facilitating androgen availability to target tissues. Cousin *et al.* (186) studied the (TAAAA)n polymorphism in hirsute women and found strong disequilibrium linkage with an Asp³²⁷Asn SNP in exon 8 of SHBG, 327Asn alleles being associated with eight-repeat (TAAAA)n alleles, and resulting in increased serum SHBG levels when compared with subjects homozygous for 327Asp alleles. Moreover, longer (TAAAA)n alleles resulted in decreased serum SHBG levels when compared with six-repeat alleles (186), in conceptual agreement with the results in PCOS women described above (185).

11. Glucocorticoid receptor. Mutations in the glucocorticoid receptor gene result in a compensatory increase in circulating ACTH, resulting in excess secretion of adrenal androgens. Therefore, the glucocorticoid receptor has been studied as a candidate gene for functional hyperandrogenism and PCOS. However, genomic abnormalities and polymorphisms in the glucocorticoid receptor gene do not appear to influence the pathogenesis of functional hyperandrogenism (187, 188) and PCOS (189).

12. Steroid 5 α -reductase (SRD5A). This enzyme catalyzes the conversion of testosterone into the more potent androgen dihydrotestosterone. SRD5A1 and SRD5A2 are the two isoforms of the enzyme. Mutations in SRD5A2 result in male pseudohermaphroditism (190, 191). Because total SRD5A activity is increased in polycystic ovaries (192), the genes encoding the SRD5A isoforms can be considered candidate genes for functional hyperandrogenism and PCOS. To date, no data have been published regarding the possible involvement of molecular genetic variants in these genes in hyperandrogenic disorders.

13. AR. The AR is a member of the superfamily of ligand-activated transcription factors that regulate many biological processes and is encoded by a gene located at Xq11–12 (193, 194). The AR has three functional domains responsible for transactivation, for ligand binding, and for binding to DNA. Exon 1 contains a VNTR polymorphism consisting of (CAG)n repeats, which encodes for a polyglutamine tract in the N-terminal transactivation domain of the AR protein (195).

The number of CAG repeats in the normal population varies between 11 and 31, with 20 repeats being the most frequent (196). The number of CAG repeats is inversely related to the transactivation of the AR and its activity (197). Thus, the decreased number of CAG repeats has been proposed to increase androgen activity at target tissues, favoring hirsutism (198), premature pubarche, and ovarian hyperandrogenism (116) in women, infertility in men (199), as well as androgen-dependent skin disorders in both men and women (200). A decreased number of AR gene CAG repeats has been suggested to explain the normal serum androgen levels found in some women with polycystic ovaries, infertility, and oligomenorrhea, in whom the hyperandrogenic symptoms would result from the intrinsic increase in the AR activity (201).

One of the two X chromosomes in every cell of a woman undergoes inactivation, a process that involves methylation of DNA and occurs in a random fashion. Skewed inactivation

of X chromosome with the larger CAG repeat, favoring expression of the shorter allele, has been proposed to play a role for idiopathic hirsutism and PCOS (202, 203). However, we have shown that both the number of CAG repeats and the prevalence of skewed X chromosome inactivation were equally distributed in hirsute patients with or without hyperandrogenemia and in healthy women (204). Moreover, no evidence for linkage or association with PCOS was found with the AR locus in the family-based study conducted in the United States cited above (132).

14. Aldosterone synthetase. The renin-angiotensin system may be hyperactive in women with PCOS (205, 206). Recently, a –344T/C SNP in the promoter of the gene encoding aldosterone synthetase, *CYP11B2*, has been proposed to influence the pathogenesis of PCOS, because C alleles are more frequent in these patients than in healthy controls (207). Interestingly, women homozygous for C alleles presented with increased plasma renin activity and increased serum angiotensin II, aldosterone, and testosterone levels compared with women homozygous for T alleles, suggesting that this polymorphism influences the activity of aldosterone synthetase and also contributes to androgen excess (207).

B. Genes involved in insulin resistance and associated disorders (Table 4)

1. Insulin receptor gene (*INSR*). The presence of insulin resistance is common in PCOS (3) and is frequent in other hyperandrogenic patients (208–210). Therefore, the genes encoding the *INSR* and those encoding several molecules involved in postreceptor signaling have been studied in hyperandrogenic patients.

The *INSR* is a heterotetrameric glycoprotein consisting of two α - and two β -subunits, and it is encoded by a gene located at chromosome 19. A marker relatively close (1 cM) to *INSR*, D19S884, has been reported in association with PCOS, defined by NICHD criteria, using the transmission disequilibrium test in a family-based study (132), and in a case-control study (211), both conducted in the United States. However, this association was not confirmed in PCOS patients from Spain and Italy using a case-control design (212). In conceptual agreement with the latter, the 22 exons of *INSR* have been sequenced in PCOS patients with negative results (213). *INSR* contains several polymorphisms, yet most of them are silent polymorphisms or are located in intronic regions and are present with similar frequencies in patients with polycystic ovaries and hyperandrogenism and in controls (214).

Recently, Siegel et al. (215) have observed a C/T SNP at the tyrosine kinase domain of *INSR* associated with PCOS defined by NICHD criteria. This SNP could be a susceptible variant for PCOS, or it could be in linkage disequilibrium with another *INSR* polymorphism; such an association must be confirmed in future studies.

Studying cultured skin fibroblasts and muscle samples from PCOS patients defined by NICHD criteria, Dunaif et al. (216) found increased *INSR* serine phosphorylation, which decreases its protein tyrosine kinase activity, in as many as 50% of the cases. Subsequent studies in these patients con-

firmed *in vivo* the defect in insulin signaling, using serial skeletal muscle biopsies obtained during euglycemic glucose clamp studies (217). However, the search for mutation in the tyrosine kinase domain of the *INSR* gene did not show abnormalities other than polymorphisms in exon 17, which were not associated with insulin resistance (218). Therefore, the still unidentified factor responsible for the increased phosphorylation of the serine residues of the *INSR* appears to be extrinsic to the receptor and might also contribute to the increased serine phosphorylation of P450c17 α also found in some PCOS patients (118).

2. IRS-1 and IRS-2. After insulin binding, autophosphorylation of tyrosine residues results in the activation of the *INSR*, and tyrosine kinase activity phosphorylates intracellular substrates such as IRS-1 and IRS-2 (3). PCOS women present a defect in insulin receptor signaling characterized by a decreased IRS-1-associated phosphatidylinositol 3-kinase activity (217). Two common SNPs in the genes encoding insulin-receptor substrates, Gly⁹⁷²Arg in *IRS-1* and Gly¹⁰⁵⁷Asp in *IRS-2*, are susceptibility genes for type 2 diabetes mellitus (219, 220); they have been studied in PCOS patients, despite the fact that evidence for linkage or association with PCOS was not found with *IRS-1* in a family-based study conducted in the United States (132).

Carriers of Arg972 *IRS-1* alleles presented with increased fasting insulin levels compared with women homozygous for Gly972 alleles, whereas carriers of Asp1057 *IRS-2* alleles presented with increased glucose and insulin levels 2 h after an oral glucose load and had an increased prevalence of glucose intolerance compared with subjects homozygous for Gly1057 alleles (102). However, a subsequent study in a larger series of PCOS patients showed only the effect of the Gly¹⁰⁵⁷Asp polymorphism in *IRS-2* on glucose tolerance, and no effect of the Gly⁹⁷²Arg polymorphism in *IRS-1* (103). Surprisingly, the effect was just the opposite found previously, because the 2-h glucose values were actually increased in subjects homozygous for Gly1057 alleles when compared with carriers of Asp1057 alleles (103). Additional studies are needed to confirm the influence of these polymorphisms on glucose tolerance and insulin resistance in PCOS.

3. INS. The presence of pancreatic β -cell dysfunction in women presenting with PCOS appears to have a genetic origin (221). Therefore, *INS* has been studied in women with PCOS and functional hyperandrogenism. Waterworth et al. (222) found that women with menstrual disturbances and/or hirsutism and polycystic ovaries, who were homozygous for class III alleles, were more frequently anovulatory and had increased body mass index and fasting insulin compared with women homozygous for class I alleles. Moreover, class III alleles were associated with symptomatic women (222, 223). Paternal transmission of class III alleles from heterozygous fathers to anovulatory PCOS patients is more frequent than maternal transmission of the allele (222–224), and class III alleles predisposed these patients to both PCOS and type 2 diabetes mellitus. However, later case-control studies in European Caucasian women, conducted outside the United Kingdom, have failed to reproduce these results (225, 226), and the *INS* locus was not associated with PCOS in a linkage study in American PCOS patients (132).

TABLE 4. Genes involved in insulin resistance and associated disorders, in functional hyperandrogenism (FH), and PCOS

Gene	Variant/locus	Design	Subjects	Phenotypic trait	Association
<i>INSR</i>					
Sorbara et al. (213)	Mutation scanning	Case series	PCOS	Insulin resistance	No
Conway et al. (218)	Mutation scanning	Case series	PCOS	Insulin resistance	No
Urbanek et al. (132)	D19S884 and other loci	FBS (TDT)	PCOS	PCOS	Yes
Talbot et al. (214)	Mutation scanning	Case-control	PCOS	Insulin resistance	No
Tucci et al. (211)	D19S884	Case-control	PCOS	PCOS	Yes
Siegel et al. (215)	C10923T	Case-control	PCOS	Lean PCOS patients	Yes

Authors are cited in chronological order. BMI, Body mass index; FBS, family-based study; IGF-IR, IGF-I receptor; IGF-IIR, IGF-II receptor; IGFBP, IGF binding protein; MPB, male premature baldness; OGTT, oral glucose tolerance test; PC-1, plasma cell differentiation antigen glycoprotein; PP, premature pubarche; PTP1B, protein tyrosine phosphatase 1B; T, total testosterone; TDT, transmission disequilibrium test.

4. IGF system. IGFs, their receptors, binding proteins, and proteases are important for the normal development of the ovary (227). IGFs stimulate ovarian cellular mitosis and steroidogenesis, inhibit apoptosis, and might be related to the development of functional hyperandrogenism and PCOS (228).

No evidence for linkage with PCOS was found for markers close to the genes encoding IGF-I and IGF-binding proteins 1 and 3 in a family study conducted in the United States (132). San Millán et al. (229) recently found an association of PCOS with homozygosity for G alleles of the *ApaI* polymorphism in *IGF-II*, but not with a dinucleotide polymorphism in *IGF-I*, a trinucleotide polymorphism in the *IGF-I receptor*, or with an ACAA-insertion/deletion polymorphism at the 3' nontranslated region of the *IGF-II receptor*, previously described (230–232). G alleles of the *ApaI* polymorphism in *IGF-II* have been attributed to increased IGF-II mRNA in leukocytes compared with A alleles (233), and possibly result in increased liver IGF-II expression and secretion (234). Given that IGF-II stimulates adrenal (235, 236) and ovarian (237) androgen secretion, the increased frequency of homozygosity for these alleles might contribute to hyperandrogenism in some PCOS patients, provided we assume that G alleles may increase IGF-II expression at the ovary, as reported for other tissues. In the same case-control study involving PCOS patients cited above (229), we found that subjects homozygous for 90-bp alleles of a trinucleotide repeat polymorphism in the gene encoding IGF-I receptor had increased fasting glucose levels and fasting insulin resistance index compared with subjects carrying 93-bp alleles, but no association of any genotype with PCOS.

5. PPAR-γ2. Activation of PPAR-γ by using the insulin sensitizer drugs, thiazolidinediones, has been one of the most important advances for the treatment of type 2 diabetes mellitus in past years. As described above, insulin resistance is a common finding in hyperandrogenic patients, and thiazolidinediones improve insulin sensitivity, hyperandrogenism, and ovulation in women with PCOS (238–243).

The Pro¹²Ala SNP in *PPAR-γ2* has been studied in women with PCOS, despite the fact that evidence for linkage or association with PCOS was not found for a marker close to the *PPAR-γ2* gene, in a family-based study conducted in the United States (132). Ala12 alleles of the *PPAR-γ2* gene favor weight gain in obese adults (244) and in obese hyperandro-

genic girls and adolescents (110). Also, Ala12 alleles preserve insulin sensitivity in Caucasian men (109) and in Caucasian women presenting with PCOS defined by NICHD criteria (245). Recently, a marginally significant decrease in the frequency of the Ala12 allele has been reported in women with polycystic ovaries from Finland (246), but this result has not been confirmed in a small case-control study of PCOS patients conducted in Spain (229) or in a recently published study in Italian PCOS patients defined by NICHD criteria and ultrasonography (247). In the latter, a silent C to T substitution at position 142 in exon 6 was differentially distributed in PCOS patients and controls, T alleles being more frequent in women with PCOS (247). This silent polymorphism was not in linkage disequilibrium with the Pro¹²Ala polymorphism, but the possibility of an association with other unknown genomic variant in the *PPAR-γ2* gene was not explored (247). Nevertheless, both Ala12 and T142 alleles are relatively uncommon (less than 20%) in normal and hyperandrogenic populations (229, 245–247), and therefore their putative influences on insulin sensitivity and/or hyperandrogenism would be restricted to a small number of PCOS patients.

6. Paraoxonase (PON1). We have recently explored the –108C/T, Leu⁵⁵Met, and Gln¹⁹²Arg polymorphisms in the gene encoding serum PON1 in PCOS patients defined by NICHD criteria. The PON1 gene is expressed mainly in the liver and encodes for serum PON1, which is an antioxidant high-density lipoprotein-associated enzyme. Liver PON1 mRNA expression is influenced by genetic and environmental factors, and both androgens and proinflammatory mediators decrease liver PON1 expression (248). Interestingly, both androgen excess and proinflammatory genotypes contribute to the pathogenesis of PCOS (249–251).

Homozygosity for T alleles of the –108C/T polymorphism in *PON1* was more frequent in patients compared with nonhyperandrogenic women (229). As expected from the association with PCOS, subjects homozygous for –108T alleles of *PON1* presented with increased hirsutism scores, total testosterone, and free testosterone and androstenedione concentrations compared with carriers of –108C alleles (229). Moreover, in a logistic regression model, homozygosity for –108T alleles of *PON1* was associated with a 7.1 odds ratio (95% confidence interval, 2.1–23.8) of having PCOS (229).

The –108C/T polymorphism is responsible of approximately 23% of PON1-expression levels in some cell systems, in which –108TT constructs showed reduced PON1 expression compared with –108CC constructs (252). We thus speculated that homozygosity for –108T alleles, hyperandrogenism, and proinflammatory genotypes might contribute to reduced PON1 expression, resulting in a higher oxidative stress in these women. The latter has been found in PCOS patients (253).

Oxidative stress may impair insulin action (254). Therefore, reduced serum PON1 activity might contribute to the insulin resistance of PCOS patients. This hypothesis is supported by the finding of reduced serum PON1 activity in other insulin-resistant disorders such as type 2 diabetes mellitus (255, 256) and cardiovascular atherosclerotic disease (257, 258). If confirmed in future studies, the association of homozygosity for –108T alleles of *PON1* with PCOS might contribute to explaining the insulin resistance and the increased risk for atherosclerosis associated with this syndrome (259).

In our study (229), subjects homozygous for Met55 alleles presented with increased body mass index and indexes of insulin resistance compared with carriers of Leu55 alleles, further suggesting the involvement of *PON1* in PCOS, despite the fact that the Leu⁵⁵Met and Gln¹⁹²Arg polymorphisms in *PON1* were not associated with PCOS.

7. Human homolog for the sorbin and SH3-domain-containing-1 gene (*SORBS1*). In addition to the studies in adolescents cited above (106), we have recently studied the Thr²²⁸Ala polymorphism in adult PCOS patients. Allele frequencies were similar in PCOS patients and nonhyperandrogenic women, but carriers of Ala228 alleles of *SORBS1* presented with increased body mass index compared with subjects homozygous for 228T alleles (229), in conceptual agreement with a large study conducted in Europe (260).

8. Calpain-10. This enzyme is a cysteine protease that plays a role in insulin secretion and action (261). The 112/121-haplotype combination of University of Chicago single nucleotide polymorphism (UCSNP)-43, UCSNP-19, and UCSNP-63 polymorphisms in the gene encoding calpain-10, located at 2q37.3, has been reported to increase the risk for diabetes (262). Ehrmann *et al.* (263) found no association between this haplotype and any of the phenotypic features of PCOS in Caucasian nondiabetic PCOS patients, defined by NICHD criteria, whereas the 112/121-haplotype was significantly associated with higher insulin levels in response to an oral glucose tolerance test in African-American, nondiabetic PCOS women. Moreover, when considering Caucasian and African-American, nondiabetic PCOS patients as a whole, the 112/121 haplotype was associated with a 2-fold increase in susceptibility to PCOS.

However, the association of *calpain-10* SNPs with PCOS, as defined by polycystic ovaries, hyperandrogenism, and/or anovulation, was not confirmed by Haddad *et al.* (264) in 330 PCOS patients from the United Kingdom. We have studied three common polymorphisms in the calpain-10 gene in 97 Spanish hyperandrogenic patients and 37 controls, including UCSNP-43 (265). C alleles at the UCSNP-45

locus were associated with idiopathic hirsutism, but neither the UCSNP-43 nor the UCSNP-44 was associated with hyperandrogenism or PCOS (265). However, in a different population from the south of Spain, González *et al.* (266, 267) recently reported an association between PCOS and UCSNP-44. Additional studies are needed to clarify this issue, especially because the physiological roles of calpain-10 remain mostly unknown.

9. Genes encoding for other molecules related to insulin resistance and associated disorders. Among other genes tested, no association has been reported in PCOS with genomic variants in the genes encoding glycogen synthetase (268), resistin (269), leptin and its receptor (270), apoprotein E (271), or with variants in the genes of plasma cell differentiation antigen glycoprotein, protein tyrosine phosphatase 1B, and adiponectin (229).

C. Proinflammatory genotypes (Table 5)

Chronic inflammation is involved in the development of metabolic syndrome and cardiovascular disease (272, 273), and serum inflammatory markers cluster in patients with cardiovascular disease, suggesting a role in the pathogenesis of atherosclerosis (272, 273).

Inverse correlations have been reported between indexes of insulin sensitivity and inflammatory markers such as circulating levels of TNF- α (274), soluble type 2 TNF receptor (TNFR2) (275), IL-6 (276), C-reactive protein (CRP) (276), and soluble intercellular cell adhesion molecule-1 (276).

Adipose tissue plays a central role in the relationship between cytokines and insulin resistance. The expression of TNF- α and TNFR2 in adipose tissue is increased in obesity (277, 278). TNF- α expression correlates with indexes of insulin resistance and decreases with weight loss in parallel with the improvement in insulin sensitivity (277). Similar results have been reported for IL-6 (279). Moreover, inflammatory cytokines may induce insulin resistance by direct actions on insulin-signaling postreceptor molecules (280) or by inducing central obesity through activation of the hypothalamic-pituitary-adrenal axis (281).

Because obesity and insulin resistance are common findings in hyperandrogenic women (3), chronic inflammation might be involved in the pathogenesis of functional hyperandrogenism and PCOS. In animal models in which polycystic ovaries were induced by neonatal administration of estradiol, the production of TNF- α and IL-6 was increased in ovaries and in peritoneal macrophages (282). The concentrations of IL-12 were decreased, and production of IL-13 and the number of activated lymphocytes were increased in follicular fluid of women with PCOS (283).

The study of serum inflammatory markers in PCOS has resulted in conflicting reports. Increased CRP levels have been reported in PCOS patients defined by NICHD criteria (284, 285). Similarly, increased serum IL-6 (286) and TNF- α (287–289) concentrations have been reported in women with PCOS or functional hyperandrogenism.

However, we have recently reported that obesity, and not PCOS, appears to be the major determinant of the increase in serum CRP and IL-6 in premenopausal women, and this and other inflammatory markers such as serum TNF- α , soluble

Authors are cited in chronological order. gp130, 130-kDa IL-6 Signal transducer; IL-6R, IL-6 receptor; TNFRSF1B, gene encoding TNFR2.

TNFR2, or soluble intercellular cell adhesion molecule-1 are not increased by PCOS when controlling for confounding factors such as smoking and obesity (290). Similar findings have been published recently by Mohlig et al. (291). These results cast doubt upon the usefulness of these serum inflammatory molecules as markers of the inflammatory process associated with hyperandrogenism. On the contrary, another novel inflammatory marker of cardiovascular risk, IL-18, is increased in serum both by obesity and by PCOS, suggesting that this molecule may be a useful marker of inflammation in PCOS patients (292).

Given that proinflammatory genotypes influence obesity, type 2 diabetes mellitus, and insulin resistance-related disorders (273), over the past years our group has studied genomic variants in the genes encoding several inflammatory mediators and their receptors. Some of these variants are associated with functional hyperandrogenism and PCOS.

1. *TNF-α*. TNF-α induces reproductive changes that closely resemble those found in patients with PCOS and functional hyperandrogenism. TNF-α facilitates the effects of insulin and IGF-I on the ovary in a dose-dependent and additive fashion (293), stimulating proliferation and steroidogenesis in rat theca cells *in vitro* (293, 294). Moreover, TNF-α may be involved in apoptosis and anovulation in the rat ovary (295).

We have recently studied serum TNF-α levels and nine common polymorphisms (-1196C/T, -1125G/C, -1031T/C, -863C/A, -857C/T, -316G/A, -308G/A, -238G/A, and -163G/A) in the TNF-α gene in 60 hyperandrogenic women and 27 healthy controls matched for body mass index (288). As a group, hyperandrogenic patients presented with increased serum TNF-α levels, but this increase was only present in lean patients when compared with lean controls, and not in obese patients (288).

No differences between patients and controls were found in the allele frequencies of any of the polymorphisms studied

(288). In conceptual agreement, -308G/A alleles were equally distributed between patients with polycystic ovaries and hyperandrogenic symptoms and controls in other studies (296, 297), and similar results were reported for the -805C/T polymorphism in the TNF-α gene (298). However, when considering patients and controls as a whole in our series, carriers of -308A alleles presented with increased serum androgen and 17-hydroxyprogesterone levels before and after stimulation with the GnRH analog leuprolide (288). Therefore, polymorphisms in the TNF-α gene do not appear to play a major role in the pathogenesis of functional hyperandrogenism and PCOS but might be a modifying factor for phenotypic traits associated with these disorders.

2. *TNFR2 gene (TNFRSF1B)*. TNFR2 mediates most of the metabolic effects of TNF-α (299). We have recently studied serum soluble TNFR2 levels and several polymorphisms in the *TNFRSF1B* in women with functional hyperandrogenism, including PCOS defined by NICHD criteria (250).

TNFRSF1B has been studied in several metabolic disorders. The 1690T/C variant in exon 10 has been described to influence body mass index and insulin resistance (300). The CA-repeat polymorphism in intron 4 and the Met¹⁹⁶Arg polymorphism in exon 6, which are in strong linkage disequilibrium, influence serum lipid levels (301–303) and diastolic blood pressure (302); linkage studies suggest that the *TNFRSF1B* locus is associated with hypertension (302) and familial combined hyperlipidemia (301). Moreover, the CA-repeat polymorphism has been recently proposed as a contributing factor to coronary artery disease (304).

In our series, the uncommon 196Arg allele of the Met¹⁹⁶Arg (676T/G) polymorphism in exon 6 of *TNFRSF1B* was more frequent in patients with PCOS compared with healthy controls (250). When the study was extended to include Italian subjects, this variant was more frequent not only in PCOS patients but also in women with hyperandrogenic hirsutism and regular

menstrual cycles (250). However, the Met¹⁹⁶Arg polymorphisms did not influence any phenotypic trait associated with hyperandrogenism, insulin resistance, or obesity when studying patients and controls separately (250).

We also studied three SNPs in the 3'-untranslated region of *TNFRSF1B* in exon 10, 1663G/A, 1668T/G, and 1690T/C, which were not associated with hyperandrogenism (250). Serum soluble TNFR2 levels were not increased in hyperandrogenic women compared with controls, but they were influenced by the interaction between the 1663G/A and 1668T/G variants. We hypothesized that the Met¹⁹⁶Arg variant in *TNFRSF1B* might contribute to PCOS by modulating TNF- α actions at target tissues.

3. IL-6. Among cytokines, IL-6 circulates in plasma and acts in distant tissues (305). TNF- α stimulates IL-6 secretion by adipocytes, and mounting evidence suggests that IL-6 is also implicated in insulin resistance and associated syndromes (273, 306–308). Although serum IL-6 levels are not increased in women presenting with functional hyperandrogenism and PCOS (249, 290), IL-6 concentrations are increased in peritoneal fluid in clomiphene-resistant, anovulatory PCOS patients, suggesting a role in the pathogenesis of hyperandrogenic disorders (309).

We recently studied four common polymorphisms in the promoter of the IL-6 gene (−597G/A, −572G/C, −373A(n)T(n), and −174G/C) in 85 hyperandrogenic patients and 25 healthy women (249). The −597G/A and −174G/C variants were in strong disequilibrium linkage. When considering the three biallelic SNPs, five haplotypes were found (relative frequencies in parentheses): GGG (0.505), AGC (0.377), GGC (0.059), GCG (0.055), and GCC (0.005). The frequency of the GGG haplotype was increased in patients (0.559) compared with controls (0.320), and conversely, the frequency of the AGC haplotype was reduced in patients (0.318) compared with controls (0.580) ($P < 0.02$). Homozygosity and heterozygosity for −597G and −174G alleles were more frequent in controls, and controls carrying these alleles presented with increased serum IL-6, cortisol, 11-deoxycortisol, and 17-hydroxyprogesterone levels, and a tendency toward increased serum total testosterone levels compared with controls homozygous for −597A and −174C alleles. These findings suggest a protective role for the latter against IL-6 excess, adrenal hyperactivity, and hyperandrogenism. The −572G/C and −373A(n)T(n) were not associated with hyperandrogenism or with any androgen-related phenotypic trait (249). In conceptual agreement, Mohlig *et al.* (291) recently reported that the heterozygous −174G/C genotype in PCOS patients was associated with lower serum androstenedione levels.

4. IL-6 receptor. This is a heterodimeric receptor consisting of two membrane-bound glycoproteins: an 80-kDa IL-6 binding unit and a 130-kDa IL-6 signal transducer (IL-6 receptor β or gp130). gp130 is a transducer chain shared by other cytokines and is responsible for signal transduction of the chain-ligand complex through the Janus kinase/signal transducer and activator of the transcription pathway (310).

We have recently studied common polymorphisms in both subunits of the IL-6 receptor in a series of 145 hyperandrogenic women and 45 controls from Spain (251). The uncommon

Arg148 allele of the Gly¹⁴⁸Arg polymorphism in the gp130 gene was more frequent in controls compared with hyperandrogenic patients, and controls carrying Arg148 alleles had lower 11-deoxycortisol and 17-hydroxyprogesterone concentrations, a lower response of androstenedione to 1–24 adrenocorticotropin, and an almost statistically significant decrease in free testosterone levels, suggesting that, as occurred for the IL-6 polymorphisms described above, Arg148 alleles in the gp130 gene have a protective effect against androgen excess and adrenal hyperactivity (251). When considering patients and controls as a whole, a microsatellite CA-repeat polymorphism in the 80-kDa IL-6 binding unit locus was associated with obesity. The frequency of the common 149-bp allele was markedly increased in obese women compared with controls, further supporting the involvement of inflammatory genotypes in obesity and related syndromes (251).

Overall, our studies over the past years suggest that chronic inflammation underlies the pathogenesis of functional hyperandrogenism and PCOS, as has been proposed for other disorders associated with insulin resistance, and that proinflammatory genotypes may be involved.

D. Other candidate genes

1. Follistatin. This protein binds to activin, inhibiting its action both *in vivo* and *in vitro* (311). Activin and follistatin are expressed in multiple tissues, including pituitary, ovary, adrenal, and pancreas (312, 313). In the ovary, activin promotes follicular development and inhibits androgen secretion by theca cells (314). Conversely, transgenic mice overexpressing follistatin present with follicular arrest and infertility (315), characteristics frequently found in hyperandrogenic women.

However, the expression of human inhibin/activin subunit, follistatin, type 2 activin receptor mRNAs, and their encoded proteins in ovarian follicles from PCOS patients suggested that an increase in the availability of activin, relative to inhibin, was actually present in the arrested follicles in PCOS patients (316). Moreover, the location of the mRNAs of the follistatin subunits is not altered in PCOS (317).

Initial molecular genetic studies in humans by Urbanek *et al.* (132) suggested evidence for linkage between the *follistatin* locus and PCOS, as cited above. Subsequent studies by these authors (318) have failed to confirm the involvement of the follistatin gene with PCOS in a large multiethnic study. The coding regions and some introns of the follistatin gene were sequenced, disclosing at least 17 polymorphisms; however, 16 of them were rare, making a significant contribution of these variants to the pathogenesis of hyperandrogenism unlikely (318). Moreover, the only common polymorphism found, located in exon 6 but not translated, was not associated with PCOS when correcting for multiple testing, and the authors concluded that contributions to the etiology of PCOS from the follistatin gene, if any, are probably small (318).

In conceptual agreement, no mutations in the follistatin gene have been found in Chinese PCOS patients defined by menstrual dysfunction, hyperandrogenism, and polycystic ovaries (319), and the only mutation found in our series of patients from Spain, a silent G951A variant, was equally distributed in PCOS patients and in healthy women (320).

2. *Thrombophilic factors.* Women with PCOS have increased miscarriage rates, as happens in women with inherited thrombophilic conditions. The secretion of plasminogen activator inhibitor-1 (PAI-1) in adipose tissue is enhanced by inflammatory cytokines and by insulin (321–323). In agreement, the increased circulating PAI-1 levels found in PCOS patients decrease after treatment with insulin sensitizers (324). Homozygosity for 4G alleles of the –675 4G/5G polymorphism in the gene encoding PAI-1, which modulates PAI-1 activity, have been reported in association with obesity (325) and PCOS (326). We have found a similar trend in our series on Spanish women, although the difference in allele frequencies did not reach statistical significance, possibly because of small sample size (229).

Other genetic abnormalities associated with thrombophilia have been studied in PCOS. Tsanadis *et al.* (327) recently reported that the prevalence of antithrombin III, protein S and protein C deficiencies, factor V Leiden, prothrombin G20210A factor, and methylene tetrahydrofolate reductase 677C/T mutations is not increased in Greek patients with polycystic ovaries, menstrual dysfunction, and hyperandrogenism when compared with nonhyperandrogenic controls. Similar results have been found for the methylene tetrahydrofolate reductase variant in Italian women (328).

3. *Microsomal epoxide hydrolase.* Two SNPs, Tyr¹¹³His and His¹³⁹Arg, in the gene encoding the detoxifying enzyme microsomal epoxide hydrolase have been studied in women with PCOS, defined by the presence of polycystic ovaries and hyperandrogenic symptoms (329). Although none of the polymorphisms was associated with PCOS, the presence of the His113-Arg139 haplotype was associated with an odds ratio for PCOS of 2.28 and 95% confidence interval of 1.1–4.8 (329). However, it is unclear how changes in the activity of this enzyme might relate to functional hyperandrogenism and PCOS, and therefore, this result should be considered with caution unless confirmed in future studies.

4. *Bone morphogenetic proteins.* The intraovarian bone morphogenetic protein system is involved in the control of granulosa cell proliferation and cytodifferentiation and plays a role in oocyte development (330). The genes encoding the growth differentiation factor 9 and bone morphogenetic protein 15 have been studied in Japanese women with polycystic ovaries, but no missense mutations have been found in these women (331).

VI. Hyperandrogenism, PCOS, and Survival Advantage

The increasing prevalence of complex metabolic disorders in developed countries raised the possibility that, from an evolutionary perspective, the pathogenetic mechanisms underlying these disorders might have provided survival advantages (332). However, these previously beneficial mechanisms may lead to disease with prolonged life expectancy or when these subjects are exposed to the present lifestyle in Western countries.

As suggested by Witchel *et al.* (333) for congenital adrenal hyperplasia, which is one of the most common inherited disorders with carrier frequencies of approximately 10% in

all world populations studied to date and a relatively common cause of hyperandrogenism in children and adults, the presence of hyperandrogenism in women might have provided survival advantage for these women and their children.

The rapid maturation of the reproductive axis found in these subjects, together with the increase in assertive behavior resulting from increased androgen secretion, might be advantageous during times of environmental stress (333–335). Moreover, the relative infertility of these women could increase the interval between pregnancies, decreasing the birth rate and favoring maternal and infant survival (333). In addition to the lower rate of pregnancies secondary to oligoovulation, pregnancies may also occur at an older age, favoring the survival of these women. In agreement, an early beginning of fecundity is associated with higher mortality rates in animal models (335).

Yet survival advantage may also contribute to explaining the association of hyperandrogenism with other disorders related to insulin resistance. Human metabolism may be genetically adapted to the dominant conditions that have predominated for ages: near-continuous physical activity, a diet rich in carbohydrates and proteins yet poor in fat, and long periods of famine or food shortage (336–338). Survival was therefore favored by a combination of thrifty genotypes and phenotypes, in which insulin resistance played a central role (Fig. 2).

Insulin resistance increases glucose availability for brain metabolism. It also increases salt and water retention and sympathetic tone and induces endothelial dysfunction, favoring an increase in blood pressure, obviously beneficial when trauma occurs. Similarly, the increased coagulability and decreased fibrinolysis associated with insulin resistance are defensive mechanisms against bleeding. But more important is that insulin resistance favors obesity, protecting against starvation, and obesity contributes to a proinflammatory state through the secretion of several cytokines, contributing to the defense against infection, and possibly to the development of functional hyperandrogenism and PCOS.

When the environmental conditions change and access to food is not restricted, significant trauma and epidemics seldom occur, and life expectancy increases markedly, these defensive mechanisms are no longer beneficial, and the price to pay is atherosclerosis and cardiovascular disease (Fig. 2).

For the reasons outlined above, it is not surprising that the genomic variants associated with obesity, type 2 diabetes mellitus, and other disorders in which insulin resistance plays a major role are frequently associated with functional hyperandrogenism and PCOS. However, genomic variants-associated insulin resistance may contribute to hyperandrogenism only indirectly, by inducing insulin resistance and hyperinsulinemia and/or by direct actions at the adrenal or the ovary. For example, TNF- α induces insulin resistance by interfering with IRS-1-mediated insulin signaling (280) and also has reproductive actions that closely resemble those found in patients with PCOS and functional hyperandrogenism, as summarized above (293, 294).

Therefore, the precise elucidation of the mechanisms underlying these associations requires studies of the functional consequences of the genomic variants associated with hy-

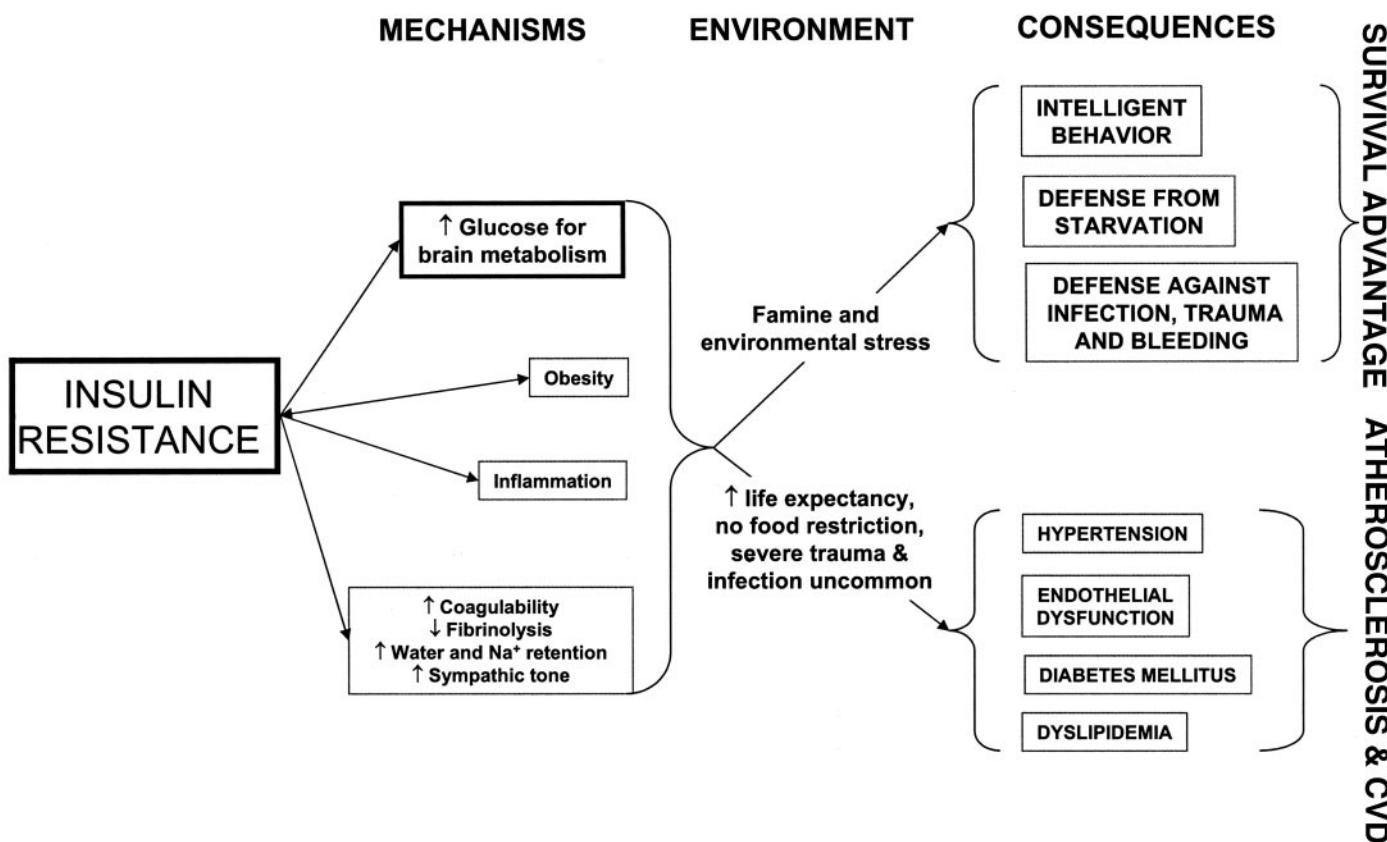

FIG. 2. Insulin resistance, survival advantage, and disease. Insulin resistance and related pathogenic mechanisms may have been selected during evolution because of survival advantage during times of environmental stress. However, with the sudden change in life conditions occurring during the last century in most developed countries, where access to food is not restricted, severe trauma and infection are relatively uncommon, and life expectancy has increased markedly, these mechanisms are no longer beneficial and result in atherosclerosis and cardiovascular disease (332). CVD, Cardiovascular disease.

perandrogenism in different target tissues, especially when some of the genomic variants appear to facilitate insulin resistance and hyperandrogenism, whereas others may protect against these disorders.

At present, the emerging picture for the molecular genetic mechanisms leading to functional hyperandrogenism and PCOS is that of a complex interaction between predisposing and protective genomic variants, and the strong impact of modifying environmental factors including diet, exercise, and lifestyle (Fig. 3).

VII. Explanations for the Lack of Reproducible Association of Hyperandrogenism and PCOS with Molecular Genetic Abnormalities and Genomic Variants

To date, most of the associations between genomic variants and functional hyperandrogenism or PCOS failed to replicate when studied in different populations. An immediate consideration is that most studies conducted to date have been modest with regard to the number of subjects included. A small sample size, leading to a lack of statistical power to detect the modest effects that genomic variants possibly play in the pathogenesis of a complex disorder such as functional hyperandrogenism, might explain the negative

results found in many cases when efforts have been made to confirm previous studies. Although at present there are no doubts about the need of studies with large sample sizes, lack of consistency of the reported findings is not limited to hyperandrogenism and is a recurrent problem in the study of many complex metabolic disorders (339). Therefore, other factors might also contribute to the discrepancies observed when studying candidate genes for hyperandrogenism in different populations, summarized below.

A. Ascertainment issues

One of the essential requirements for the effectiveness of molecular genetic studies is a clear definition of the phenotype under study. This has not been the case for functional hyperandrogenism and PCOS. As an example, the linkage studies cited above (140, 222) of *CYP11A* and *INS* in women from the United Kingdom relied mostly on the use of ultrasonography for the diagnosis of PCOS, and this series included "ovulatory" PCOS patients. On the contrary, a linkage study conducted in the United States relied on the NICHD criteria (132), in which chronic anovulation is strictly required for the diagnosis of PCOS (9). Given the considerable differences in the criteria used to define the phenotype, it is unlikely that the genes associated with the disease would be the same in both studies.

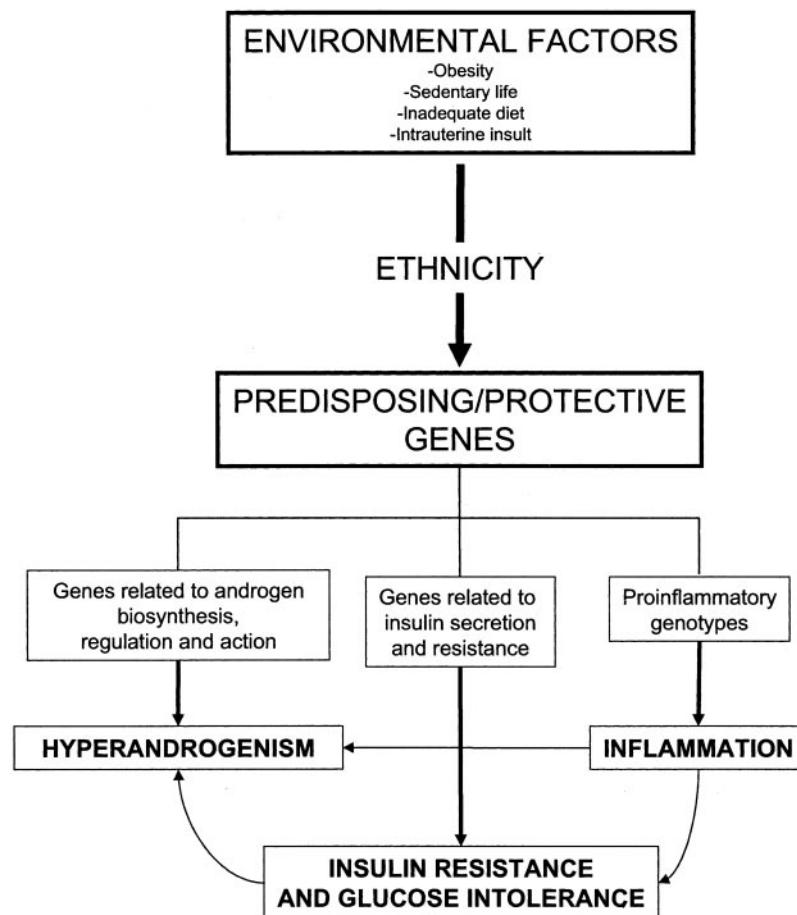

FIG. 3. A unifying hypothesis for the association of hyperandrogenism, inflammation, and insulin resistance. Environmental factors, influenced by ethnicity, act on a delicate balance between predisposing and protective common genetic variants that have been selected during evolution because of previous survival advantage. The genes involved in the pathogenesis of hyperandrogenism may vary depending on the particular and/or ethnic factors that predominate in the different populations studied, providing an explanation for the phenotypic variability of hyperandrogenic disorders.

Moreover, the spectrum of disorders covered by the criteria derived from the Rotterdam Consensus Workshop (11, 12) is even broader than those included with the NICHD definition: PCOS would be diagnosed not only in women presenting with hirsutism, hyperandrogenemia, and anovulation, but also in patients presenting with anovulation and polycystic ovaries but no clinical and/or biochemical evidence of hyperandrogenism. Therefore, these revised criteria are unlikely to be of significant advantage over previous ones with respect to molecular genetic studies. And to further complicate the search for PCOS-related genomic abnormalities in family-based studies, the male PCOS phenotype is still uncertain.

Because of the heterogeneous and syndromic nature of PCOS, it would be more helpful for molecular genetic studies to use criteria oriented toward the identification of specific clinical, reproductive, and metabolic traits associated with hyperandrogenism. This would require an important effort to identify and especially to standardize the methods used to identify these traits in large populations such as those needed for family-based or case-control designs.

Instead of trying to reach a consensus on how to diagnose precisely a disorder that is heterogeneous by definition, the practical issue would be to standardize the definitions and methods used to identify specific traits such as insulin resistance, overweight, visceral adiposity, dyslipidemia, hirsutism, acne, oligoovulation, and many others that characterize or are frequently found in hyperandrogenic women.

Given the apparently multigenic etiology for functional hyperandrogenism and PCOS, this approach would permit a more precise definition of the kind of hyperandrogenic patients included in the different molecular genetic studies. It would facilitate well-sized multicollaborative studies and thereby increase the probability of success in identifying genomic variants and abnormalities related to these particular traits that might be used as diagnostic and/or therapeutic targets in the future. It is hoped that scientific societies that address the study of hyperandrogenism, such as the recently created Androgen Excess Society (<http://www.androgenexcesssociety.org>), will serve as an adequate forum where these efforts in standardization could be made.

In addition to the problems of defining the PCOS phenotype, sampling issues also should be considered. For family-based studies, a common sampling procedure is to collect from an affected proband with at least one or two affected relatives, instead of the ideal, but rarely performed, procedure of selecting families from the population at random (340). Nonrandom ascertainment makes it more likely that families with multiple PCOS members enter the study than families with no affected relative, resulting in biased heritability estimates (340, 341). Another common source of error is that the affected status in relatives of the proband is typically determined on the basis of his or her report because of constraints in time and resources (340). Moreover, affected subjects may be more likely to be aware of the diagnosis in their relatives than nonaffected subjects (340), or more likely

to misinterpret the symptoms of their relatives (340), such as considering the presence or absence of hirsutism as the equivalent of having or not having PCOS.

B. Involvement of environmental factors

The interactions between genetic and environmental factors are essential for the comprehension of the pathogenesis of common complex disorders (342). The precise knowledge of these interactions requires long-term studies analyzing the impact of different environmental factors in specific subgroups of patients, because controlling all the confounding environmental variables is extremely difficult (342).

Environmental factors such as weight gain may trigger the development of PCOS in predisposed women, as occurs in other complex metabolic disorders in which insulin resistance plays a major role. The identification and precise delimitation of the contribution of the environmental influences triggering the development of functional hyperandrogenism and PCOS may direct the search for the specific proteins and/or genomic variants involved to the metabolic pathways influenced by these environmental factors.

However, the environmental factors contributing to complex metabolic disorders may change depending on the population studied, because diet, exercise, and lifestyle have wide ethnic variations. Therefore, it should not be surprising that the genomic abnormalities contributing to these disorders may also change depending on the environmental conditions (*i.e.*, the genes contributing to PCOS in obese sedentary women from a Western country are probably different from those involved in the PCOS phenotype of lean women from the Mediterranean area or from Asia). Finally, to further complicate the study of complex metabolic disorders, the phenotype changes during the life of the affected subjects as age advances. Therefore, different phenotypic traits may not be present when these women were phenotyped, but became apparent later in life, constituting one more confounding factor that is especially difficult to control in molecular genetic studies.

C. Possible polygenic etiology for functional hyperandrogenism and PCOS

It has been suggested that the phenotypic heterogeneity observed in PCOS patients, even within the same family, could be attributed to the interaction of a small number of genes with one another and with environmental factors (18, 22, 33). Furthermore, given the large number of genomic variants found associated with functional hyperandrogenism and PCOS to date, the emerging picture may be that of a complex metabolic disorder resulting from small predisposing or protecting effects arising from the interaction of multiple genomic variants and several environmental factors.

Even if a more precise definition for hyperandrogenic phenotypes was used, and that has not been the case, the classic requisite of replication of linkage or association of a genomic abnormality with monogenic diseases may not be applicable for complex disorders because the functional consequences of the genomic variant may be only apparent in certain pop-

ulations or when a particular environmental factor is present (339). However, it is important that internal replication of findings is provided in larger series, because this might reveal false-positive associations reported in preliminary studies when limited sample sizes were studied.

Nowadays, it is technically feasible to genotype large series of individuals for multiple genomic variants, allowing whole-genome scans and high-throughput candidate gene analysis. These approaches will disclose reliable information of the relative contribution of these genomic variants to functional hyperandrogenism and PCOS and will facilitate the study of gene to gene and gene-environment interactions that probably contribute to the development of these prevalent disorders.

Finally, to avoid spurious associations from being considered causative of any disease-associated trait, every effort should be made to demonstrate *in vivo* or *in vitro* a functional consequence of the associated genomic variant that might reasonably account for the contribution of the variant to the disorder or its associated traits.

D. Limitations of the genetic techniques used to date

As discussed previously, the molecular genetic studies regarding PCOS and functional hyperandrogenism conducted to date had important limitations, especially because adequately sized whole-genome scans and large case-control association studies are still lacking, and therefore associations with genomic variants that have small effects on hyperandrogenism might have been missed by these studies.

Another source of confusion is the fact that quality control of genetic data has not been as strict as that applied to other methods used in clinical research or even in routine clinical practice. Genetic data are usually obtained from a single measure, and reliability and reproducibility of these analyses might be a problem, because genotyping errors may severely bias the estimates of genetic studies (339, 343). Although departure from the Hardy-Weinberg equilibrium may be useful for the detection of these genotyping errors (344), and although modern methods incorporate models of typing error (343, 345), efforts in standardization of these techniques should be made in the future (339).

VIII. Future Perspective: Functional Hyperandrogenism and PCOS in the Age of “Omics”

The suffix “omics” is being applied to recent technologies that are exponentially increasing our knowledge of human biology. Perhaps at present the most developed one is genomics.

Genomics aims to map, sequence, and analyze all the genes and their products in the genome, with the final intention of providing the complete and accurate DNA sequence of an organism (56, 346). The number of genes in the human genome is in the order of 35,000, and because of exon shuffling, alternative splicing, and posttranslational modifications, as many as 100,000 different proteins may be encoded in the human genome. Therefore, identification of all the genes and proteins of the human organism and their interactions requires an enormous effort.

Genomics is in constant evolution, and more specific subspecialties are being developed, such as functional genomics. Its aim is the identification of the biological functions of genes and their products, and how they interact with the environment in health and disease (347). To date, functional genomics has contributed to unravel the mechanisms of many diseases (348–350), and the genomic approach might be especially adequate for the study for complex polygenic disorders, given that traditional molecular genetic approaches have not been successful to date (351).

Genomic techniques, such as differential gene expression analyzed by DNA microarrays, allow the identification of genes that are differentially overexpressed or suppressed in patients compared with controls. This approach has the advantage over molecular genetic analyses in that the result integrates the presence of molecular genetic abnormalities with both gene-gene and gene-environment interactions. Therefore, the genes identified can be considered potential candidates to explain the disorder and also potential diagnostic and therapeutic targets. Recently, comparison of gene expression in cultured theca cells from PCOS patients and controls using DNA microarrays identified the genes encoding aldehyde dehydrogenase 6 and retinol dehydrogenase 2 as candidate genes for PCOS (352). These factors play a role in all-trans-retinoic acid biosynthesis and the transcription factor GATA6, which increase the expression of 17 α -hydroxylase (352), a characteristic of PCOS theca cells (137). In the near future, undergoing studies using DNA microarrays to compare the expression profiles of tissues such as adipose tissue and muscle, which are essential for the development of insulin resistance, will undoubtedly contribute to the identification of candidate genes in hyperandrogenic women.

But given that gene expression and protein concentration and activity are poorly correlated (353), modern techniques have been developed to study the “proteome” of a cell, tissue, or organism. Proteomics allows large-scale analysis of proteins, including their relative abundance, distribution, post-translational modifications, functions, and interactions with other molecules (347). For example, it is possible to examine the expression of more than 1000 proteins by coupling mass spectrometry technology with several separation methods. Proteomic analysis of tissues involved in the pathogenesis of functional hyperandrogenism and PCOS, such as ovarian theca and granulosa cells, adrenal cortex, sc and omental adipose tissue, and muscle, are essential for our understanding of the complex interactions between the genome and the environment that underlie these disorders.

Ultimately, the identification of genes and proteins related to functional hyperandrogenism and PCOS, and their interactions with the environment, will be an essential step for the development of more precise diagnostic techniques, the identification of new therapeutic targets, and the identification of particular individuals that, because of their genetic background, may be predisposed to certain complications of the syndrome or respond differently to available treatments.

IX. Summary

Functional hyperandrogenism and PCOS appear to be complex multigenic disorders, arising from the interaction of

predisposing and protective genetic variants that might have been selected during evolution because of a previous survival advantage, with environmental influences that play an important role in the expression of the hyperandrogenic phenotype.

Among others, genomic variants in genes pertaining to the regulation of androgen biosynthesis, insulin resistance, metabolic syndrome, and proinflammatory genotypes are involved in the genetic predisposition to functional hyperandrogenism and PCOS. Progress in this area requires adequately sized multicenter collaborative studies in which modifying environmental factors such as ethnicity, diet, and lifestyle are identified with precision.

In the future, classic molecular genetic techniques such as linkage analysis in the form of a whole-genome scan and large case-control studies, as well as modern genomic and proteomic approaches, will hopefully provide new insights into the pathogenesis of functional hyperandrogenism and PCOS, with the ultimate aim of improving the prevention, diagnosis, and treatment of these prevalent disorders.

Abstract:

BACKGROUND: Lifestyle training is of a key important in adolescent age for better life in the future. Healthy lifestyle in adolescents can management of any disease such as diabetes and polycystic ovarian syndrome (PCOS). Schools can provide an important environment to identify and change the lifestyle of students. The aim of this protocol is designing and evaluating the effectiveness of school-based lifestyle training program improving the PCOS of adolescents.

MATERIALS AND METHODS: A cluster-randomized controlled trial will be conducted to examine the effectiveness of school-based lifestyle training program in 16 to 18 years old adolescent girls. The healthy lifestyle program will be designed by modification of behavioral habit, dietary intake, and physical activity and educated in eight sessions for adolescents and one session for parents in the intervention groups with sixty participants.

RESULTS: Changes in primary and secondary outcomes in PCOS and healthy adolescents before and after intervention in the intervention and control groups will be analyzed for evaluation effectiveness by one-way ANOVA or other nonparametric equivalents.

CONCLUSION: The current study will provide information on the effectiveness of school-based lifestyle training programs for adolescents. With increasing numbers of PCOS at risk for long-term and/or late effects of treatment and other chronic diseases, efforts for promoting the healthy lifestyle of this important group are urgently needed. This lifestyle program may provide valuable information relating to the development of other healthy lifestyle interventions for PCOS and result in appropriate behavior change and self-management strategies.

Keywords:

Adolescence, education, lifestyle, polycystic ovarian syndrome

Introduction

Polycystic ovarian syndrome (PCOS) is a long-term recognized, and complex, heterogeneous familial disorder.^[1] Some clinical symptoms of this multifactorial syndrome, including hyperandrogenism and chronic anovulation initially appears

in puberty^[2]. Insulin resistance seemed inherent in PCOS independent of obesity;^[3] regardless of weight, PCOS can present in each girl with family history.^[4] Researchers in an international consortium update in PCOS adolescents reported that lifestyle modification is a first step PCOS treatment in adolescents.^[5]

How to cite this article: Nahidi F, Tehrani FR, Ghodsi D, Jafari M, Majd HA, Abdolahian S. The effectiveness of lifestyle training program promoting adolescent health with polycystic ovarian syndrome: A study protocol for a randomized controlled study. J Edu Health Promot 2021;10:351.

Lifestyle modification based on weight loss and increased activity is useful, especially in obese and overweight girls with PCOS.^[6] Even 5%–10% weight loss in obese patients has been beneficial effects. The benefits of lifestyle education for PCOS patients include improved clinical, hormonal, metabolic parameters of PCOS, improved mood and quality of life, body composition, sleep, self-esteem, depression, anxiety, and tiredness in PCOS patients.^[7] Although healthy lifestyle has positive effects on PCOS girls with obesity and overweight, these effects in normal weight or underweight adolescents are not proven.^[8]

Several studies in some countries investigated lifestyle education for PCOS management in adolescent girls with different significant outcomes.^[9-11] Parent role in achieving a healthy lifestyle by their adolescent is very important, and for this participant, facilitator and barrier should be considered.^[12] Next to the parents, schools are the major center for providing the guideline that prepares adolescents for their healthy lifestyle.^[13-15] The lifestyle intervention in PCOS including dietary, physical activity, and behavioral habits strategies need at least 6–12 months to be effective.^[16]

A variety of balance dietary approaches could be recommended to reduce dietary energy intake and induce weight loss in obese and/or overweight women with PCOS.^[17] Moreover, an energy deficit of 30% or 500–750 kcal/day could be suggested for PCOS women.^[18] Since there has been no evidence for specific diet in PCOS patients, a healthy dietary intake with energy balance for PCOS adolescents is recommended.^[19] Usage by taking some herbal medicines in Iranian women can help improving the symptoms for short time.^[20]

According to the World Health Organization, an adequate daily physical activity from 60 to 90 min is recommended. In particular, all young people should be active for at least 60 min each day (including at least 3 days a week and 30 min of structured physical activity or around 3000 steps).^[16] The presence of lifestyle guideline for adolescents based on indigenous culture and native language in each country can be an important step in the effectiveness of this type of intervention,^[21] however, the information alone is not sufficient to create changes in health behaviors. Information and awareness are the first step of healthy lifestyle training but not the final step toward behavior change.^[22]

Applying behavioral strategies, such as life skills reinforcement (self-monitoring, problem-solving, and coping with stress) can be effective in the elimination of bad habits during adolescents.^[23] The individual must be motivated and prepared to make health behavior

change.^[24] Without motivation and preparation for change, health behavior changes cannot be maintained over time.^[25] Motivational interviewing may be a good strategy to support adolescents in making decisions that will help them appropriately to manage their weight.^[26]

Although some studies stated that lifestyle along with weight loss can be effective in improving PCOS problems in adolescents^[9,10,27] but in another articles the effectiveness of this treatment was not confirmed.^[28,29] The researchers decided to design and evaluate school-based lifestyle training program in Iranian adolescents for managing of PCOS.

Objectives

- Design of a school-based lifestyle training program in adolescents for PCOS management
- Education of school-based lifestyle training program in intervention groups
- Evaluation of the primary outcomes before and after school-based lifestyle training program
- Evaluation of the secondary outcomes before and after school-based lifestyle training program.

Materials and Methods

Study design and setting

The methodological approach for lifestyle training in adolescents is a cluster-randomized clinical trials study. The design, conduct, and reporting of this study will adhere to the Consolidated Standards of Reporting Trials guidelines.

This study will be carried out in three phases: (1) design of a school-based lifestyle training program, (2) education of this program, and (3) evaluation of this program by comparison of clinical assessment 6 and 12 months after intervention [Figure 1]. This study will be done on high school girls in Tehran, Iran.

Study participants and sampling

Single girls between the range of 16 and 18 years old

Procedure

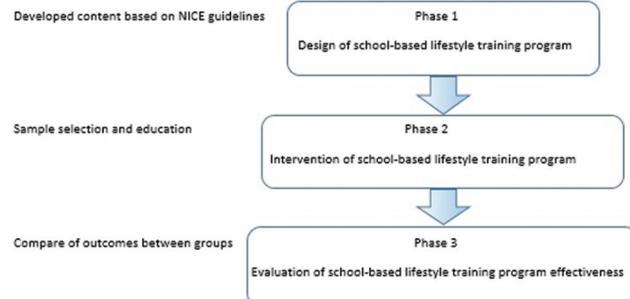

Figure 1: Study visual design

without sexual relation that at least 2 years has passed from their juvenile menarche and been healthy in terms of all diseases, including liver, kidney, thyroid, mental, heart, and skeletal diseases, are included in this study. They no use any drug, smoke, and alcohol. They should not exercise professionally or attend sporting teams, or have a specific diet. PCOS adolescents based on the American Society for Reproductive Medicine criteria will be diagnosed and included in the study. Finally, healthy and PCOS adolescents, regardless body mass index, will be included in the study.

Adolescents who for any reason will fail to attend a one-third of the classes hold at the school or will be affected by a specific illness or need to take a particular drug after entering the plan are excluded from the study.

Participants will be recruited via school screening methods, including referrals by health professionals to Endocrine Sciences Laboratory Center at Shahid Beheshti University of Medical Sciences for assessment. Our strategies for achieving adequate participant enrollment to study are using student medical history that has been saved by school health educators.

Allocation will be done by stratified randomization by cluster method. In this study, the unit of randomization will be a school group in four geographical directions (west, east, south, and north) of Tehran, Iran. The researcher will use a random number table to allocate consenting school to intervention or control group, stratified by girls' high school code. Two schools will be selected in each direction (one school for the intervention and one school for the control). Finally, eight high schools will be enrolled in this study. Girls and their parents will be asked to read and sign an informed consent form before attending the project. After participants enrolled in the study, they will be referred for tests: blood tests and ultrasounds. They should also submit anthropometric indices, physical activity status, and dietary intake status information.

We will recruit 60 healthy adolescent girls and 60 PCOS adolescent girls, which will be divided into four groups: intervention groups (30 PCOS + 30 healthy) and control groups (30 PCOS + 30 healthy) [Figure 2]. One researcher (S.A) will generate the allocation sequence, another researcher (F.R.T) in endocrine research will enroll participants and will assign participants to interventions, and finally, S.A will hold a school-based lifestyle training program. In this study, the data analyzer will be blinded only after the assignment to interventions. All students in four groups are coded by ID number.

Adolescent girls in the intervention group will be school-based trained and control groups will receive only

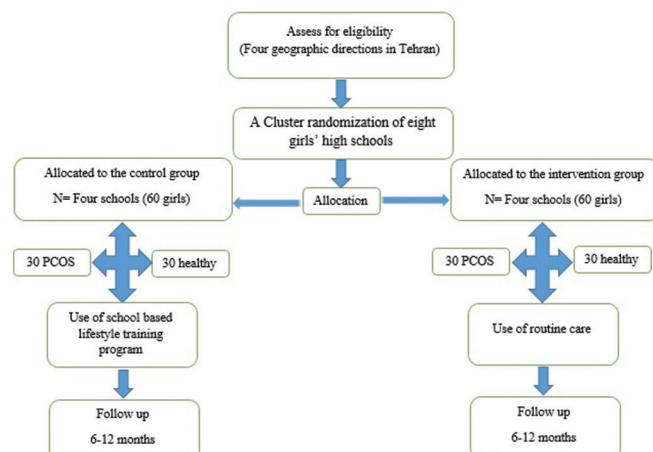

Figure 2: Consort diagram of study

routine care. The draft content of the healthy lifestyle program will be prepared in the first phase of the study. The content of lifestyle in intervention adolescents for PCOS management will be developed based on the National Institute for Health and Care Excellence guideline [Figure 3] and literature review. The program will be developed by a group of experts (reproductive health specialist, gynecologist, midwife, health psychologist, and nutritionist). The three main goals of the intervention are to increase physical activity, healthy diet, and change of behavior habit. The design of physical activity content was based on minimum facility and equipment availability at school or community. Each standard aerobic exercise is explained in terms of duration, repetition, and intensity. Traditional sports are also considered. The healthy diet regime is based on the consumption of essential nutrients, such as fluid, macronutrients, micronutrients, and adequate calories including five main food groups. The usage of supplements and herbal drugs will be considered. Change of behavior habit designed is based on life skill and motivational reinforcement in adolescents for daily energy balance.

Lifestyle training in high school will be conducted face to face, teaching in 45-min sessions of lecture and question-answer for eight training classes every week. The educator is obliged to teach the educational content based on the behavioral goals set for each session by the use of movie, PowerPoint, speech, and peer review of teaching.

A pamphlet for adolescents and their parents will be prepared and provided to them. Motivational interviewing strategy will be used for lifestyle training in school, thus asking open-ended questions, reflection statement, affirming response, and summaries. An educational session is also held for parents to participate in home to accompany the adolescent in maintaining a healthy lifestyle.

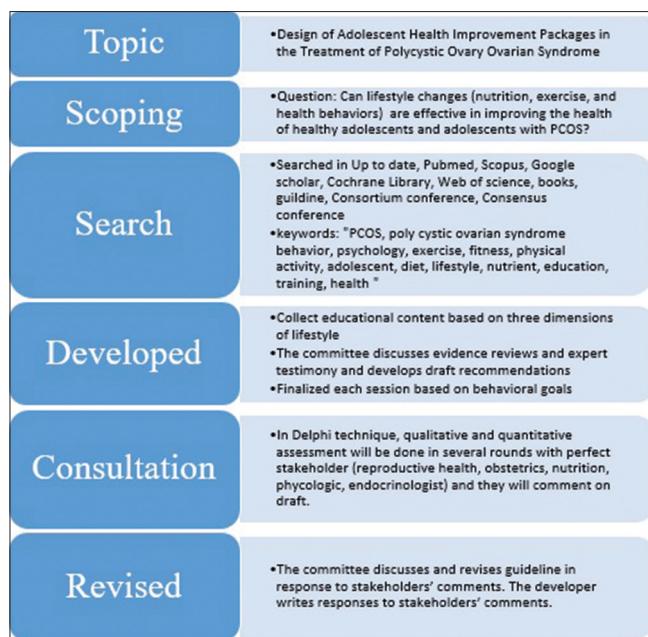

Figure 3: Stage of developed content of school-based lifestyle training program based on NICE guideline

Participant evaluation of the educational program and sessions will be measured via a participant program evaluation form (to be completed by participants at the final educational session). The program evaluation form will consist of nine questions from the course evaluation module of the Health Education Impact Questionnaire.^[30] Participants in the intervention and control groups were required to take hormonal medications at any time during the study, they could be excluded from the study, and there was no interference with their treatment.

Data collection tool and technique

In this study for evaluation of program effectiveness, primary outcomes (anthropometric indices, clinical symptom, physical activity status, and dietary intake status) will be compared at baseline, 6, and 12 months after intervention and secondary outcomes (blood biomarkers and Sonography factors): will be compared at baseline and 12 months after intervention.

In anthropometric index measurement, weight, height, waist, and hip circumstance will be submitted. Participants will be relaxed for 15 min before the measurements are taken. Body weight (to nearest 0.1 kg) and height (to nearest 0.01 m) will be measured while subjects had light clothing and stood barefoot, with eyes directed straight ahead.^[31] The waist circumstance will be obtained by inelastic tape measure, with an accuracy of 0.1 cm, directly on the skin at the umbilicus level.^[32] Hip circumference will be measured at the point yielding the maximum circumference over the buttocks using a tape measure to measure to the nearest 1 cm at the widest part of the hips.^[33]

In clinical symptom measurement, menstrual cycle regularity, hirsutism status will be submitted. Participants who are 1–3 years postmenarche and their menstrual cycles are <21 days or more than 45 days will be considered an irregular menstrual cycle. Furthermore, more than 3 years postmenarche adolescents whose menstrual cycles are <21 or more than 35 days or have <8 cycles per year will be considered irregular.^[34] The Ferriman–Gallwey scale will be used for hirsutism status; a score of 1–4 is given for nine areas of the body. A total score <9 is considered normal, a score of 9–15 indicates mild hirsutism, and a score >15 indicates moderate or severe hirsutism.^[35]

Physical activity will be measured using the International Physical Activity Questionnaire (IPAQ). IPAQ has undergone extensive reliability and validity testing in 12 countries.^[36] This instrument has acceptable measurement properties for use in many settings and is specifically designed for population-based prevalence studies of physical activity. Dietary intake will be measured using a 24-h recall questionnaire.

Blood biomarkers (prolactin, testosterone, dehydroepiandrosterone sulfate, luteinizing hormone, follicle-stimulating hormone, sex hormone-binding globulin, thyroid-stimulating hormone, T4, triglyceride, low-density lipoprotein, high-density lipoprotein, anti-Mullerian hormone, and fasting blood sugar) will be measured in the Research Institute for Endocrine Sciences Laboratory Center at Shahid Beheshti University of Medical Sciences with blood sample before and after 12 months after intervention. Participants without oligomenorrhea will be referred to laboratory test in the follicular phase of menstrual cycle with 8 h fasting.

Sonography factors will be measured by one sonographer via transabdominal ultrasound, the usage of probes with 8 MHz, in Research Institute for Endocrine Sciences Laboratory Center at Shahid Beheshti University of Medical Sciences. Participants without oligomenorrhea will be referred to this center in the follicular phase of menstrual cycle. Sonography factors will include three dimensions and volume of each ovary and endometrial thickness.

It should be noted that all clinical tests have been performed at the Endocrine Research Institute of Shahid Beheshti University of Medical Sciences and no cost will be imposed on students.

The sample size was calculated in order to detect, with at least 90% power, and 95% certainty, and 0.05 level of statistical significance. Based on this formula, sample size was calculated to be 56 for intervention and 56 for control. Due to the follow-up duration time (12 months),

and considering the 20% attrition of sample, finally 60 samples will be assumed for each group. Data will be entered into IBM SPSS Statistics 25 (Chicago, IL, USA).

Ethical consideration

Ethical approval was obtained from the Ethics Committee of Shahid Beheshti University of Medical Sciences (reference number IR.SBMU.PHARMACY. REC.1397.100). Students and parents gave written active informed consent for participation of the student.

Results

Changes in primary and secondary outcomes in PCOS and healthy adolescents before and after intervention in the intervention and control groups will be analyzed for evaluation effectiveness by one-way ANOVA or other nonparametric equivalents.

Discussion

The current protocol describes a study that will investigate the design and effectiveness of school-based lifestyle training program targeting healthy lifestyle to deal with improving behavioral habit promoting dietary intake and physical activity in adolescents for PCOS management. The healthy lifestyle program meets a current gap in the provision of care to PCOS women during the adolescent phase of life. A healthy lifestyle is not only beneficial for obese or overweight adolescents but also protects normal or underweight adolescents against inherited diseases such as PCOS, diabetes, and cardiovascular disease in the future,^[37] and prevention is a cost-effective strategy for adolescents and its benefits are long-lasting.

It is of crucial importance that the school environment can provide students with competition and motivation interventions to help them for maintaining a healthy lifestyle. Lifestyle education at school makes school staff more sensitive to the health of adolescents and, as a result, oversees the school's food environment.^[38]

Training of lifestyle program focuses on important behavior strategy via motivational interviews that have the potential to address long-term and late effects. It is important that the educators have a good understanding of the interviewee's stage of readiness to make a change in behavior.^[24] Although the benefits of a healthy lifestyle intervention have been documented in many studies and suggested as a scientific fact for the treatment and prevention of PCOS,^[39] There are still many challenges regarding treatment of PCOS, especially in lean or normal weight adolescents. The best training time, the best training style, and the best training place which will be most effective on lifestyle change are challenging in other scientific studies.^[40,41]

If this study program works, it can become one of the lifestyle education guidelines for improving health in adolescent girls with PCOS.

Limitation and recommendation

Limitations of the study include the reliance on self-report data on adolescents in terms of physical activity and dietary behavior. A novel approach of the program is the emphasis on self-management constructs and training in socioeconomic variations in one metropolis and comparison of clinical assessment in health and PCOS women into four groups for control of several confounders. There is further potential for this program to be done school based. If this lifestyle program works, it can become one of the lifestyle education guidelines for improving health in Iranian adolescent girls with PCOS.

Conclusion

The current study will provide information on the effectiveness of school-based lifestyle training programs for adolescents. With increasing numbers of PCOS at risk for long-term and/or late effects of treatment and other chronic diseases, efforts for promoting the healthy lifestyle of this important group are urgently needed. This lifestyle program may provide valuable information relating to the development of other healthy lifestyle interventions for PCOS and result in appropriate behavior change and self-management strategies.

Acknowledgment

This article is part of PhD thesis in midwifery and reproductive health department and the Research Institute for endocrine science of Shahid Beheshti University of Medical Sciences. We would like to thank the collaborating schools and youth care organizations for their corporation and practical support for this study. This study was approved by the Ethics and Research Committee of Shahid Beheshti University of Medical Sciences (reference number IR.SBMU.PHARMACY. REC.1397.100).

BACKGROUND: We wished to evaluate the psychometric properties of the Polycystic Ovary Syndrome Questionnaire (PCOSQ), a questionnaire developed to measure the health-related quality of life (HRQoL) of women with polycystic ovary syndrome. **METHOD:** To assess reliability and validity, women recruited from an outpatient gynaecology clinic at the Jessop Wing, Royal Hallamshire Hospital, Sheffield completed two copies of the PCOSQ and the Short Form-36 (SF-36). Secondary factor analysis was carried out to verify the composition of the dimensions. Semi-structured interviews were conducted to assess face validity. **RESULTS:** Of the 92 women who consented, 82 women (89%) returned questionnaires at time 1, and 69 women (75%) returned questionnaires at time 2. All five PCOSQ dimensions were internally reliable with Cronbach's α scores ranging from 0.70 to 0.97. Intra-class correlation coefficients to evaluate test-retest reliability were high (range 0.89–0.95, $P < 0.001$). Construct validity was demonstrated by high correlations for all comparisons of similar scales of the SF-36 and PCOSQ (0.49 and 0.54). Acne was identified as an important area of HRQoL missing from the questionnaire. **CONCLUSIONS:** The PCOSQ is a reliable instrument for measuring the HRQoL in women with PCOS. However, the validity of the questionnaire needs to be improved by incorporating a dimension on acne into the instrument.

Key words: health-related quality of life/health status/polycystic ovary syndrome/psychometric properties/questionnaires

Introduction

Polycystic ovary syndrome (PCOS) affects 5–10% of women in the developed world, making it the most common endocrine disorder among women of reproductive age (for review see Franks, 1995; Solomon, 1999). It is typically defined as the association of hyperandrogenism with chronic anovulation in women without specific underlying disease of the adrenal or pituitary glands (Franks, 1995). PCOS is diagnosed on the clinical picture, supported in some women by biochemical abnormalities and/or polycystic ovaries on ultrasonography (Zawadski and Dunaif, 1992).

The symptoms typically associated with PCOS—amenorrhoea, oligomenorrhoea, hirsutism, obesity, subfertility, anovulation and acne—can lead to a significant reduction in quality of life. For example, hirsutism has been shown to cause marked psychological stress (Sonino *et al.*, 1993) and infertility issues can cause tensions within the family, altered self-perception, and problems at work (Paulson *et al.*, 1988; Downey *et al.*, 1989). Despite this, a recent systematic review revealed that limited research had been carried out to assess the impact that the symptoms and associated treatments for PCOS

have upon the quality of life of women with the condition (Jones *et al.*, 2002).

Health-Related Quality of Life (HRQoL) is a multidimensional, dynamic concept that encompasses physical, psychological and social aspects that are associated with a particular disease or its treatment (Naughton and McBee, 1997; Colwell *et al.*, 1998). Although HRQoL measurement has an important role in evaluative research, the reliable assessment of quality of life depends upon the psychometric properties of the questionnaire (i.e. the tests underlying the construction and evaluation of the questionnaire) and the statistical methods employed to analyse and interpret the data (Fayers and Machin, 2000). It is important therefore that any HRQoL questionnaire to be used is based upon these psychometric properties. Although there are many tests which can be performed to evaluate these properties, the general consensus is that they should be reliable, valid and sensitive to change (Nunally, 1978).

At present, one reason for the limited research on the impact of PCOS upon quality of life may be because no validated health outcome measure exists to measure the health status of

women with the condition. One disease specific questionnaire has been developed, the Polycystic Ovary Syndrome Questionnaire (PCOSQ) (Cronin *et al.*, 1998). It contains 26 items, measuring the following five areas of HRQoL: emotions (eight items, e.g. moody as a result of having PCOS?), body hair (five items, e.g. growth of visible hair on chin?), weight (five items e.g. had trouble dealing with your weight?), infertility problems (four items, e.g. concerned with infertility problems?) and menstrual problems (four items, e.g. irregular menstrual periods?). However, only the content validity of the instrument had been evaluated, thus preventing its use in clinical settings and limiting the research that can be carried out to evaluate the impact of PCOS-associated symptoms and their treatment upon quality of life. While generic questionnaires exist to measure HRQoL, such as the SF-36, they may not be sensitive enough to measure changes in specific illnesses as they were designed to measure health status across a wide variety of diseases (Streiner and Norman, 2000).

Consequently, the aim of this study was to evaluate the other psychometric properties of the PCOSQ, in particular the reliability, validity and factor structure of the domains when assessing the HRQoL in women with PCOS.

Materials and methods

Ethical approval for this study was obtained from the South Sheffield Research Ethics Committee.

A total of 186 women of reproductive age with PCOS was recruited from a gynaecology clinic at the Jessop Wing, Royal Hallamshire Hospital, Sheffield. We defined the inclusion criteria as two out of three of the following: a physical symptom, a biochemical abnormality or polycystic ovaries visualized on ultrasound scan (Lewis, 2001). Physical symptoms included hirsutism, oligo/amenorrhoea, infertility, body mass index $>28 \text{ kg/m}^2$ or acne (Heineman, 1997). Biochemical abnormalities included an LH/FSH ratio >1.5 , a testosterone level >2.0 or sex hormone binding globin <30 (Balen, 1999). Women were excluded from the study if they had another major illness that substantially influenced their quality of life or another cause of androgen excess, e.g. congenital adrenal hyperplasia. The patients' notes were reviewed to identify those who met the study inclusion criteria, from which 172 women were eligible. These women were sent a consent form and a letter inviting them to participate, to which 92 (53.5%) responded.

The PCOSQ was then administered by postal survey to the 92 women who had consented (time 1). Included with the questionnaire was the SF-36 (Ware *et al.*, 1992). The SF-36 was used for two reasons. First, it has been argued that different health status measures (ideally generic and disease-specific health questionnaires) should be used in studies concerned with quality of life measurement (Fitzpatrick *et al.*, 1993). Second, it was necessary to include another instrument to evaluate the construct validity of the PCOSQ.

Construct validity is a powerful measure of evaluating the validity of an instrument (Kline, 1986). It is usually evaluated by testing the instrument against hypotheses concerning the scores in the test (Kline, 1986). The test is said to have demonstrated construct validity if the hypothesis is supported but poor construct validity if it is rejected (Kline, 2000). In the absence of another disease-specific PCOS questionnaire, the SF-36 was chosen. It is a well-validated generic questionnaire (Kosinski *et al.*, 1999) and contained two scales which could be used to help evaluate the construct validity of the PCOSQ.

A second copy of the PCOSQ and SF-36 was also included in a sealed envelope and respondents were requested to complete the second copies 3–6 days after they had completed and returned the first (time 2). This was to evaluate the test-retest reliability of the questionnaire. Test-retest reliability (i.e. how stable the questionnaire is over time) is fundamental if the purpose of the instrument is to measure outcome (McDowell and Newell, 1996). Usually a test is administered to a set of subjects on two occasions (given that there has been no change during this time) and then the scores obtained from the test and the retest are correlated (Kline, 1986). A 'change' letter was also included in the sealed envelope for the respondent to report any important changes in their health status. This was because test-retest reliability would only be analysed on those patients who reported 'no change' to their health status during that time.

Face validity is concerned with how appropriate, relevant and understandable items on a questionnaire are to the focus or aim of the questionnaire (Jenkinson and McGee, 1998). Although on its own, face validity does not ascertain the true validity of a questionnaire, it is important to establish as it can improve the co-operation of respondents completing a questionnaire (Kline, 2000), identify any ambiguities in the wording of items (Jenkinson and McGee, 1998) and identify any irrelevant or missed-out items.

To check the face validity of the PCOSQ, individual interviews with 12 women with PCOS recruited from an outpatient gynaecology clinic at the Jessop Wing Hospital, Sheffield were carried out. These explored whether the PCOSQ was addressing the relevant issues regarding the impact of PCOS upon the health status of women suffering from the condition. This sample size was determined at the point where no new issues emerged regarding the face validity of the questionnaire (Peto *et al.*, 1998).

Analysis

The PCOSQ consists of five domains, each relating to a common symptom of PCOS; body hair, emotions, infertility, menstrual problems and infertility. Each question on the PCOSQ is associated with a 7-point scale in which 7 represents optimal function and 1 the poorest function. In order to compare it with the SF-36, each question was re-coded from 0 to 6 in which 6 represents optimal function and 0 the poorest. Each scale was then transformed on a range from 0 (indicating worst health status) to 100 (best health status) enabling the extent of ill health to be measured (scale score = total of raw scores for each item in the scale/maximum possible raw score $\times 100$). This was repeated for time 2 responses. Similar tables were constructed for the SF-36.

To verify the factor structure and compositions of the PCOSQ dimensions, secondary factor analysis was used. Factor analysis is a statistical procedure which enables the underlying dimensions (or scales) of a questionnaire to be determined (Kline, 2000). The data from the questionnaires returned at time 1 were analysed using principal component analysis (varimax rotation) as used in the development of the original questionnaire (Cronin *et al.*, 1998). To reduce statistical error, it has been postulated that ≥ 100 subjects are needed for factor analysis or a $\geq 2:1$ ratio of subjects to items (Kline, 2000).

To measure the internal consistency reliability of the questionnaire, Cronbach's α statistic was used. Internal consistency reliability is an indication of how well the items within a scale are associated with each other or their 'homogeneity' (Velikova *et al.*, 1999) and Cronbach's α is the measure which is most frequently used for establishing this. Scores >0.7 usually indicate that scale items are measuring related constructs (Cronbach, 1951). Item-total consistency was also calculated to check the internal reliability of a dimension. This is the extent to which there is a linear relationship between an

item and its scale score, which has been corrected for overlap (Gandek *et al.*, 1998). To correct for overlap, the item which is to be correlated with the scale is omitted from the scale total. A correlation coefficient of ≥ 0.40 indicates satisfactory item-total consistency (Ware *et al.*, 1980).

To analyse test-retest reliability, the Wilcoxon signed rank test (nonparametric) was used to calculate if there were any statistical differences between the scores at times 1 and 2 on those patients who had reported 'no change' to their health status during that time. The intra-class correlation coefficient was calculated to examine the

relationship between the scale scores at time 1 and 2. The results were taken to be significant if $P < 0.05$.

To assess construct validity, we hypothesized a significant correlation (Spearman's ρ non-parametric coefficient) would be found between scales with a similar content on the PCOSQ and SF-36 (the 'emotions' scale of the PCOSQ with the domains 'mental health' and 'role-emotional' of the SF-36). We also hypothesized that these two domains of the SF-36 would correlate more strongly with the 'emotions' domain of the PCOSQ than any of its other four scales. All statistical analyses were performed using SPSS v 11.5.

Table I. Clinical features of the patient sample

Clinical features	No. of total data set affected (%) (n = 186)	No. of sample set affected (%) (n = 92)
Symptoms		
Excessive body hair	94 (50.6)	46 (50.0)
BMI >28 kg/m ²	100 (53.8)	48 (52.2)
Acne	54 (29.0)	31 (33.7)
Infertility	120 (64.5)	59 (64.1)
Oligo/amenorrhoea	160 (86.0)	80 (87.0)
Biochemical abnormalities		
LH/FSH ratio > 1.5	89 (47.8)	50 (54.3)
Testosterone > 2.0	43 (23.1)	40 (43.5)
SHBG < 30	19 (10.2)	28 (30.4)
PCO diagnosed on ultrasound	133 (71.5)	75 (81.5)

BMI = body mass index; SHBG = sex hormone-binding globulin; PCO = polycystic ovaries.

Results

Of the 92 women who agreed to take part in the study, 82 returned questionnaires at time 1 (89.1%) and 69 at time 2 (75.0%). The mean age of the sample was 29.4 ± 5.7 (range 20–41). Ethnicity was also recorded; 78 (84.9 %) of the respondents were white, five (5.4%) were Pakistani, 1 (1.1%) was Chinese, and no ethnicity data were provided for seven (7.6%) respondents. The clinical features of the sample are reported in Table I.

Secondary factor analysis was carried out on the 82 questionnaires returned at time 1, producing a ratio of 3:1 items to subjects. The results from the secondary factor analysis (principal component analysis, varimax rotation) are shown in Table II. Initially, only factors which gained an eigenvalue (raw sum of the squares) of ≥ 1 were retained. This procedure identified six factors which accounted for 78.8% of

Table II. Secondary factor analysis on the Polycystic Ovary Syndrome Health-Related Quality of Life Questionnaire (PCOSQ)

Items	Rotated component matrix mactors					
	1	2	3	4	5	6
W3. Concerned about being overweight	0.841					
W10. Had trouble dealing with weight	0.851

MEN8. Irregular menstrual periods						0.789

Extraction method: principal component analysis; rotation method: varimax with Kaiser normalization.

A factor indicates the relationships between a set of items. A factor is therefore defined by the items which load on it or the factor loadings. Loadings > 0.5 are considered satisfactory.

Bold type indicates the items which loaded on original factors as determined by Cronin *et al.* (1998).

W = items from weight domain; BH = body hair; EM = emotions; INF = infertility; MEN = menstrual; PCOS = polycystic ovary syndrome.

Table III. Distribution of the scale scores for the Polycystic Ovary Syndrome Health-Related Quality of Life Questionnaire (PCOSQ) and Short Form-36 (SF-36) from the questionnaires returned at time 1

Scale	<i>n</i>	Mean	SD	Range of scores	% scoring minimum (floor)	% scoring maximum (ceiling)
PCOSQ						
Body hair	81	55.6	34.1	0–100	3.7	18.5
Emotions	78	49.8	30.0	8–100	2.6	2.6
Infertility	81	39.3	31.4	0–100	13.6	4.9

Change in health	82	60.0	17.3	20–100	3.7	6.1

The scales run from 0 (poor health) through to 100 (good health).

Table IV. Internal reliability and test-retest reliability correlation of scales generated from time 1 and time 2 on the Polycystic Ovary Syndrome Health-Related Quality of Life Questionnaire (PCOSQ) and the Short Form-36 (SF-36)

Scale	Internal reliability, time 1 ^a α (<i>n</i>)	Internal reliability, time 2 ^b α (<i>n</i>)	Differences between time 1 and time 2 ^c Wilcoxon signed rank test (Z)*	Test-retest reliability ^c Intra-class correlation**
PCOSQ				
Body hair	0.95 (81)	0.97 (69)	-1.44	0.95 (60)
Emotions	0.88 (78)	0.91 (67)	-0.86	0.93 (56)
Infertility	0.87 (81)	0.91 (68)	-1.82	0.92 (59)
Menstrual problems	0.70 (81)	0.73 (67)	-1.35	0.89 (56)
Weight	0.96 (82)	0.95 (68)	-1.48	0.95 (54)
SF-36				
Bodily pain	0.91 (82)	0.90 (68)	-0.29	0.67 (61)
Energy and vitality	0.79 (82)	0.83 (68)	-0.97	0.79 (61)
General health	0.81 (80)	0.83 (68)	-0.20	0.88 (59)
Mental health	0.77 (82)	0.79 (66)	-1.46	0.80 (59)
Physical functioning	0.85 (80)	0.83 (67)	-1.63	0.84 (59)
Role limit/emotion	0.74 (82)	0.88 (68)	-0.19	0.89 (61)
Role limit/physical	0.82 (82)	0.85 (68)	-1.42	0.75 (61)
Social functioning	0.83 (82)	0.85 (68)	-1.27	0.81 (60)

Values in parentheses are numbers (*n*).

Cronbach's α -values indicate how well the items within a scale are associated with each other and are used to establish internal reliability; α -values >0.7 are usually considered satisfactory.

^aEveryone who completed questionnaires from the survey at time 1.

^bEveryone who completed questionnaires from the survey at time 2.

^cEveryone who completed questionnaires at time 1 and time 2 and reported no significant change in their health/life during that period.

* $P > 0.05$ for all values.

** $P < 0.001$ for all values.

the variance. Only those questions which obtained a value of ≥ 0.50 on any of the factors were initially retained and any factors which scored less than this were omitted.

From this analysis, two dimensions (weight and body hair) were identical to the initial composition of the scales on the PCOSQ, with the same items loading on each factor.

The infertility scale was identical except that item 23, 'feel a lack of control over the situation with PCOS', loaded on the emotions scale instead. The remaining two scales were the same except that two original items (frightened of getting cancer, and late menstrual period) did not load on the emotions

scale and one item (irregular menstrual periods) did not load on the menstrual problems domain. Only one item failed to obtain a value of 0.50 which was originally in the emotions scale (easily tired) but this was close at 0.40.

The distribution of the scale scores for the five domains on the PCOSQ and SF-36 are shown in Table III. The mean scale scores for the PCOSQ showed that 'weight' (32.4) and 'infertility' (39.3) scored the lowest, indicating worst health in these dimensions. This was in comparison to the body hair domain which had the highest mean score (55.6) suggesting that this symptom was causing the least negative impact upon

quality of life. The SF-36 questionnaire results indicated that the 'role limitation-emotional' and 'energy and vitality' domains were the areas of poorest health with mean scores of 50.4 and 51.5 respectively. The highest mean score was evident for physical functioning (89.8), indicating the best area of health as measured on the SF-36.

The internal reliability consistency of the scales was assessed using Cronbach's α . As shown in Table IV, all the scales on the PCOSQ reached the required 0.7 at both time 1 (range 0.70–0.96) and time 2 (range 0.73–0.97). All the item-total correlations of the individual items exceeded the minimum value of 0.40 except for item 14 at time 1 on the emotions scale (felt frightened of getting cancer). However, this was close at 0.39. At time 2, both item 17 (worried about having PCOS) and item 8 (irregular menstrual periods) achieved an item correlation <0.40 with the scores reaching 0.13 and 0.37 respectively.

The SF-36 was tested in the same way. The Cronbach's α value results are shown in Table IV. At both times 1 and 2, all of the domains showed internal reliability with Cronbach's α scores >0.7 (range 0.74–0.91). The item-total correlation scores were >0.40 for all individual questions, except for three items in the physical functioning domain which achieved item-total correlations of 0.39 ('vigorous activities', time 1), 0.31 ('lifting or carrying groceries', time 2) and 0.12 ('bathing or dressing', time 2).

Sixty-nine women (75.0%) returned the questionnaires at time 1 and 2. Of these, 57 (82.61%) women reported no change in their health status during this time. No significant differences (Wilcoxon signed rank test) between the scores at times 1 and 2 were found on the five scales of the PCOSQ or SF-36 (Table IV).

The intra-class correlation coefficients to evaluate the test-retest reliability of the PCOSQ were high for all domains. As shown in Table IV, they ranged from 0.89 to 0.95 ($P < 0.001$). The SF-36 was less well correlated (0.67–0.89) with a greater P -value for some domains, showing less significance (Table IV).

Construct validity was assessed by correlating the 'emotions' scale of the PCOSQ with the 'mental health' and 'role-emotional' scales of the SF-36. As hypothesized, a good positive correlation was found for both analyses. Emotions (PCOSQ) correlated with role-emotional (SF-36) ($r = 0.49$, $P < 0.01$, $n = 55$). This correlation was greater than with the weight domain ($r = 0.37$, $P < 0.05$, $n = 47$), the infertility domain ($r = 0.37$, $P > 0.05$, $n = 58$) and the body hair domain ($r = 0.41$, $P > 0.05$, $n = 60$), but not for the menstrual domain ($r = 0.50$, $P < 0.01$, $n = 56$). Emotions (PCOSQ) correlated with mental health (SF-36) ($r = 0.62$, $P < 0.01$, $n = 54$) and this was more strongly correlated than with the other four scales of the PCOSQ, including infertility ($r = 0.43$, $P < 0.01$, $n = 53$), body hair ($r = 0.22$, $P > 0.05$, $n = 50$), weight ($r = 0.34$, $P < 0.05$, $n = 47$) and menstrual problems ($r = 0.59$, $P < 0.01$, $n = 50$).

Face validity

Of the 12 women interviewed to assess face validity, 11 felt that overall the questionnaire did address the areas of HRQoL

negatively affected as a result of PCOS. However, some limitations with the instrument were reported.

Three women (25%) mentioned that questions relating to their symptom of acne were missing from the questionnaire. Three women (25%) were worried by the question that asked 'during the past two weeks, have you felt frightened of getting cancer?' (no. 16). One woman (8%) expressed concern that the wording of the questionnaire implied that PCOS was a short-term condition. Two women (17%) felt the questionnaire did not address their feelings of frustration about the lack of available information on PCOS. One woman (8%) mentioned the omission of a question about weight-related prejudice from infertility services.

Discussion

At present, no validated health outcome measure exists to measure the quality of life of women with PCOS. Although a disease-specific questionnaire has been developed, only the content validity of the instrument has been established, therefore preventing its use in clinical and research settings. While generic questionnaires exist to measure HRQoL, such as the SF-36, they do not collect information on all the areas of well-being and functioning that may be important to women with PCOS. For example, infertility and hirsutism can place a considerable strain on the emotional well-being and personal relationships of women with this disease. However, this information is not collected on the SF-36 generic health measure.

The mean scale scores on the PCOSQ reflect the negative impact PCOS can have upon the quality of life of women with the condition. Perhaps not surprisingly, weight and infertility appeared to be the most significant aspects of the illness. Other studies have reported the negative impact infertility can have upon women and their personal relationships (Epstein and Rosenberg, 1997; Leiblum and Greenfeld, 1997). The finding that weight caused the most negative impact on quality of life has implications for the management of the condition, especially as it has been estimated that ~50% of women with PCOS suffer from obesity or are overweight (Gambineri *et al.*, 2002), yet the best way to manage and aid weight loss in this group of women is unclear (Moran and Norman, 2002).

The secondary factor analysis carried out in this new data set would suggest that overall the structure of the PCOSQ domains are verified, especially for weight, body hair, menstrual problems and infertility. The composition of the emotions scale was less supported. Two original items failed to load on this scale, and an item originally from the infertility scale (lack of control over PCOS) did, suggesting that there may be limitations with this scale. In addition, the item 'felt frightened of getting cancer' loaded on the infertility domain. This was consistent with the original factor analysis carried out by Cronin *et al.* (1998), although the authors subsequently moved this item to the emotions scale as they felt it to be more appropriate to that domain.

One limitation with the results produced from our factor analysis may be that the ratio of respondents to items was not large enough. Although it has been shown that a ratio of 2:1 of

respondents to variables is satisfactory and can produce similar results to a larger ratio (Kline, 2000), it has been argued that the ratio of the number of subjects to the number of items on the instrument should be $\geq 5:1$ (McDowell and Newell, 1996). A study containing such a ratio of respondents to items would be recommended for the future before amending the composition of the emotions scales on the PCOSQ.

The internal reliability of the PCOSQ was found to be high, with all the scales exceeding the accepted α value of 0.70, although the menstrual problems scale was weaker than the other domains with an α of just 0.7. This indicates that this scale may benefit from further analysis. This is further supported as item 20 (late menstrual period) and item 8 (irregular menstrual period) loaded on a new factor, suggesting that a new scale referring to menstrual periods specifically may be required.

The test-retest reliability of the PCOSQ was found to be high. All scales achieved high intra-class correlations >0.8 and were overall higher than for the SF-36. This indicates that the questionnaire produces consistent results from subjects at different times, when no evidence of change in health status exists.

The small sample size, and the absence of another questionnaire which contained similar domains to the PCOSQ, limited the testing of construct validity in this study. However, because scales on the PCOSQ correlated significantly with similar scales on the SF-36 as hypothesized and overall less with the other scales on the questionnaire, it suggests that the construct validity of the instrument is supported. Further analysis on the construct validity of the questionnaire needs to be carried out to verify this further.

In terms of face validity, the women interviewed felt that, on the whole, the questionnaire was addressing the relevant issues to women with PCOS. However, the lack of questions about acne was raised as a serious omission. Acne is recognized as a common symptom of the condition. The finding that 34% of respondents in the study suffered from acne would support this and suggest that the addition of a new acne domain to the PCOSQ would be important if the instrument is to be used in a clinical setting.

One explanation for the omission of an acne domain may be due to the item selection phase of the PCOSQ. During this phase, only 10 PCOS patients were interviewed. Although it was reported that these women had the full range of complaints, it is not known exactly what the symptom profile or presenting symptoms of these patients were. This small number was justified by the fact that no further items were generated after the first five interviews (Cronin *et al.*, 1998). Although this may have been an acceptable number, other studies have interviewed more subjects to generate items for disease-specific questionnaires (Jenkinson *et al.*, 1998; Jones *et al.*, 2001).

There are two methodological issues which are important to discuss. First, the definition of PCOS used in our study differed from that in the original paper by Cronin *et al.* (1998). For this validation study, a definition of the syndrome commonly used in Europe and the UK was used (Balen *et al.*, 1999; Lewis *et al.*, 2001) instead of the National Institutes of Health (NIH)

definition as used in the development of the PCOSQ. The aim of our study was to validate the use of the questionnaire in UK practice and we therefore have applied it to a group of women who have PCOS using the definition currently accepted in this country. For this reason, it was felt that using the NIH definition to recruit patients would not help ascertain the validity of the PCOSQ for measuring the HRQoL of PCOS patients within Europe and the UK.

Another potential limitation to the study is that patients were recruited from a gynaecology clinic. Consequently, it could be argued that there was a bias towards PCOS patients with menstrual disturbance and infertility and not those presenting with other PCOS-related conditions (i.e. weight increase and acne) that are often referred to endocrinology and dermatology clinics. However, it was felt that sufficient patients with complaints of a dermatological or endocrinological nature to allow us to validate the PCOSQ were seen in the gynaecology clinics. For example, in our group of patients 50.6% of the population had hirsutism and 29% of the population had acne. The findings are therefore of interest to dermatologists and endocrinologists and the validation of the questionnaire seems relevant to women with PCOS, notwithstanding which subspecialist sees them. Furthermore, our finding that a domain on acne needs to be included was generated by the composition of our group of patients, which, in distinction from the patients selected to develop the instrument, did include a large number of women with acne and is therefore more representative of the PCOS population than used to develop the initial questionnaire.

In conclusion, the PCOSQ is a promising tool for measuring the HRQoL of women with PCOS. The next phase of our research is to develop and incorporate an acne domain into the PCOSQ. The amended PCOSQ will be tested by the same criteria on a new sample of PCOS patients, along with the 'sensitivity to change' of the new instrument. This is the ability of a questionnaire to detect and describe changes in patients' health status over time and whether these changes are clinically relevant (Kazis *et al.*, 1989). An improved questionnaire could potentially be used to assess the full impact of treatment regimes, for example, in randomized controlled trials for patients with PCOS and be used to generate more understanding into the impact that symptoms and treatments for this condition have upon HRQoL.

Abstract

Polycystic ovary syndrome (PCOS) is one of the most common reproductive endocrine disorders in women and despite this, diagnostic challenges, delayed diagnosis, and less-than-optimal treatment regimens plague the condition. The International PCOS network, consisting of geographically diverse international experts in PCOS as well as consumers, engaged in a multi-year international evidence-based guideline development process that was jointly sponsored by the European Society for Human Reproduction and Embryology (ESHRE) and the American Society of Reproductive Medicine (ASRM). The guideline was published in 2018 and endorsed by more than 40 international societies involved in PCOS. Translation of this evidence-based guideline to medical practice and consumer groups remains a priority. However, there remain many challenges to both understanding the diagnosis and treatment of PCOS. Evidence suggests that both clinicians and consumers are not satisfied with the timeliness of diagnosis and treatment options. This review summarizes the important findings for diagnosis and treatment from the guidelines and expands on recent developments in the literature since its publication. Special attention to diagnosis at the ends of the reproductive spectrum are discussed and remaining areas of controversy are noted. Additionally, the review highlights some of the remaining challenges in the understanding and management of PCOS to help guide clinicians and investigators in this perplexing condition.

Key Words: PCOS, pathophysiology, diagnostic criteria, metabolic disease, lifestyle intervention

Polycystic ovary syndrome (PCOS) is the most common endocrinologic condition in women, affecting from 8% to 13% of reproductive-aged women ([1](#), [2](#)). It is an enigmatic

condition that, while extremely common, creates challenges in its diagnosis and management, as leading symptoms may vary with age, and treatment may be tailored

to specific requirements of individual need. The vast array of possible diagnostic schemes, treatment offerings, and often conflicting recommendations, led to the formation of a large international consortium to examine the evidence in a rigorous way and produce evidence-based guidelines on diagnosis and management published in 2018 (3, 4). What was clear, however, in this published guideline is that there remain many challenges in the diagnosis and treatment of PCOS. Additionally, research has exposed the still-large gap between the available evidence and its translation to improved diagnostic timing and evidence-based treatments (5, 6). There are still knowledge gaps in different disciplines of medicine (e.g., Obstetrics and Gynecology (OBGYN), Medicine, Pediatrics, Dermatology) regarding the diagnosis and treatment of PCOS, and women with PCOS report significant delays in the diagnosis (7), dissatisfaction with the treatment and recommendations they receive (8), and a lack of satisfactory treatment options. This gap is not limited to practicing physicians who completed training before the international guidelines were published, but recent assessment of OBGYN residents in training identified significant deficiencies in the knowledge of the diagnostic criteria for PCOS. In one recent survey of US-based OBGYN residents, 85.4% of 347 trainees completing the survey reported using Rotterdam criteria to diagnose PCOS. However, only 55% correctly identified the 3 main criteria used in the diagnosis (9).

This paper will review the diagnostic criteria and the challenges that continue to present for clear diagnosis. PCOS impacts all aspects of the reproductive hormone physiology; however, the precise pathophysiology remains incompletely elucidated. The current evidence for leading pathophysiologic disturbance in PCOS will be reviewed, as well as the best evidence of reproductive, psychological, and metabolic consequences. Finally, an update on the best evidence-based treatments for PCOS will be reviewed. This review will highlight the challenges that remain in the diagnosis and treatment of PCOS and bring forth the most recent evidence to support the recommendations.

Search Strategies

This mini-review is a limited qualitative narrative review of the literature in PCOS, intended to inform clinical guidance in PCOS and summarizing and building on the International Evidence-Based Guidelines published in 2018 (3). In addition to the literature reviewed by the international guidelines (3), PubMed was searched with the MeSH term of *Polycystic Ovary Syndrome*, combined with the subcategories of *clinical trials, meta-analysis, systematic reviews* for the period from June 2017 to June

2020. Articles were excluded from the review if they were pilot trials, only included animal data, limited in population scope, or the focus was not on PCOS. Articles from the international guidelines were referenced (15 references from this guideline cited here) if there was specific quality without substantive change or additional guidance in more recent literature.

Pathophysiology

The pathogenesis of PCOS is complex and multifactorial, including genetic, environmental, and transgenerational components. These sources drive the underpinnings of unbalanced hypothalamus-pituitary-ovarian axis signaling, promoting ovarian and adrenal hyperandrogenism. The syndrome is also burdened with insulin resistance that is worsened by hyperandrogenism-related adipose tissue accumulation and dysfunction with lipotoxicity and oxidative stress (10). Thus, the full clinical spectrum of the syndrome involves metabolic, reproductive, and psychological impairments. In addition to genetic factors, environmental factors likely also play a role. The link between obesity and the prevalence of PCOS is highly correlated; among women with body mass index (BMI) $<25 \text{ kg/m}^2$, the prevalence is 4.3%, and in women with BMI $>30\text{kg/m}^2$ it is 14%, although selection bias may play a role in assessment (11).

Neuroendocrine link to PCOS

Women with PCOS present with gonadotropin-releasing hormone (GnRH) neuronal network dysfunction and increased pulse amplitude for pituitary activity, shown as high serum luteinizing hormone levels and high ovarian androgen response, most likely relating to decreased responsiveness to steroid hormone negative feedback (12). Different animal models have successfully been able to recapitulate the hyperandrogenism driven neuroendocrine pathology of PCOS and other central mechanisms involved (13). Recently, aberrant neuroendocrine signaling was linked with adipose tissue dysfunction in a murine model (14), whereas other studies have proposed high anti-Müllerian hormone (AMH) promoting GnRH neuron activation and PCOS onset (15). Given the central role of hyperandrogenism and obesity in the impairments in neuronal circuitry and the high prevalence of psychological distress among women with PCOS, the central dysfunction most likely involves larger and more complex neuronal networks than previously recognized (16, 17).

Genetic factors

The genetic factors and familial clustering are described in the early PCOS literature (18); however, as more genetic data has started to accumulate, it has become obvious that the syndrome harbors multigenetic background. Indeed, the genome-wide association studies have identified a total of 19 risk gene loci for PCOS located in the neuroendocrine, metabolic, and reproductive pathways (19), with the reproductive and metabolic populations segregating in a recent unsupervised clustering analysis (20). In line with this, Mendelian randomization analyses suggest a causal link between PCOS and variants associated with BMI, fasting insulin, menopause timing, depression, and male-pattern balding (21). From all genes of interest, the gene loci with the most potential, namely *THADA*, *FSHR*, *INS-VNTR*, and *DENND1A*, would require validation in the future. Interestingly, the clinically validated PCOS cases have similar genetic profile to the self-reported ones, allowing data generation in the future also through less burdensome and more inexpensive means (21). Known genetic risk alleles account for less than 10% of PCOS heritability; therefore, other etiological factors also have to be considered.

Transgenerational transmission of PCOS

Animal studies and human data show the syndrome having transgenerational origins, with a 5-fold higher risk for daughters born to mothers with PCOS for inheriting the syndrome (13, 22). In a murine model, prenatal androgen excess alone can predispose to transgenerational transmission of PCOS. Early androgen exposure may increase susceptibility to the syndrome. Longer anogenital distance (AGD) has been shown in infant girls born to PCOS mothers, and daughters of PCOS mothers have higher metabolic and androgenic risk (22, 23). Maternal testosterone in women with PCOS was found to be a predictor of infant AGD (24). The mechanism through which the daughters are exposed to hyperandrogenism remains elusive, although AMH could be one of the players. Interestingly, a recent study showed that mice subjected to high levels of AMH at late pregnancy produced PCOS offspring with high luteinizing hormone pulsatility and increased androgen levels (25). The mechanism was thought to transit via AMH effect on aromatase activity in the placenta, promoting hyperandrogenism. Even though AMH levels have been reported to be high in the second and third trimesters in women with PCOS (25, 26), the role of AMH on transgenerational transmission in humans warrants further studies.

Diagnosis

Criteria for diagnosis

There is no specific diagnostic test that unequivocally identifies PCOS, but rather the diagnosis is based on the varying presence of 3 specific elements, namely oligo-anovulation, androgen excess, either clinical or biochemical, and the ultrasound assessment of ovarian morphology. The International Evidence-Based Guideline (3) endorsed the use of the Rotterdam criteria (27) that requires 2 of the 3 diagnostic criteria be present for the diagnosis in adult women. Exclusion of thyroid disease (thyroid stimulating hormone, TSH), hyperprolactinemia (prolactin), and nonclassic congenital adrenal hyperplasia (screening with 17-hydroxy progesterone) is recommended. Further evaluation is recommended in those with amenorrhea and more atypical features, with consideration to assess for hypogonadotropic hypogonadism or Cushing disease, and where there is a more severe androgenic picture, consideration for evaluation for androgen-producing tumors. Severe androgenic profiles are present if serum androgen measures are elevated more than 2-fold the upper limits of normal for the local clinical assay standard. The guidelines also endorse the use of phenotype descriptions when diagnosing PCOS and present 4 phenotypes (A-D) based on the presence or absence of the 3 diagnostic criteria (see Table 1). The specific clinical implications or natural history of each of the phenotypes remains unclear at this time, although recent study has found, using unsupervised phenotypic clustering analysis, reproductive and metabolic phenotypes segregating by novel genetic findings (20). Moreover, a review of metabolic features and phenotypes noted that while androgenic phenotypes were more often associated with more severe metabolic dysfunction, this was confounded in most studies by the presence of adiposity, with increased adiposity leading to more severe complications and not all studies controlled for BMI (28, 29). Diagnostic features of the condition also vary across the lifespan and by ethnicity, which complicates the categorization and natural history.

Table 1. Phenotypes of PCOS Based on Rotterdam Criteria

Phenotype	Androgen excess	Ovulatory dysfunction	PCOM on ultrasound
A	✓	✓	✓
B	✓	✓	
C	✓		✓
D		✓	✓

Abbreviations: PCOM, polycystic ovary morphology; PCOS, polycystic ovary syndrome.

The recommendations for the diagnostic criteria from the international guidelines are noted in Table 2. Androgenic status can be assessed by either biochemical measures or clinical measures. The presence of androgenic excess is clinically indicated by cutaneous manifestations such as the presence of hirsutism (indicated by modified Ferriman-Gallwey (mFG) score) (30), acne, or alopecia. There is significant ethnic variation in clinical androgenic expression and examination is often limited by self-treatment of hirsutism. There are limited data from diverse populations, making the interpretation of the mFG score challenging. Current recommendations in the guidelines are based on limited controlled data, with an overall reduction in mFG score threshold required to be consistent with hyperandrogenism. Ovulatory dysfunction is signaled by oligo-anovulation, with irregular menses as the marker based on published data as noted in Table 2. If irregular menses is present along with hyperandrogenism, biochemical or clinical, then the use of pelvic ultrasound is not required for diagnosis. Although assignment of the full phenotype is limited without this measure, clinical diagnosis is possible without ultrasound.

Challenges for the ultrasound diagnostic criteria and role of AMH

Ultrasound morphology is the most challenging of the criteria, as there has been variation in the standards in the reporting of the follicle count cutoffs. As technology has improved, the ability to see more follicles increases, so the cutoffs previously published were not based on current technology (31) and are no longer valid to distinguish populations. The Androgen Excess and Polycystic Ovary Syndrome Society published guidelines in 2014 (32). Reviewing the available literature, the guideline recommended using follicle number per ovary (FNPO) for the definition of polycystic ovary morphology (PCOM) and recommended the threshold be set at ≥ 25 , but only when using newer technology that affords maximal resolution of ovarian follicles (ie, transducer frequency ≥ 8 MHz). The guidelines recommend the use of ovarian volume for diagnosis of PCOM if such technology was not available for routine daily practice. When using ultrasound in PCOS research, use of newer technology to adequately characterize follicle count is suggested. The International Evidence-Based Guideline (3) included a systematic review (11 studies with 2961 adult participants) of ultrasound for FNPO criteria in the diagnosis of PCOM and concluded that the optimal sensitivity and specificity for FNPO was ≥ 20 follicles per ovary in at least one ovary. The available ovarian volume data did not indicate a recommended change in the ovarian volume criteria for PCOM at ≥ 10 mL.

Table 2. Definitions of Features of PCOS for Diagnosis

Feature	Definition
Irregular menses	<ul style="list-style-type: none"> • > 1 year and < 3 years post menarche: < 21 or > 45 days • > 3 years post menarche: < 21 or > 35 days • > 1 year post menarche: any cycle > 90 days • Primary amenorrhea at age 15 or > 3 years post thelarche
Biochemical hyperandrogenism	<ul style="list-style-type: none"> • Calculated free testosterone or free androgen index • Calculated bioavailable testosterone • Liquid chromatography/mass spectrometer with extraction is the preferred method of assay measure; reference range upper limits of normal free testosterone 1.06 ng/dL, total testosterone 60 ng/dL • Can consider androstenedione or DHEAS if testosterone is normal and high index of suspicion for hyperandrogenism
Clinical hyperandrogenism	<ul style="list-style-type: none"> • Examination specifically for acne, alopecia, and hirsutism • For adolescents use severe acne and hirsutism • Use standardized visual scale of mFG $\geq 4-6$ recognizing there are ethnic variations that are not well defined
Ultrasound criteria	<ul style="list-style-type: none"> • Ultrasound should be transvaginal and using high resolution • In this setting follicle count per ovary should be ≥ 20 or ovarian volume ≥ 10 mL • Ultrasound should not be used in those < 8 years post menarche

Abbreviations: DHEAS, dehydroepiandrosterone sulfate; mFG, modified Ferriman-Gallwey.

AMH levels have been considered as a surrogate marker or as an alternative to ultrasound FNPO count for the diagnosis of PCOM or as an independent marker of PCOS. Overall serum AMH levels are 2- to 3-fold higher in women with a diagnosis of PCOS than in women with normal reproductive function and the levels correlate with FNPO ultrasound measures. The assays utilized vary significantly between reports, with PCOS median AMH levels ranging from 20 to 81.6 pmol/L and normal control medians from 16.7 to 33.5 pmol/L (33-36). There are recognized challenges in the AMH measurement (37), such as proteolysis,

changes in the AMH dimer, or interfering substances that lead to poor performance of the assay in predictive models. Additionally, there are variations across the reproductive lifespan in AMH ranges, making it difficult to distinguish cases from controls on this criterion (38). Recent study also showed overlap between PCOS and hypogonadotropic hypogonadism as for AMH measure, warranting awareness and in some cases also further serum assessments to discriminate between these 2 phenotypes (39). Given all this and the limitations of AMH measurement, AMH alone is not sufficient to establish the diagnosis. A recent systematic review of the use of AMH in replacing ultrasound in PCOS diagnosis identified the research gaps that remain before AMH can be considered in the diagnostic algorithm (40).

Special age-group considerations

Adolescence, the period of time between 10 and 19 years of age and the time of pubertal maturation, represents a distinct dilemma in the diagnosis of PCOS. The diagnosis in adolescence is challenged by the overlap of normal pubertal physiology changes and those that mimic adult diagnostic criteria for PCOS, namely irregular menstrual cycles and multifollicular ovaries. Additionally, the time from menarche to full maturation of the reproductive axis (41-43) can be variable post menarche, which may bridge young adulthood (44). Since there is evidence for the underpinnings of PCOS presenting in adolescence and the normal pubertal overlap, there is the risk of both underdiagnosis (7) and that of overdiagnosis, without adequate support for disease. As such, it is recommended that the diagnosis of PCOS not be made early in the post menarchal timeframe. The recommendation for diagnosis in adolescence cannot depend on pelvic ultrasound findings given the increased overlap with normal ovarian findings in this age group and instead is based on irregular menses and hyperandrogenism. Care should be taken when using biochemical evidence of hyperandrogenism to establish a normative range for the assay used in this population. AMH is also unhelpful in distinguishing PCOS in this age group. In adolescents, levels are high and overlap considerably between adolescents with and without diagnostic features of PCOS (38). Menstrual cycles may not establish a regular pattern until >2 years post menarche (45). In a recent study of 317 Danish 16-year old adolescents, the majority had regular cycles within 3 years post menarche (46). Therefore, the diagnosis should not be made within 2 years of menarche to allow for this maturation. There is a recommendation regarding adolescents who are not yet at the developmental stage for full endorsement of a PCOS diagnosis, but who demonstrate concerning features like persistent irregular menses or clinical androgen

concerns requiring clinical intervention, that they be considered “at risk for PCOS.” There may therefore be utility in reinvestigating the possibility of PCOS in the future. It is then recommended that further evaluation of androgens and consideration for ultrasound at the appropriate gynecologic age be completed to fully assess the diagnosis (47). On the other end of the reproductive spectrum, there are challenges to diagnosis in women in the peri- and postmenopausal reproductive spectrum. The average age of menopause is 51 years, but menstrual changes occur much earlier than this in normal aging (48), so ovulatory dysfunction is unreliable as a diagnostic criterion. In fact, there is evidence of increase in regular menstruation in women diagnosed with PCOS as they approach perimenopause (49-51). Also, ovarian volumes and follicle counts decline with age. Ovarian androgen production may decline in both groups, but clinical hyperandrogenism may be more prevalent due to decline in estrogen levels in menopause (52). At this point, there is insufficient evidence about natural history to specifically distinguish the phenotype in menopausal women. The Guidelines suggest that a diagnosis of PCOS could be considered if there is a past diagnosis of PCOS, a long-term history of irregular menstrual cycles, and hyperandrogenism, and/or PCOM, during the reproductive years, but they do not endorse specific diagnostic criteria separately (53).

Consequences

What is known

Metabolic/obesity

PCOS is associated with an increased risk of metabolic complications starting from a young age. These comorbidities include traditional cardiovascular disease (CVD) risk factors such as obesity, impaired glucose tolerance, type 2 diabetes (DM), dyslipidemia, and hypertension. Obesity is one of the most common concerns expressed in surveys of patients with PCOS (7). Depending on the ethnicity and study population assessed, the obesity rate varies from 50% to 80%. According to an examination of high-quality studies in a large meta-analysis, the risk of obesity in women with PCOS was reported to be 4-fold higher compared with controls and also higher in white women compared with Asian women (54). Importantly, women with PCOS have been shown to present with long-term overweight or obesity, with the onset of BMI trajectory deviation occurring as early as age 5 (55). Evidence from cross-sectional studies suggests that the risk of overweight/obesity persists beyond the fourth decade of life (56) and a few longitudinal studies also suggest an increase in weight with age (57). The increased preference for abdominal fat deposition, seen primarily in

the hyperandrogenic phenotype, further predisposes this population to other cardiometabolic complications (58). The risk of impaired glucose tolerance is 3-fold higher with PCOS, independent of BMI, and highest in women living in Asia and in North and South America (59). Although the risk of DM is also increased in this reproductive-age population, there are mixed data regarding these findings independent of weight. In women over age 40, a few longitudinal studies and other cross-sectional studies indicate an increased risk of type 2 DM independent of BMI (56). In adolescents with PCOS, there are only a few small studies examining the risk of DM, and these show an overall low prevalence. When examining the differences based on PCOS phenotype, a large cross-sectional study showed a similar risk of DM in all 4 phenotypes (60). Dyslipidemia, reflected by high triglycerides and low high-density lipoprotein cholesterol, is the commonest metabolic abnormality detected in PCOS (61). Some studies have performed deep lipid phenotyping and demonstrate high low-density lipoprotein cholesterol levels, an increase in atherogenic lipoproteins and a decrease in high-density lipoprotein cholesterol efflux capacity, indicating increased CVD risk (62). When examining the risk in different age groups, there are few studies in adolescents and those in older women show a higher prevalence of dyslipidemia in the hyperandrogenic phenotype (63). The association between hypertension and PCOS is mixed. Most studies do not demonstrate a higher risk of hypertension independent of BMI, although longitudinal data demonstrate elevated blood pressure even in lean women with PCOS (64). The few studies in adolescents and older women do not show significant differences compared with control groups (65). Given that most of the data on metabolic risk is derived from cross-sectional studies, the long-term significance of mild to moderately abnormal values for blood pressure measurements and serum lipids is not clear. Another approach is to evaluate the prevalence of metabolic syndrome as it assesses early evidence of dyslipidemia, hypertension, glucose intolerance, and obesity as a composite score and may predict long-term risk of DM and CVD. Reproductive-age women with PCOS have a 2-fold increased risk of metabolic syndrome (66), with a higher risk in the hyperandrogenic phenotype (29). More importantly, in adolescents with PCOS, the risk of metabolic syndrome is at least 2-fold higher than in girls without PCOS (67).

Reproductive/obstetric

Women with PCOS are at an increased risk of endometrial hyperplasia and infertility related to anovulation. Premenopausal women with PCOS may have a 4-fold increased risk of endometrial cancer (68). For women with PCOS who are seeking pregnancy, the ovulation induction

agent letrozole is associated with higher live birth rates compared with clomiphene citrate (69). Use of metformin in conjunction with these medications may improve the ovulation rate in a subpopulation of obese women. Depending on the ethnicity and study population assessed (eg, clinical cohorts vs population-based studies) the obesity rate varies from 50% to 80% (70). Metformin, on the other hand, has not been shown to reduce the risk of gestational diabetes (GDM); thus, its use should be limited to prior to pregnancy for metabolic management and to facilitate weight loss. Once pregnant, women with PCOS are at an increased risk of miscarriage, GDM, pregnancy-induced hypertension, and preeclampsia (71). These complications are increased in the hyperandrogenic phenotypes.

Behavioral/emotional

PCOS is associated with a higher prevalence of psychiatric disorders. Both moderate-to-severe depressive and anxiety symptoms are increased in cross-sectional studies (72), while a few longitudinal studies support an increased risk of incident depression and anxiety (73). However, there is limited data on the persistence of depressive and anxiety symptoms in adolescents and beyond the fourth decade, although recent data implies psychological distress prevailing long-term (74, 75). In addition, women with PCOS have a higher prevalence of disordered eating (76) and body image distress (77). Interestingly, in the latter study various aspects of body image distress predicted anxiety and depressive scores, indicating that improvement in body image could potentially decrease anxiety and depressive symptoms. Both eating disorders and body image distress add to difficulty in losing weight, highlighting the importance of routine screening for these disorders and use of interventions such as cognitive behavioral therapy (72, 78).

Quality of life

PCOS symptoms and comorbidities burden women with PCOS. Women with PCOS report poorer health status than non-PCOS counterparts (79) and indeed, health professionals and women should be aware of the adverse impact of PCOS on health-related quality of life (80, 81), which seems to prevail at least until the late reproductive years (79).

What remains to be clarified

Cardiovascular disease

The risk of dyslipidemia, DM, and metabolic syndrome in older women with PCOS have been compared in fewer studies relative to the outcomes of obesity and impaired glucose tolerance. Most of the available data in perimenopause and beyond is obtained from small cross-sectional

studies that included women with a presumed diagnosis of PCOS, limiting the validity of the findings. In order to adequately counsel patients, the prevalence of traditional CVD biomarkers needs to be assessed in different phenotypes of PCOS. There is some evidence for increased subclinical atherosclerosis in young women with PCOS. Increase in carotid intima media thickness measurements have been described (82), with data suggesting an increased risk for stroke and myocardial infarction (64). Ultimately, we need more longitudinal studies examining the incidence of cardiovascular events in this populations. Although there is some evidence from population-based studies for increased cardiovascular events in late reproductive-age women with PCOS, most studies lack adequate power to evaluate these outcomes and do not include menopausal women with well-defined PCOS. (83)

Perimenopausal disease course

In a large proportion of women, the clinical features of PCOS improve with age, such that by the fourth decade the menstrual cycles become more regular and serum androgen levels normalize (51). High serum levels of AMH and high antral follicle counts suggest increased ovarian reserve in early reproductive years. These biomarkers also decrease with age, and their trajectory suggests that women with PCOS may go through menopause later than controls (84).

Management

The management of comorbidities related to PCOS such as obesity, type 2 DM, and all health impairments related to metabolic syndrome and psychological distress should be treated following the current common guidelines regardless of PCOS diagnosis. What should be noted is that PCOS increases the risk for all these comorbidities at least 2- to 3-fold (mental distress even up to 5-fold), with the onset occurring several years earlier than in other women. This should be considered when screening and testing for these comorbidities.

The new international PCOS guideline recommends assessing weight and measuring waist circumference during every visit and otherwise every 6 to 12 months also giving high importance for weight gain prevention and pre-pregnancy weight management (3). Given that even lean women with PCOS are insulin resistant, all women should be tested for glycated hemoglobin A1c (HbA1c) levels every 3 years and administered an oral glucose tolerance test every 1 to 3 years if any known risk factors for type 2 DM. During pregnancy, an oral glucose tolerance test should initially be performed in the first trimester and repeated in the second, in gestational weeks 24 to 28, if normal in the first

trimester. Obesity has been shown to be a high-risk factor for GDM also in PCOS, although PCOS also presents as an independent risk factor (85).

Hypertension should be screened annually, whereas dyslipidemia should be considered and tested for in overweight and obese women at diagnosis, although according to a recent Nordic study among women <35 years, only a minority have values warranting statin medication (86). Considering the different PCOS phenotypes and risk profiles for different comorbidities, future studies should target building algorithms or tools facilitating targeted screening for women with PCOS with high metabolic risk.

Mental disorders should be tested and treated similarly to common guidelines for the general population. However, psychological distress should be systematically screened in all women with PCOS by using the common tools and short questionnaires and further assessed and/or referred for assessment if needed. Regarding adolescents, similar increases in emotional disturbance are noted; thus, there is a need to address the management of mental distress in this population, as well.

Lifestyle interventions

Obesity worsens the presentation of the symptoms of PCOS and weight management has been proposed as an initial treatment strategy (3). Lifestyle intervention consists of changes in diet, exercise, and behavioral interventions designed to improve weight. Women with and without PCOS have similar diet and physical activity levels (87), suggesting that interventions can focus on general healthy principles. However, interventions have been studied in only small populations in PCOS and the evidence is of low quality. Meta-analysis of lifestyle interventions (88) demonstrated improvement in weight, free androgen index, and BMI with weight reduction from lifestyle interventions (low-quality evidence). However, there was no specific impact on livebirth or menstrual regularity. An additional randomized trial of behavioral modification in PCOS with a primary outcome of menstrual regularity was reported in 2019 (89). A 4-month intervention resulted in significant weight reduction (-2.1%) and improved menstrual irregularity but did not show improvements in ovulation (89). The majority of women in the trial had moderate-to-severe distress in a global index of psychological wellbeing. There was evidence of improved anxiety, reduced depressed mood, and overall higher general health in the intervention group with no change in the minimal intervention group (90). Exercise alone as intervention in PCOS has been studied (91). Most studies of exercise intervention are small and involved varying exercise interventions— aerobic, resistance,

and combined exercise. There was little evidence of impact on exercise alone on reproductive or hormonal outcomes but evidence for reduction in BMI was moderate.

Adherence to diet and physical activity recommendations for lifestyle intervention is challenging. Critically, such adherence is important to achieve goals, and therefore real-world outcomes of lifestyle interventions may be significantly less over time (92). A review of studies in PCOS involving lifestyle intervention did not provide significant data on adherence to the programs in the majority of trials (93). A detailed look at 4 randomized trials of lifestyle intervention in PCOS involving a total of 221 women showed that attrition from the programs was 47.1%. However, weight loss of $\geq 5\%$ occurred in 63% of the women. Women who were more likely to experience attrition had higher depressive indices at baseline and those who had better appointment attendance had lower attrition and greater weight reduction (94). It is likely that many genetic, psychosocial, sociodemographic, and physiological factors impact the success of a lifestyle/weight loss intervention. The inclusion of behavioral support in these interventions is suggested based on psychological factors that are present with higher attrition from these programs. Overall available evidence suggests that lifestyle intervention involving weight reduction has a positive effect on hyperandrogenism and metabolic features of PCOS as well as on quality of life, however there is less support for improvements in reproductive and fertility outcomes.

Medical interventions

PCOS symptoms

The International PCOS guideline set recommendations for treating PCOS-related symptoms that are core to diagnosis, namely, irregular cycles, hirsutism, and anovulation. As hyperinsulinemia promotes hyperandrogenism, medical treatment is recommended only as second-line therapy after lifestyle modification. For medical interventions, combined contraceptives (COCs) are effective in treating irregular cycles and they are also superior for the treatment of hirsutism and acne compared with progestin-only preparations. Given that there are no data showing superiority for any particular estrogen-progestin combination, the choice for COC can be done according to administration preference and minimizing the side effect profile to ensure compliance (3). Of note, as recommended by the World Health Organization, 35 µg estrogen in combination with cyproterone acetate should only be used as a second-line choice for persistent acne or hirsutism, given the increased risk for vascular thromboembolism related to these preparations.

Metformin-only therapy exerts only mild-to-moderate changes on cycle regularity and hyperandrogenism and has

been reported to be inferior to COC treatment. However, as a novel approach, the new guideline encourages combining metformin with COCs, especially in overweight or obese women with PCOS. This recommendation also applies to adolescents. The data regarding antiandrogen medication were limited due to a lack of high-quality studies, and the already existing data did not show antiandrogens having major advantages when combined with COCs. A recent placebo-controlled randomized controlled trial also confirmed this, as only minimal additional benefit was shown when combining bicalutamide, an androgen receptor antagonist, with COC treatment for 12 months (95). In clinical practice, when treating reproductive-aged women, the risk of virilization of the male offspring in case of pregnancy should be noted, warranting effective contraception when prescribing antiandrogens.

Metabolic outcomes

Metformin, especially in combination with lifestyle modifications, has the most data on improving menstrual cycles, glucose levels, and adiposity in PCOS; mild-to-moderate alleviation of insulin resistance and minimal-to-moderate effect on improving lipid profile (96). Low cost, availability, and the low adverse event profile of metformin supports its use. The most common side effects related to metformin are gastrointestinal symptoms, which are important to emphasize in patient consultation to ensure adherence to the treatment. The use of obesity drugs is limited by their high price and availability, but emerging evidence suggests their efficacy, especially glucagon-like peptide-1 (GLP-1) receptor agonists, in treating obesity in women with PCOS, compared with metformin (97). Future efforts should aim to assess the efficacy of combination therapies, for example metformin and GLP-1 receptor agonist agents, and to anticipate when these obesity drugs will become available in low-income countries and communities.

Reproductive outcomes

A recent meta-analysis concluded that letrozole improves live birth and clinical pregnancy rates and reduces time-to-pregnancy compared to clomiphene citrate and was it recommended as the first-line treatment for women with PCOS and infertility (70). As for metformin, a recent review suggests very modest improvement of ovulation and live birth with metformin over placebo. However, the benefit of combining metformin with clomiphene citrate was inconclusive (98). The data on the benefit of myoinositol for improving live birth rate or clinical pregnancy rate in subfertile women with PCOS undergoing in vitro fertilization are poor and therefore inadequate to form a recommendation. A recent Cochrane analysis was not able to draw a conclusion on inositol benefit due to insufficient data

(99). Future studies should focus on assessment of whether priming with metformin before ovulation induction with letrozole would have beneficial effects on live birth rates in PCOS. In cases where in vitro fertilization is needed, an antagonist protocol with GnRH trigger is preferred to reduce the risk for ovarian hyperstimulation syndrome.

Surgical interventions

Surgical interventions can sometimes relieve PCOS-related symptoms. Bariatric surgery is an effective treatment for obesity and PCOS symptoms after all other treatment options have failed and it should be offered to severely obese patients (100). The risks, however, include surgical and dietary complications and pregnancy should not be pursued during the 12 months following the surgery.

Laparoscopic ovarian drilling is a procedure in which ovarian tissue is destroyed with a laser beam or with a surgical needle using minimally invasive laparoscopic techniques, aiming to rebalance and improve ovarian function in PCOS. The procedure is not commonly used, but it has remained as an option in cases of clomiphene citrate-resistant ovaries and when letrozole is not an option due to off-label use. However, the recent Cochrane Review summarized that although reducing the number of multiple pregnancies and the risk for ovarian hyperstimulation syndrome, laparoscopic ovarian drilling may actually decrease the live birth rate in women with anovulatory PCOS and clomiphene citrate resistance compared with medical ovulation induction alone (101). One should also bear in mind that laparoscopic ovarian drilling also subjects women to the risks associated with surgery, such as complications from anesthesia, infection, and adhesions.

Cognitive behavioral therapy

Recent studies have also suggested that cognitive behavioral therapy (CBT) may be effective in treating women with PCOS (78). A recent randomized controlled trial reported 3-component treatment, including diet, exercise, and CBT, improved depression and self-esteem in obese women with PCOS (102).

Conclusions

Despite its prevalence in reproductive-aged women, the diagnosis and management of PCOS remains challenging. Some of these challenges are highlighted in Table 3. Clear diagnostic protocols should allow for more timely and accurate diagnosis, which will address the concerns of both clinicians and consumers resulting from diagnostic delay. The pathogenesis of PCOS is complex and multifactorial.

New insights into the pathophysiology of PCOS suggest that there may be antenatal drivers for development of PCOS, specifically, evidence of hyperandrogenism in mothers appears to influence development of PCOS features in offspring. Insulin resistance is a near-uniform finding in PCOS and is worsened by hyperandrogenism-related adiposity. The role for abnormal AMH in the pathophysiology is also emerging, but AMH is not yet a diagnostic tool for PCOS. Comorbidities in PCOS are well-described and it is important to evaluate and address these comorbidities early in the treatment course, including attention to mental health and quality-of-life measures. While metabolic abnormalities are well described, the role of PCOS in cardiovascular disease remains uncertain. Evidence-based treatment guidelines include recommendations for lifestyle intervention as primary management for metabolic disease, although

Table 3. Highlights of Controversial Areas in the Diagnosis and Treatment of PCOS

Controversy	Current recommendation
Use of AMH in diagnosis	While AMH is typically elevated in women with PCOS and reflects the increase in follicle pool, AMH is not currently recommended as a diagnostic criteria as there is overlap with normal reproductive measures and it does not sufficiently distinguish PCOS.
Diagnosis in adolescence	Adolescents must be at least 2 years post menarche to consider the diagnosis. Ultrasound is not recommended in this age group before 8 years post menarche due to overlap with normal physiologic findings. Consideration may be given to the label "at risk for PCOS" for those in transition where the diagnostic criteria are uncertain.
Diagnosis in perimenopause	Menstrual regularity improves with aging in PCOS; therefore, a retrospective diagnosis is necessary in this age group.
Use of metformin without evidence of diabetes	While there is little support as a single agent for use in ovulation induction, there is evidence of improved metabolic parameters with the use of metformin. There is modest impact to reduce weight and prevention of diabetes development noted in other populations and can be considered for these indications in PCOS.
Type of oral contraceptive	There is no evidence that one type of combined oral contraceptive is better than another for either improvement in menstrual cycles or for suppression of hyperandrogenism.
Use of combination therapy with metformin	There is evidence that adding metformin to combination oral contraceptives may improve response particularly in obese women with PCOS.

Abbreviations: AMH, anti-Müllerian hormone; PCOS, polycystic ovary syndrome.

specific benefit in reproduction is not yet defined in weight loss trials. Oral contraceptives remain a first-line therapy for management of hyperandrogenism and irregular cycles and the role for metformin, while limited, may still add benefit for metabolic dysfunction and weight management, including in adolescents. There remain a number of challenges in the management of PCOS. A high prevalence of obesity is a significant contributor to morbidity. Early attention to weight gain in childhood and adolescence in those at risk for PCOS may be an important measure of prevention, since early markers of PCOS are better defined.

³University of Roehampton

Objectives: Polycystic ovary syndrome (PCOS) is a complex endocrine disorder affecting 13% of reproductive-aged women. Lifestyle management is the first-line treatment for improving reproductive, metabolic and psychological complications in PCOS, however women experience challenges with implementing behavioral change. This indicates a clear need to better understand how women with PCOS engage with evidence-based dietary and physical activity (PA) interventions. The primary aim of this study was to identify the types and sources of dietary and PA interventions implemented by women with PCOS. A secondary aim was to understand how they use behavioral and cognitive self-management strategies to support behavioral change.

Methods: In this cross-sectional study an online questionnaire was disseminated via the PCOS Nutrition Centre (a consumer-based website) between May 2015-May 2016. Women ($n = 1167$) were aged

18–45 years, primarily born within the United States (70%) and self-reported a PCOS diagnosis.

Results: While only 33% and 16% of women reported following formal nutrition or PA guidelines (respectively), 57% had implemented a ‘special diet’ to help manage their PCOS. Many of these diets were not supported by evidence-based PCOS practice. Participants also displayed a low level of engagement with important self-management behaviors, including goal setting and positive self-talk. The internet was the primary source of nutrition (36%) and PA (32%) information, with few turning to health professionals including doctors (nutrition 16%; PA 13%) and dietitians (nutrition 4.8%; PA 2.4%).

Conclusions: These findings suggest that online information may promote inaccurate non-evidence-based lifestyle advice, and indicates a need to increase engagement with qualified health professionals. As current lifestyle advice for PCOS management utilized by health professionals are based on generic national guidelines, it is possible that this one-size-fits-all approach does not satisfy their desire for more personalized recommendations. It is also likely that health professionals will need to diversify their mode of communication through the delivery of online lifestyle education.

Funding Sources: This research received funding from the National Heart Foundation of Australia and the National Health and Medical Research Council.

concerned a squamous stratified epithelioma extending from a metaplastic fundal mucosa. It was combined with a large submucous myoma.
(c) The third was an adenocarcinoma combined with a submucous myoma which had undergone changes into a polymorphous spindle-cell sarcoma.

AMENORRHEA ASSOCIATED WITH BILATERAL POLYCYSTIC OVARIES*

IRVING F. STEIN, M.D., AND MICHAEL L. LEVENTHAL, M.D.,
CHICAGO, ILL.

(From Michael Reese Hospital and Northwestern University Medical School)

ACCORDING to leading authoritative works on gynecology, the bilateral polycystic ovary is most commonly found in association with *uterine bleeding* (Fig. 1). This association has been recognized by the medical profession and is not infrequent in occurrence. Endometrial hyperplasia, multiple follicle cysts with granulosa cell lining, and a notable absence of corpora lutea in the ovary are the significant pathologic findings in such cases. The bleeding in these patients is readily explained by the fact that the increase in number of follicles lined by granulosa cells produces an excess of secretion of estrogenic hormone.

According to the same authoritative works, little or no mention is made of bilateral polycystic ovaries accompanied by *amenorrhea*, and inasmuch as we have encountered a series of cases exemplifying the latter conditions, we desire to present the results of our study of them.

Cyst formation in the follicular apparatus of the ovary is very common and is regarded to some extent as a physiologic process. When these structures are visible to the naked eye, they are regarded as cysts; when not, they are called follicles. When this process becomes excessive, persistent or progressive, the ovary becomes enlarged, tense, tender and painful, and produces what has been termed "cystic degen-

Abstract

Background: Polycystic ovary syndrome is a common endocrinopathy affecting women of reproductive age. Commonly manifested by polycystic ovary, menstrual irregularities and hyperandrogenism even though the presentation could be heterogeneous. Insulin resistance (IR) is considered to be accountable for the associated hormonal and metabolic derangements. Polycystic ovary syndrome has two phenotypes, overweight/obese and lean.

Objectives & Methodology: Quasi experimental one group pre and posttest timeseries research design was adopted to assess the effect of Life Style Modification Regimen on Polycystic Ovary Syndrome among 16 Adolescent Girls in selected Arts and Science Colleges, Puducherry. Baseline screening was done for 112 adolescent girls by census method using modified PCOS risk assessment questionnaire and identified adolescent girls with PCOS. Adolescent girls at moderate risk of PCOS with BMI 23 and above were included in the study. PCOS risk and Lifestyle habits were assessed before and after implementation of Lifestyle Modification Regimen, whereas clinical features of PCOS were assessed at baseline, at 2months (Posttest-1), 4 months (Posttest-2) and at 5 months (Posttest-3).

Results: Study results shows that significant difference between Pre and posttest PCOS risk (17.507) and lifestyle habits (Dietary habits: -3.873 and Physical activity: -2.236) at $p < 0.05$ level. Improvement found in the clinical features of PCOS including weight, BMI, menstrual cycle, Hirsutism and Acne at $p < 0.05$ level. Similar percentage (50%) of them had unfavorable and moderately favorable dietary habits during pretest, whereas in posttest 81.3% and 18.7% had moderately favorable and fa-

vorble dietary habits and highest percentage (62.5%) of them had Moderately favorable physical activity in pretest, whereas 75.8 and 24.2% had Moderately favorable and favorable physical activity respectively in posttest. Significant association found between the pretest level of PCOS risk and lifestyle habits of adolescent girls (dietary habits: 12.444 & Physical activity: 6.661) at $p < 0.05$ level and also observed association between the pretest level of PCOS risk and selected demographic variables such as age in years and monthly family income in Rs at $p < 0.05$ level.

Conclusion: Lifestyle Modification brings positive change in lifestyle habits, risk of PCOS and clinical features of PCOS among adolescent girls at risk of PCOS. Study concludes that Healthy lifestyle practices prevents the development of PCOS by risk reduction. Primordial prevention involving early identification of Risk of PCOS promotes reproductive health of the adolescent girls.

Key words

Adolescent Girls and Risk of PCOS, lifestyle habits, lifestyle modification regimen.

Cardiometry; Issue 24; November 2022; p. 1073-1078; DOI: 10.18137/cardiology.2022.24.10731078; Available from: <http://www.cardiometry.net/issues/no24-november-2022/assess-effectiveness-life-style>

BACKGROUND

Health is a fuel that runs a human body with the regular activities and functions. In women's, reproductive health plays an important role of general health which needs universal concern. It is very important to care themselves during their reproductive age in order to prevent reproductive health related problems. Improper reproductive life pose risk to the life of a woman. Many times, woman has the risk of infertility, contraception, and other reproductive infections caused by sexual practices. Irregular menstrual periods among women cause such ovulatory dysfunctions and polycystic ovarian syndrome. Women with PCOS have no regular periods, and are not able to ovulate and get pregnant.⁽¹⁾

Polycystic ovary syndrome is a common endocrinopathy affecting women of reproductive age. Com-

monly manifested by polycystic ovary, menstrual irregularities and hyperandrogenism even though the presentation could be heterogeneous. Insulin resistance (IR) is considered to be accountable for the associated hormonal and metabolic derangements. Polycystic ovary syndrome has two phenotypes, overweight/obese and lean. The prevalence of lean PCOS is much less common comparatively overweight/obese PCOS.⁽²⁾

Poly Cystic Ovarian Syndrome (PCOS) is the common endocrine disorder globally increased the prevalence of overweight and obesity among women and young women. It is a heterogeneous disorder involved with multiple etiology that has been made it difficult to define the syndrome by diagnostic test. It is very important for women to take care of their health during their reproductive years because much reproductive health related problems can arise during this period. Any failure in living a healthy reproductive life could cause a risk to the life of women and adds to the maternal mortality rate. Women bear the risk of infertility and many other reproductive infections.⁽³⁾

NEED FOR THE STUDY

Polycystic ovary syndrome (PCOS) is a common endocrine disorder with a global prevalence of 5-10% and is an important cause of chronic anovulation in young women. PCOS is characterized by menstrual irregularity, signs of hyperandrogenism such as acne, excess body hairs, male-pattern baldness and infertility. In addition, PCOS is linked to many long-term health problems such as cardiovascular diseases and diabetes.⁽⁴⁾

Polycystic ovarian disease in teenager is characterized irregular or completely absent periods, heavier than normal menstrual bleeding, ovarian cysts, hirsutism and alopecia. Other symptoms range from acne, skin tags and brown skin patches to reduced sex drive, exhaustion or lack of mental alertness, depression anxiety, sleep apnea and thyroid problems. Teens with overweight are increasingly being linked with Polycystic Ovarian Disease.⁽⁵⁾ Women diagnosed with Polycystic ovary syndrome (PCOS) experienced poor quality of life, greater anxiety and depression than women without PCOS related to BMI status.⁽⁶⁾

A community based cross sectional study conducted on prevalence of PCOS among 778 young girls and adolescents aged between 15-24 years in Mumbai. Clinical, USG and biochemical investigations were completed by 600 adolescent girls. Results reveals that,

prevalence of PCOS was 22.5% by Rotterdam criteria and 10.7% by Androgen Excess Society criteria. Prevalence of PCOS among nonobese comprised of 71.8% diagnosed by Rotterdam criteria. Mild PCOS comprised of 52.6%.⁽⁷⁾

A cross sectional study was conducted to assess the dietary habits and life style among 384 pre-university college students, Raichur, India. Results reveals that 45.6 % were male and 54.4% were females. The mean age was 16.75 yrs. 184 (48%) students were predominantly vegetarians. 176 (45.8%) reported consumption of junk food more than once in a week and 338 (88%) reported to use fruits and vegetables occasionally in their diet. Only 147 (38.3%) students walked at least for 30 minutes and did exercise daily. The study concludes that prevalence of unhealthy dietary habits and life style are more also with obesity.⁽⁸⁾

Cross-sectional study was carried out among 420 girls residing in the social welfare hostels in urban area of Vizianagaram District, Andhra Pradesh, India. The result shows that 56.4 % girls were undernourished. 2.9% was found to be overweight and none of the girls was found to be obese. According to the new guidelines by the Government of India 56.4 % was found to be undernourished while 5.8 % was found to be Overweight.⁽⁹⁾

METHODOLOGY

Quasi experimental one group pre and posttest study was conducted to investigate the effect of Lifestyle modification Regimen on the risk of PCOS among Adolescent Girls in selected Arts and Science College, Puducherry.

Tool for data collection

Section -I: Modified PCOS risk assessment questionnaire consist of 09 items

Section -II: Demographic variable consist of 13 items

Section - III: Five-point rating scale on lifestyle habits consist of 30 items in two sections for dietary habits and physical activity

Section -IV: Tool to assess the clinical features of PCOS

Description of Intervention

Duration: Four months

1. Group Counseling Session

2. Aerobic exercise for weekly three days for 30 minutes

3. Structured dietary guidelines for PCOS

Ethical consideration

Formal permission taken from Institutional Review Board, Directorate of Technical & Higher Education and Principal of the College, Puducherry. Informed consent was taken after explaining the study purpose and assent and parent consent taken for the minors.

Data collection procedure

Data collection was carried out from four months in 2021. Baseline screening was done for 112 adolescent girls by census method using modified PCOS risk assessment questionnaire and identified adolescent girls with PCOS. Adolescent girls at moderate risk of PCOS with BMI 23 and above (16) were included in the study. SAQ used to collect data on demographic variable, PCOS risk and Lifestyle habits were assessed before and after implementation of Life Style Modification Regimen, whereas clinical features of PCOS were assessed at baseline, at 2months (Posttest-1), 4 months (Posttest-2) and at 5 months (Posttest-3).

RESULTS

Demographic characteristics shows that 62.5% of them were in 19 years, 62.5% belongs science background, 43.7% of them attained menarche at 14-15 years of age, similar percentage (87.5%) were non-vegetarian and Hindus, 31.3% had monthly family income of Rs.10,110 – 15,159, 81.2% of them were belongs to nuclear family, 56.3% from rural, similar percentage (37.5%) of the mother and father studied Higher secondary education, 31.3% and 6.3% had family history DM and PCOS respectively and 25.0% got previous information about PCOS. (Table no.1)

Pretest PCOS risk and Physical activity	6.661a	.036

p < 0.05 significant.

Table 9

Association between Pretest PCOS risk with selected Demographic variables of the adolescent girls
(N = 16)

S Sl.no	Demographic variable	Pretest PCOS risk	
		χ^2	p-value
1	Age in years	9.813a	.044
4	Diet	1.778a	.411
8	Monthly family income in Rs	18.560a	.017
9	Type of family	4.622a	.099
10	Residence	062a	.969
11	Family history of PCOS	2.216a	.330

p < 0.05 significant.

DISCUSSION

Study results suggests that significant reduction in posttest PCOS risk (17.507) and improvement in lifestyle habits (Dietary habits: -3.873 and Physical activity: -2.236) at p < 0.05 level, and also improvement found in the clinical features of PCOS including weight, BMI, menstrual cycle, Hirsutism and Acne at p < 0.05 level. Anju Krishnan Nair et.al⁽¹⁰⁾ also observed similar findings after implementation of lifestyle modification package among adolescent girls that 66.4% and 15.2% had weight loss and weight stabilization respectively. Lass et.al⁽¹¹⁾ also reported that weight loss after lifestyle intervention was significantly associated with positive change in the menstrual pattern.

Similar percentage (50%) of them had unfavorable and moderately favorable dietary habits during pretest, whereas in posttest 81.3% and 18.7% had moderately favorable and favorable dietary habits and highest percentage (62.5%) of them had Moderately favorable physical activity in pretest, whereas 75.8 and 24.2% had Moderately favorable and favorable physical activity respectively in posttest. Manijeh Alavi et.al⁽¹²⁾ also reported that 54.4% of the adolescent girls had moderate nutrition behavior and Binati Behera et.al⁽¹³⁾ reported that 52.3% and 46.4% of the adolescents and young adult students had slow and moderate physical activity respectively.

Significant association found between the pretest level of PCOS risk and lifestyle habits of adolescent girls (dietary habits: 12.444 & Physical activity: 6.661) at p < 0.05 level and also observed association between the pretest level of PCOS risk and selected demographic variables such as age in years and monthly family income in Rs at p < 0.05 level.

CONCLUSION

Lifestyle Modification brings positive change in lifestyle habits, risk of PCOS and clinical features of PCOS among adolescent girls at risk of PCOS. Study concludes that Healthy lifestyle practices prevents the development of PCOS by risk reduction. Primordial prevention involving early identification of Risk of PCOS promotes reproductive health of the adolescent girls.

Assessment of Risk Factors of Polycystic Ovarian Syndrome Among Women: An Online Based Survey

S. M. G. Ishrar^{1*}, Goruntla Narayana¹, Asma Aneesa.K. S¹, Chennampalli Priya¹ and Roddam Swetha¹

¹Department of Pharmacy Practice, Raghavendra Institute of Pharmaceutical Education and Research (RIPER), KR Palli Cross, Chiyyedu Post, Anantapur – 515721, Andhra Pradesh, India

Abstract: Polycystic ovary disorder is a fluctuated and regularly intricate cluster of metabolic and endocrine anomalies. This study aims to assess the risk of PCOS among women aged 15-45 years. This is an online-based cross-sectional survey conducted among women of childbearing age in South India. The data was collected online by providing google links to fill out questionnaire forms by various social media platforms. The questionnaire consists of demographic details and assessment questions. Microsoft Excel was used to interpret data. Statistical analysis done by using chi-square test. A total of 466 women responded, among which the women of 15-25 years and 25-36 years, 32.46% have hirsutism, 22.7% have infertility and overweight problems, 24.7% have mood swings, 49.2% have sleep disturbances, 55.5% have tiredness, 41.9% people have good awareness regarding exercise and lifestyle modifications. This study reveals that there is no proper knowledge about PCOS in the population, especially among girls and women, therefore there is a need to educate the public regarding PCOS at a younger age for better health outcomes.

I. INTRODUCTION

Polycysticovarydisorderisafluctuatedandregularlyanintricateclusterofmetabolic and endocrine anomalies. The polycystic ovarian condition was first portrayed by Dr Irving Stein and Michael Leventhal in Chicago in 1935 alluding to a condition endured by women with feminine brokenness, weight, hirsutism and two-sided polycystic ovaries. At that point, it was known as a Stein-Leventhal disorder.¹ According to NIH measures and Rotterdam models, PCOS is characterized as a hormonal issue recognized by the presence of, in any event, one polycystic ovary joined by ovulatory brokenness and unnecessary emission of androgens.² It is the most widely recognized complex endocrine issue, which is regularly found in the regenerative time of women. The determinants of the polycystic ovarian disorder are connected to hereditary and natural variables. The early period of menarche Premature foetal advancement Family history of PCOS among first-degree relatives.³ The primary underlying defect in PCOS remains unknown, but critical features include insulin resistance, impaired gonadotropin and androgen excess. Anovulation is defined as menstrual cycles of more than 35 or <21 days while ovarian morphology is considered significant in the presence of follicles greater than equal to 12 with a diameter of 2-9mm or an ovarian volume of 10cm³.⁴ These diagnostic criteria cannot be applied to adolescents because changes that occur physiologically are associated with puberty overlap with pathological changes observed in PCOS.

1.1. Prevalence of PCOS

The polycystic ovarian syndrome is seen among 1 in 10 women of reproductive-aged women. Not only in women but it is also seen in the girls who enter the reproductive age nowadays. The prevalence of PCOS ranges from 2.2% to 26% in India among childbearing-aged women and affects 116 million women worldwide, according to WHO estimation.^{5,6} The yearly mean cost for the initial evaluation of PCOS was 2.1% of total costs, and further treatment was 31%. The factors like complications, expenses and the age in which it occurs make to study more about Polycystic ovarian syndrome. There are four sorts of PCOS: Insulin-safe PCOS, Inflammatory PCOS, Hidden-cause PCOS and Pill-incited PCOS.^{7,8} Infertility was one of the most originally characteristic symptoms of PCOS⁹. The evidence shows that PCOS is the most common cause of the ovulatory disorder and oligo anovulation is related to the increased risk of infertility.¹⁰ Obesity and insulin resistance were autonomously identified with an expanded danger of early termination and diminished pregnancy and live rates of birth.¹¹ Endometrial anomalies are additionally announced in PCOS ladies.¹² Gestational Diabetes Mellitus (GDM) is the most commonly described pregnancy complication in women with PCOS. In addition, women with PCOS have a high prevalence of classic risk factors for cardiovascular disease(CVD).¹⁴ Causes of PCOS include resistance to insulin, hormonal imbalance and genetics. The effects of yoga alone and its accessibility to individuals of all ages and fitness levels provide unique benefits and make it a powerful therapeutic option for women with PCOS. This study aims to assess the risk of PCOS among women aged 15-45 years. Need of the study is to find the risk of developing PCOS among women and associate the disorder's manifestation with lifestyle variations. It also aims to analyze the influence of lifestyle factors like

Diet, Physical Activity, Stress and Family History with PCOS manifestation.

2. MATERIALS AND METHODS

2.1. Study site

In and around South India

2.2. Selection of Study

Cross-sectional Study: As the study has to be conducted in a certain period, the cross-sectional study was used. In cross-sectional studies, data can be collected from as many participants only for a certain period.

2.3. Study criteria

The age group of women ranging from 15-45 years were included.

2.3.1. Inclusion criteria

The age group of women ranging from 15-45 years are included.

2.3.2. Exclusion criteria

Women of menopause were excluded. Other complications that mimic the conditions of PCOS were excluded. Women diagnosed with PCOS were excluded. Responses without appropriate information were excluded.

2.4. Study duration

The study was conducted for six months.

2.5. Ethical considerations

The study was conducted after getting ethical clearance from Institutional Review Board (RIPER/IRB/2021/035). As we conducted this study online, consent forms were obtained among the participants online. The confidentiality of the participants was maintained during and after the trial completion.

2.6. Sampling technique and Sample size

Non Probability sampling technique was used. The sample size was calculated using Epi-info software 7 with a confidence interval of 95%, a margin of error of 5% and design effect 1. The obtained sample size is 356.

2.7. Search strategy

Authors conducted a literature review in databases like Cochrane library, PubMed, and Google Scholar and collected suitable journals for the questionnaire preparation from September to November 2021. The search strategy is as follows, (PCOS OR Risk factors OR Cross-sectional studies OR Women's health OR Online study OR Questionnaire-based study OR polycystic ovarian syndrome). After conducting a literature review, a questionnaire was prepared for conducting the study. The prepared questionnaire was sent for face validation to the experienced professionals related to the healthcare sectors, the suggestions were

considered, and the final questionnaire was submitted to IRB. The IRB panellists approved the questionnaire for the study.

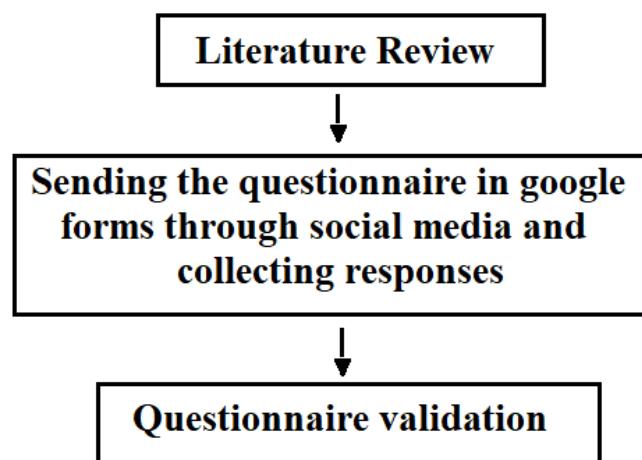

2.8. Study design and procedure

Authors planned to conduct a cross-sectional study in the female population of South India. The entire duration of the study is six months. The prepared questionnaire was presented in Google form and circulated among the female population through WhatsApp, Facebook, Telegram, and Gmail. Electronic consent was taken from participants before filling out the questionnaire, and responses were recorded. A total of 477 responses were collected, of which 466 were selected for final analysis because 11 did not meet the inclusion criteria.

2.9. Risk of bias

Out of 477 responses collected, we removed 11 study

2.11. Flow chart of data extraction

The data extraction process's outcome is 477 responses, of which only 466 were considered, as the remaining needed to meet the criteria.

3. RESULTS

A total of 477 responses were collected using an online questionnaire form. Eleven were excluded as they needed to meet the inclusion criteria. Therefore 466 were the final sample used for the analysis of the data.

Table 1: Weight of the study population (n=466)

Variable	15-25yrs	26-35yrs	36-45yrs	p-value
Weight				
30-50kgs	232(57.5%)	149(36.9%)	22(5.4%)	
51-70kgs	10(40%)	10(40%)	5(20%)	0.000
71-90kgs	7(18.42%)	28(73.68%)	3(7.89%)	

Study participants were categorized according to different age groups (15-25 years, 26-35years and 36- 45 years), and the weight was categorized, which is represented in the above (Table .01) and the obtained p-value was 0.000, which is statistically significant.

Table 2: Menarche started to age (n=466)

Variable	11-15yrs	16-20yrs	p-value
At what age did menarche has been started?			
15-25yrs	380(94.2%)	23(5.8%)	
26-35yrs	25(100%)	0(0)	0.39
36-45yrs	35(92.1%)	3(7.9%)	

Table2 menarche age of women who underwent the study was represented above (Table.02) according to the age groups (15-25 years, 26-35years and 36- 45 years) for the majority of the respondent's menarche started between the age of 11- 15 years

participants, as they did not meet our study criteria, so that we could get accurate results with the available data.

2.10. Statistical Analysis

Descriptive statistics were used for socio-demographic details; data was retrieved from google forms and interpreted in Microsoft excel. The chi-square test was used to determine the association between the categorical variables, i.e., the age of the participants and other variables like weight, age of menarche, and regularity history of PCOS correlated. The Correlation between the clinical features and physiological characteristics was determined by the Pearson correlation test using IBM SPSS statistics 26 version 26.0.0.0. We used the two-tailed Pearson correlation test to determine the Correlation between the clinical features and the psychological symptoms.

(92.2%, n=430) and remaining were in between the age of 16-20years (7.8%, n=26). Therefore, the obtained p-value was 0.39, which is not statistically insignificant.

Table 3: Regularity of menstrual cycle (n=466)

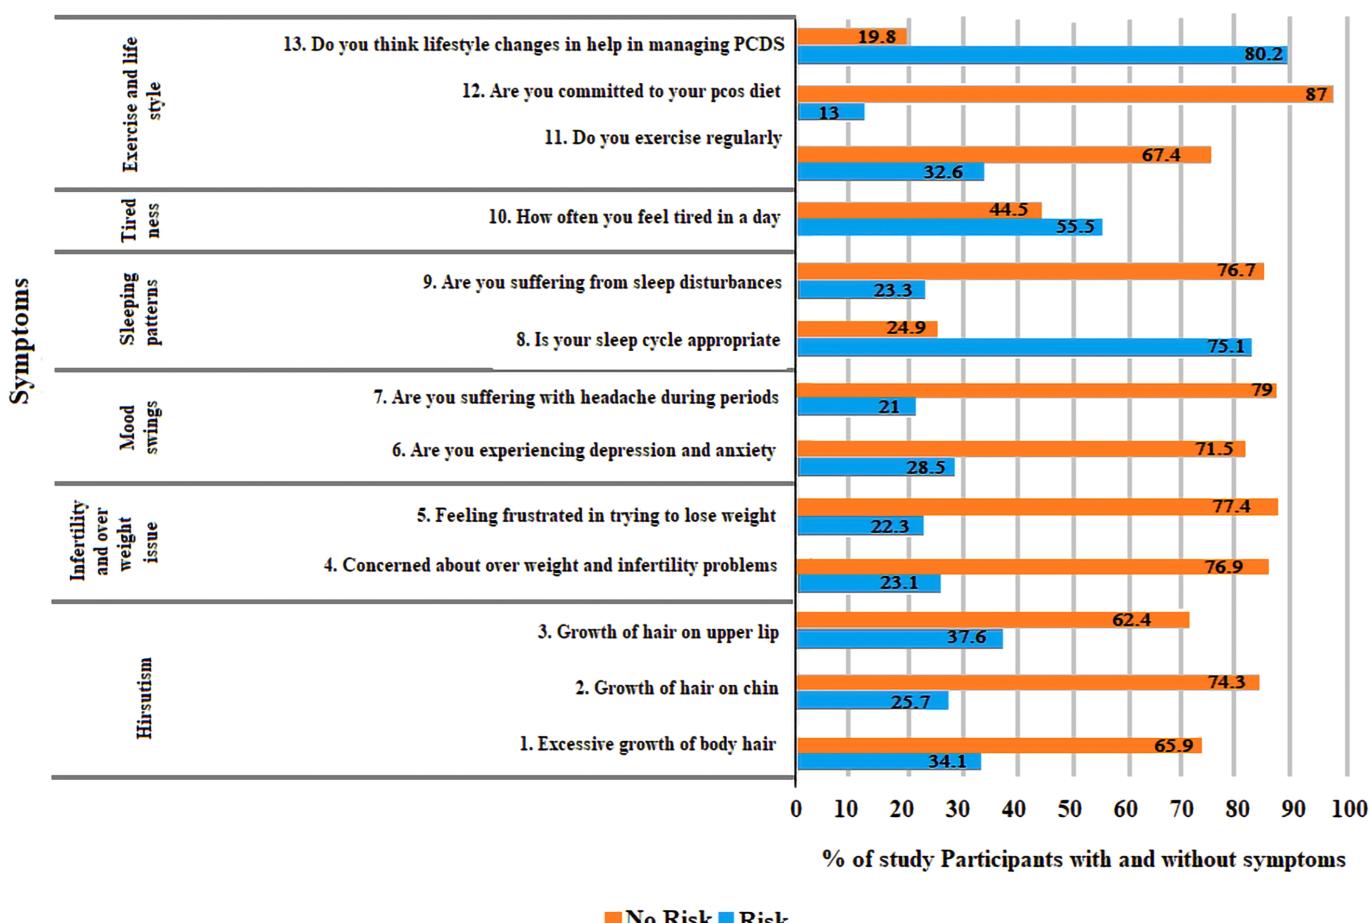

Variable	Yes	No	p-value
Is your menstrual cycle regular?			
15-25yrs	329(81.6%)	74(18.4%)	
26-35yrs	20(80%)	5(20%)	0.71 *
36-45yrs	29(76.3%)	9(2.34%)	

the regularity of the menstrual cycle of study participants. Was represented in the above (Table.03) which Majority of the respondents have a regular menstrual cycle (81.1%, n=378), while the remaining have irregular menstrual cycles (18.9%, n=88), and the obtained p-value was 0.71, which was not statistically significant

Table 4: History of PCOS (n=466)

Variable	Yes	No	Maybe	p-value
Is there a family history of PCOS?				
15-25yrs	21(5.21%)	338(83.8%)	44(10.9%)	
26-35yrs	1(4%)	19(76%)	5(20%)	0.23*
36-45yrs	3(7.89%)	27(71.05%)	8(21.05%)	

history of PCOS of study participants was represented in (Table 4). The majority responded that there is no family history of PCOS (82.4%, n=384). Some responded that there might be a history of PCOS (12.2%, n=57), and the remaining respondents had a history of PCOS (5.36%, n=25), and the obtained p-value was 0.23, which was statistically insignificant.

**Fig 1: Risk Assessment of PCOS based on symptoms**

In the current study, the symptoms related to PCOS are mostly concentrated, which are represented in the above graphical presentation (Figure.01), which include hirsutism: excessive growth of body hair (34.1%), growth of hair on the chin (25.7%), growth of hair on the upper lip (37.6%). Infertility and overweight issues: concerned about being

overweight and infertility (23.1%), feeling frustrated in trying to lose weight (22.3%). Mood swings: Are you experiencing depression and anxiety (28.5%), are you suffering from headaches during periods (21%). Sleeping patterns is your sleep cycle appropriate (75.1%), sleep disturbances (23.3%). Tiredness: How often you feel tired in a day (55.5%).

4. DISCUSSION

The current study on polycystic ovarian syndrome was conducted in and around the Anantapuramu region, Andhra Pradesh, in an online population-based survey. The sample size was 477, out of which 11 were deleted due to inappropriate data. The sample size was calculated using Epiinfo software with a confidence interval of 95%. In the current study, we assessed PCOS risk by using the associated symptoms⁽¹³⁾. Irregularity of the menstrual cycle was observed as a major problem in the age group of 26-35 years (20%) which is majorly associated with the symptoms of PCOS. Among the three age groups, 15-25 years of the respondent population had severe and moderate problems

with the growth of hair on the body (35.66%) and on the upper lip (39.44%), the respondent population of 26-35 years had severe and moderate problems associated with the hair on the chin (32%). Respondents among 26-35 years were majorly concerned with infertility (28%) and being overweight (24%). Depression and anxiety were observed prominently in the 26-35 age group (32%), and headaches during periods were seen mostly in the age group of 15-25 years (21.5%). Sleep cycle was inappropriate in the age group of 26-35 years (28%), and sleep disturbances were seen mostly in the age group of 26-35 years (24%)⁶. Population among 15-25 years exhibited tiredness most of the day (55.6%), and performing exercises were not included in their daily routine (68.4%)^{5, 10}.

Table 5: Pearson Correlation

		Depression and anxiety	Headache during periods	Tiredness	Appropriate sleep cycle	Sleep disturbances
Regularity of menstrual cycle	Pearson correlation	-.193**	.020	-.111*	.229**	-.161**
	Sig. (2-tailed)	.000	.663	.017	.000	.000
Excessive growth of body hair	Pearson correlation	.259**	.041	.140**	-.101*	.145**
	Sig. (2-tailed)	.000	.376	.002	.029	.002
Growth of visible hair on the chin	Pearson correlation	.132**	.081	.161**	-.083	.1428**
	Sig. (2-tailed)	.004	.081	.000	.074	.006
Growth of visible hair on the upper lip	Pearson correlation	.185**	.028	.191**	-.082	.144**
	Sig. (2-tailed)	.000	.547	.000	.076	.002
Infertility concerns	Pearson correlation	.301**	.072	.131**	-.091	.196**
	Sig. (2-tailed)	.000	.120	.005	.050	.000
Overweight	Pearson correlation	.293**	.166**	.054	-.149**	.263**
	Sig. (2-tailed)	.000	.000	.245	.001	.000

** Correlation is significant at the 0.01 level (2-tailed).

*Correlation is significant at the 0.05 level (2-tailed).

Symptoms associated with PCOS and psychological disturbances are correlated as in (Table 05). which is mentioned above.

PCOS is the major cause of psychological morbidity and has a negative impact on women's HRQOL¹⁷. The different aspects of the QOL in PCOSQ were evaluated, including physical, psychological and social. Therefore, the major factors, which cause a reduction in quality of life in PCOS, were found to be different in a variety of respondents. The physical aspect of quality of life predicted by obesity and hirsutism²⁰. In adolescents, excessive body weight is widely reported as an important concern in PCOS women. Obesity is the primary source of poor HRQOL¹⁷ and contributes to negative psychological symptoms in women with PCOS. Changes in body weight and physical beauty, as well as an imbalance of hormones, could reduce QOL.⁹ Anxiety symptoms are very common in the general female and occur at an early age,²⁴, along with other mood disorders such as depression. HRQOL¹⁷ surveys suggest that women with PCOS may be at higher risk of anxiety symptoms related to the clinical signs of hyperandrogenism, weight gain, and health problems, including infertility.^{19,21} Coexisting GAD in depressed patients, may worsen the outcome by increasing the risk of suicide, worsening overall symptoms, increasing the number of unexplained clinical symptoms, and high functional disability.⁵ Untreated GAD is also associated with increased rates of co-

morbidity and high utilization of medical health care²². Studies concerned about the risk of PCOS among women in particular age groups were very less; most of the studies were regarding the co-morbidities associated with the syndrome and the interventions to prevent PCOS.² Hirsutism¹⁵, irregular menstrual cycle and infertility problems¹⁸, and Obesity¹⁹ are different aspects of PCOS which showed a negative impact on HRQOL that would not easily be detected by employing only a self-administered questionnaire by using PCOSQ, and it was demonstrated that clinical symptoms of PCOS especially excess body weight and hirsutism, could compromising the women QOL. Zahra BehboodiMoghadam, BitaFereidooni, and Ali Montazeri performed a study on PCOS titled polycystic ovary syndrome and its impact on Iranian women's quality of life: a population-based survey, the findings of the study indicated that hirsutism followed of infertility and menstrual irregularity had a greater impact on the quality of life of menstruating women. The difference between their study and our current study is that they recruited the sample population with PCOS and focused on the impact of the quality of life of women.¹⁴ Some published articles show that women with PCOS may have a greater prevalence of anxiety

symptoms compared with normal women.²³ It is suggested that childbearing-aged women with PCOS should undergo regular screening tests for anxiety and mood disorders using screening tools and for appropriate diagnostic evaluation and appropriate therapy. Most of the studies were regarding the co-morbidities associated with the syndrome and interventions to prevent PCOS, but our study was concerned about the risk of PCOS among women at particular age¹⁴

5. STRENGTHS AND LIMITATIONS

The online-based survey is more convenient and gets better responses, is significantly less cost and can be accessed from any device like a computer, laptop or mobile. As the study is an online based survey, illiterates were not able to participate in the study. Furthermore, the sampling technique used is a snowball technique; therefore, the sample recruitment may be biased, as there are no Ultra sonographic (USG) and blood tests concerned with PCOS the risk assessment is not profound.

6. CONCLUSION

The study results showed that females between 15-25 years and 26-35 years are at higher risk of developing PCOS. The study revealed that there is no proper knowledge about PCOS in the population, which is the need of the hour;

therefore, there is a need to educate the public regarding PCOS at an age for better health outcomes. Most importantly, adolescent girls and women of childbearing age should be aware of PCOS. How to identify the root cause, how to understand the symptoms, the treatment that should be followed, the lifestyle that should be made, and physical activity should be made aware by conducting campaigns about PCOS in schools, colleges and hospitals. As 1 in 5 women is suffering from PCOS nowadays, the government should actively take the initiative to increase awareness about PCOS.

7. ACKNOWLEDGEMENT

We thank every participant for actively participating in the study.

8. AUTHORS CONTRIBUTION STATEMENT

Dr SMG. Ishrar conceptualized and designed the study. Next, Goruntla Narayana reviewed the data. R.Swetha, C.Priya, AsmaAneesa.K.S discussed the introduction, methodology, and result and prepared the original draft. All the authors reviewed and approved the final version.

Abstract

Objective: Polycystic ovarian syndrome (PCOS) is a prevalent endocrinological disorder in reproductive-age women. Due to varied presentations, it's often difficult to diagnose and manage women with PCOS. Management usually focuses on treating the symptoms and preventing long-term sequelae of the disease. This study was planned to assess the knowledge among reproductive-age women (15-44 years) regarding the risk factors, symptoms, complications, and management of PCOS.

Material and methods: This is a hospital-based descriptive cross-sectional study. A pre-validated well-structured questionnaire which included basic demographic data, menstrual history, knowledge about PCOS symptoms, risk factors, complications, prevention, and treatment, was administered. Completed questionnaires were analyzed to calculate the knowledge score of the participants and its association with their education level and occupation was seen.

Results: A total of 350 women participated but only 334 completed questionnaires were included for final evaluation. The mean age of the study population was 28.70 ± 6.29 years. Around 9.3% of the participants were already diagnosed with PCOS. Most of the women (43.4%) had heard about PCOS. The source of information was doctors (26.6%), the internet (6.28%), teachers (5.6%), and friends (4.7%). Obesity (33.5%), unhealthy dietary habits (35%), and genetic predisposition (40.7%) were thought as risk factors for PCOS. Most of the participants were aware that subfertility (40.1%), abortions (34.4%), diabetes (28.7%), hypertension (31.7%), cardiovascular disease (33.5%), endometrial carcinoma (35.9%), and psychological disturbances (37.1%) are among the known PCOS related complications. Eating a healthy diet (37.1%) and weight reduction (41%) can help in the management of PCOS. Around 60.5% of women showed poor knowledge, 14.7% fair knowledge, and 24.9% good knowledge regarding PCOS. Education level and occupation status were found to be significantly related to the knowledge score ($P < 0.001$).

Conclusion: PCOS is a prevalent condition with varied presentations which significantly affects one's quality of life. Since there is no definitive treatment for PCOS the management generally aims at managing symptoms and reducing the risk of long-term complications. To reduce the burden of PCOS-related long-term complications behavioral changes in terms of regular exercise and healthy dietary habits need to be incorporated from childhood.

Keywords: polycystic ovary syndrome, adolescent pcos, knowledge attitude, lifestyle behaviour, pcos and metabolic syndrome

Introduction

Polycystic ovarian syndrome (PCOS) has emerged as a new epidemic in the last few decades. The prevalence of PCOS varies between 6% and 25% globally [1-6]. Due to the complex presentation of the disease diagnosis is difficult and is often delayed [7-9]. Women with PCOS may present with menstrual irregularities, subfertility, obesity, and dermatological manifestations like hirsutism and acne. The long-term sequelae of the disorder include metabolic disorders, impaired glucose tolerance, diabetes, hypertension, and cardiovascular disorders. Due to chronic anovulation and the unopposed effect of estrogen on the uterus, these women are at higher risk of developing endometrial cancer later in life. Adolescent women with PCOS may suffer from various psychological issues like depression, anxiety, sleep disturbances, and body image disorders which significantly affect their quality of life. The exact etiology of the disorder is not known however oxidative stress, genetic predisposition, and certain gene polymorphisms are thought to be the culprit for PCOS [10-14]. Various environmental factors, sedentary lifestyles, and unhealthy eating habits are also seen to be related. Rotterdam criteria, National Institute of Health (NIH), and androgen excess-PCOS Society criteria are used to diagnose the disorder. The management is usually targeted to treat the symptoms and prevent long-term sequelae. Lifestyle modifications in terms of adopting an active lifestyle, healthy and balanced diet, avoiding junk and unhealthy eating habits, weight reduction in those who are overweight and stress management have been seen to be effective. Even in those who need pharmacotherapy coupling drug

therapy with lifestyle modification has shown better results [15,16].

This study was planned to assess the level of knowledge among the reproductive age woman about PCOS, risk factors and complications, and the source of information about the disease so that strategies can be planned to disseminate awareness regarding PCOS at the community level.

This article was previously posted to the research square preprint server on 25th February 2022.

Materials And Methods

A hospital-based descriptive cross-sectional study was done in reproductive-age women attending the outpatient department of Gynaecology at a tertiary care hospital. After obtaining ethical clearance from the ethical committee of the institute, a pre-validated well-structured questionnaire containing 40 items was administered by the interviewers after explaining the purpose of the study and obtaining informed consent. All the women between the age group of 15-50 years who attended the Gynecology OPD of the hospital and were able to understand either Hindi or English language were invited to fill out the questionnaire. For those who could not read or write but consented to participate in the study, the questionnaire was read out to them by the investigator and answers were marked as per the response by the participants. A total of 350 women participated. Out of all around 16 forms were incomplete so were not included in the final analysis. Demographic data (Item no. 1-7), information related to the menstrual history (Item no. 8-11), presence of any symptom of PCOS (Item no. 9-18), information regarding knowledge about PCOS, source of information, its symptoms and complications related to it (Item no. 19-30), regarding their knowledge about the prevention and treatment of the PCOS related symptoms and complication (Item no. 31-36) were collected. Information was also collected about the healthy lifestyle activities being practiced by the study cohort (Item no. 37-40).

Statistical analysis

In the present study, descriptive and inferential statistical analysis has been carried out. Results on continuous measurements are presented as mean \pm SD (Min-Max). Results on categorical measurements are presented as numbers (%). Significance is assessed at a 5% level of significance. The one-way analysis of variance (ANOVA) is employed to determine whether there are any statistically significant differences between the means of three or more independent (unrelated) groups. The significance of the parameters on the categorical scale between two or more groups has been calculated using Chi-square/Fisher Exact test. The non-parametric setting was used for qualitative data analysis. For very small cell samples Fisher Exact test is used. P-value: $0.05 < P < 0.10$ was taken as suggestive significant, P-value: $0.01 < P < 0.05$ as moderately significant, and P-value: $P < 0.01$ as strongly significant. Statistical software namely Statistical Product and Service Solutions (SPSS) (IBM SPSS Statistics for Windows, Version 22.0, Armonk, NY), and R environment ver. 3.2.2 were used for the analysis of the data, and Microsoft Word and Excel have been used to generate graphs, tables, etc.

Results

The demographic data of the study participants are depicted in Table 1. The mean age of the study population was 28.70 ± 6.29 years. Most of the women in the study group were between 21 and 30 years (61.4%). The majority of the study participants had normal BMI (49.4%). Only 13.5% were underweight (<18.5), and around 28.7% were overweight (25.0-29.9). Around 8.4% of participants were obese (>30). Most of the women in the study group were graduates (42.8%). Most of them were housewives (49.4%) and more than half of the study participants were married (61.7%).

TABLE 1: Demographic Profile of Study Population

The mean age of menarche in the study cohort was found to be 13.48 ± 1 years. The mean cycle length was 21.56 ± 3.28 days with cycle lengths of 21-35 days in 64.37%, <21 days in 8.9%, 35-60 days in 23.35%, and >60

days in 1.49%.

Table 2 shows the distribution of symptoms related to PCOS among the study participants. Among all 35.6% of the participants experienced a change in the cycle length in the past six months. Around 9.0% said they were having frequent cycles (<21 days), 24.8% reported delayed cycles (>35 days), 1.5% reported scanty flow, and 0.3% were having heavy flow during the cycle. Out of all 9.8% of the participants had taken medication for the regularization of their menstrual cycles. Among the study participants, 6.3% experienced weight gain, and 1.2% weight loss in the past six months. However, the majority experienced no change in their weight in the previous six months. Around 2.4% of women experienced excessive hair growth on the body, 9.0% said they were having excessive hair fall, and 8.7% reported acne and needed treatment. Around 8.1% of the women were desirous of pregnancy out of which 6.6% were having some difficulty in spontaneous conception and 4.4% were already on treatment for subfertility. In the present study, 9.3% of the participant were already diagnosed to have PCOS.

S.No.	Symptoms Present	N=334	% age
1.	Change in cycle length in previous 6 months		
	Yes	119	35.6%
	No	215	64.4%
2.	What change		
	Frequent Cycle	30	9.0%
	Delayed Cycles	83	24.8%
	Heavy Cycles	1	0.3%
	Scanty Cycles	5	1.5%
3.	Treatment taken to correct menstrual irregularity in past 6 months		
	Yes	33	9.8%
	No	301	90.1%
4.	Change in weight in previous 6 months

11.	Taking any fertility treatment	15	4.4%

TABLE 2: Presence of Symptoms Related to PCOS

PCOS: polycystic ovarian syndrome

Table 3 depicts the knowledge of study participants regarding PCOS. It was seen that only 43.4% of the women had heard about PCOS and the most common source of their information was doctors (26.6%) followed by the internet (6.28%), teachers (5.6%), and friends (4.7%). Assessment of knowledge for risk factors showed that out of those who had heard of PCOS, a significant proportion of women were aware of the association of obesity (33.5%), unhealthy dietary habits (35%), and genetic predisposition (40.7%) with PCOS. When asked about complications and long-term sequelae of PCOS 40.1% of women said that patients with PCOS can have problems in conception, 34.4% said it PCOS women are at higher risk of pregnancy loss, 28.7% said women with PCOS are prone to develop diabetes, 31.7% said they can have hypertension, 33.5% said it can raise the chances of cardiovascular disease, 35.9% said there could be an association with endometrial carcinoma and 37.1% said it could be related to psychological problems, sleep disturbances, body image disorder, and anxiety in women. Around 37.1% were aware that eating a healthy and balanced diet can be one of the management methods, 41% believed weight reduction could help, and 35.6% said trying ways to reduce stress could be one of the methods to manage the stress and mood-related symptoms in PCOS women. However, 34.1% said only medications can treat the condition and 2.7% believed only surgery can treat PCOS.

TABLE 3: Awareness Regarding Symptoms, Risk Factors, Complications, and Management of PCOS

PCOS: polycystic ovarian syndrome

A total of 14 items were used to assess the knowledge regarding risk factors, symptoms, long-term complications, prevention, and treatment of PCOS. For every correct answer participants were given one mark each. The total score was 14 and those who scored <5 were categorized as having poor knowledge, between 6 and 10 as fair knowledge, and >10 as good knowledge. On analyzing the data, it was seen that out of those who had heard of PCOS around 60.5% showed poor knowledge. However, 14.7% had fair knowledge, and 24.9% had good knowledge regarding PCOS. When we analyzed the score categories with the education level and occupation status of the women it was seen that those who are graduates and postgraduates scored better and the results were statistically significant ($P \leq 0.001$). Those who were working had better knowledge than the rest of the participants ($P \leq 0.001$) (Tables 4-5). Lastly, we inquired about the healthy lifestyle practices followed by the study group in their day-to-day life and it was found that around 23.9% of women were doing some kind of exercise.

Total Score	Education					Total
	ILLITERATE	PRIMARY	HIGH SCHOOL/PUC	GRADUATE	POSTGRADUATE	
0	59 (95.2%)	27 (100%)	52 (70.3%)	44 (30.8%)	8 (28.6%)	190 (56.9%)
1-5	0 (0%)	0 (0%)	4 (5.4%)	8 (5.6%)	0 (0%)	12 (3.6%)
6-10	0 (0%)	0 (0%)	7 (9.5%)	32 (22.4%)	10 (35.7%)	49 (14.7%)
11-15	3 (4.8%)	0 (0%)	11 (14.9%)	59 (41.3%)	10 (35.7%)	83 (24.9%)
Total	62 (100%)	27 (100%)	74 (100%)	143 (100%)	28 (100%)	334 (100%)
Mean ± SD	0.68±3.03	0±0	2.99±4.83	7.41±5.67	7.89±5.71	4.62±5.71

TABLE 4: Correlation between Education Level and Knowledge Score

	HOUSEWIFE	STUDENTS	WORKING WOMEN	
0	151 (91.5%)	16 (20.3%)	23 (25.6%)	190 (56.9%)
1-5	0 (0%)	4 (5.1%)	8 (8.9%)	12 (3.6%)
6-10	1 (0.6%)	26 (32.9%)	22 (24.4%)	49 (14.7%)
11-15	13 (7.9%)	33 (41.8%)	37 (41.1%)	83 (24.9%)
Total	165 (100%)	79 (100%)	90 (100%)	334 (100%)

TABLE 5: Correlation of Knowledge Score and Occupation Status of the Women

Out of all 9.8% go for walk daily, 1.76% were practicing weight training, 2.69% were doing aerobic exercises, 23% were doing yoga, and 2.64% were doing swimming. Around 11.7% of the study population was practicing meditation as stress-relieving management. Around 54.6% of the women were taking healthy food items most of the time in their diet and take junk food only occasionally, however, the rest were taking junk food quite often (45.40%).

Discussion

PCOS is a complex endocrine disorder affecting women across all stages of their life. Adolescent girls often present with menstrual irregularities, acne, hirsutism, and obesity which can further lead to body image disorders, low self-esteem, anxiety, and depression in them. Women with PCOS may have difficulty in spontaneous conception and often need fertility treatment. These women can also experience repeated pregnancy losses. Later in life, they are at increased risk of diabetes, hypertension, and cardiovascular disorders. Due to the unopposed estrogen, they are at risk of developing endometrial hyperplasia and endometrial cancer [17]. Management often includes measures targeted to reduce the symptoms or to prevent the complications associated with the disorder. There is no permanent cure but the lifestyle modifications in PCOS women like weight reduction, exercise, meditation, and a healthy diet is seen to help them to fight their symptoms. Hence it is very important to spread knowledge and awareness in the community regarding the risk factors, symptoms, complications when to seek help, and whom to seek help from. In today's world where a sedentary lifestyle, preserved food, pollution, and stressful day-to-day life have become a new norm, the importance of adopting a healthy lifestyle should be stressed upon. Several studies done previously by researchers have shown a lack of knowledge regarding the signs and symptoms of PCOS among the general population [18,19].

In the present study, researchers found that around 43.4% had heard about the term PCOS. The above findings are similar to the findings published by Alessa et al. in their study where researchers found that 56.7% of the women had heard about PCOS [20]. A significant percentage of women had heard about the disorder but still, awareness is not 100%, and a lot of efforts are required to disseminate this knowledge in the community. The most common source of information in our study was health care provider/doctor (26.6%) followed by the internet (6.28%), teacher (5.6%), and friends (4.7%), and the results are similar to studies were done by Abu-Taha M et al. and Alshdaifat E et al. [21,22]. However, the most common source of information in the study conducted by Alessa et al. was the internet (21.3%) followed by PCOS patients (10.4%), doctors (10.8%), and books (3%). Government websites and PCOS support groups were the other mentioned sources in the study. The difference could be because in our study the study participants were those attending the Gynaecological OPD for various reasons however the study done by Alessa et al. included college students. Around 9.3% of the study population was already diagnosed to have PCOS in contrast to 15.3% of the women in the study by Alessa et al. and 28.5% in a study by Rao et al. [23]. The difference can be explained by the regional variation in the distribution and variation in the sample size of the studies. In the present study, researchers found that the women who were not diagnosed with PCOS also had certain symptoms which need further evaluation. Around 35.6% reported a change in their cycle length, 9.0% had excessive hair fall, 8.7% had acne, 6.6% had a problem with conception, 6.3% reported weight gain, and 2.4% had excessive hair growth. Rao et al. in their study also found that around 40.5% of women not formally diagnosed with PCOS had PCOS-like symptoms. While assessing knowledge regarding risk factors associated with PCOS it was found that around 35% knew unhealthy eating habits can be related to PCOS while 33.3% were aware that excess weight is associated with PCOS. Around 32% said it is familial. When asked about complications related to PCOS it is seen that similar to the study by Alessa et al. in the present study participants are aware of its association with subfertility (40% vs 39%), psychological disturbances (37.1% vs 34.1%), endometrial cancer (35.9% vs 30.2%) and diabetes (28.7% vs 14.5%). Both studies found that the participants were aware that exercise and losing weight can help reduce the symptoms and related complications (37.1% vs 39.9%). Around 41% of the women were aware that eating a healthy and balanced diet is helpful and the findings are similar to the finding in the study by Alessa et al. where 34.2% were aware

of the benefits of eating healthy food. In the present study around 34% of women said that medications and surgery are the other options to manage PCOS while in a study by Alessa et al. around 29.4% of women were aware of the medical management. In the study done by Alessa et al., the author has not mentioned the awareness of surgical procedures for PCOS. The present study shows education level and working status of the women were significantly associated with high knowledge scores among the study participants and the results are similar to the studies done by Alessa et al. and Alshdaifat E at el.

With increasing education levels the percentage of women who know about the risk factors, symptoms, complications, and management is also rising across the globe but is this knowledge getting translated into actual practice? To assess that we asked the study participants what health lifestyle practices they are following. In this study, only 23.95% of the study participants were exercising daily, and only 11.7% were practicing meditation. However, a significant proportion of women were taking a healthy diet and avoiding junk food (54.60%). These findings suggest that only disseminated knowledge and awareness are not enough it requires a tremendous effort to bring about behavioral changes at the community level. To bring about these behavioral changes authors suggest that knowledge and awareness about a healthy lifestyle need to be incorporated right from childhood so that they become an integral part of our lives. Behavioral modification can start from home where the parents need to be educated, schools where teachers need to be educated to disseminate the knowledge, and then social media, the internet, government websites, and television advertisements can play an important role. At community levels, teams of volunteers can arrange nuked Natak and stage shows. Hospitals and support groups should provide educational material and can arrange talks in the outpatient area of the hospital or in the community regarding PCOS awareness and the benefits of lifestyle modifications for PCOS women.

Limitations of the study

This study is done in the hospital setting so the study population is not the true representative of the general population. The knowledge regarding PCOS is assessed only in female participants and male partners are not included. The sample size is also small so the findings cannot be generalized to the whole population.

Conclusions

PCOS is an endocrine disorder affecting women at every stage of their life. The presentation of the disorder is varied and if not diagnosed earlier can lead to dreadful long-term sequelae. No definitive management is available. The management is targeted to treat the immediate symptoms and reduce the risk of long-term sequelae. Lifestyle modifications in terms of an active lifestyle and healthy dietary habits are the first line of management and can significantly reduce the symptoms and morbidity related to the disorder. Since habits are difficult to change, hence incorporating these healthy habits early in life is vital. Despite the increasing prevalence of PCOS globally the knowledge and awareness related to the disease remain poor among the general population and calls for measures to increase community-level educational programs. Spreading awareness regarding PCOS, its risk factors, symptoms, and complications, and adherence to a healthy lifestyle is essential to reduce the burden of disease and related complications. Education level and working status are seen to be directly associated with better knowledge.

Appendices

Annexure I: Questionnaire

Name (Optional):

1. Age:

2. Weight:

3. Height: BMI:

4. Age of menarche:

5. Educational Qualification:

6. Occupation:

7. Marital Status:

Question 8. What is your cycle length:

1. <21 days

2. 21-35 days

3. 35-60 days

4. >60 days

5. Invariable

Question 9. Any change in cycle recently?

1. Yes

2. No

Question 10. If Yes? what changes?

1. Frequent cycles

2. Delayed cycles

3. Scanty periods

4. Heavy flow

5. Others (Specify)

Question 11. Have you taken any treatment for menstrual irregularity in the past 6 months?

1. Yes

2. No

Question 12. Have you experienced any weight changes recently?

1. Yes

2. No

Question 13. If Yes, what changes?

1. Weight gain

2. Weight loss

3. No Change

Question 14. Have you ever taken any treatment for excessive hair growth in the body in the past 5 years?

1. Yes

2. No

Question 15. Did you need to visit a dermatologist for excessive hair loss in the past 6 months?

1. Yes

2. No

Question 16. Did you need to visit a dermatologist for any excessive acne not responding to home remedies?

1. Yes

2. No

Question 17. Are you trying for pregnancy?

1. Yes

2. No

Question 18. If yes is there any problem in conception for which you are seeking or planning to seek treatment?

1. Yes

2. No

Question 19. Have you heard about PCOS?

1. Yes

2. No

Question 20. Have you been diagnosed with PCOS?

1. Yes

2. No

Question 21. From where did you hear about PCOS?

1. Teacher

2. Doctor

3. Friend

4. TV

5. Newspaper

6. Others

Question 22. Who do you think is more prone to PCOS?

1. Overweight

2. Underweight

3. Normal weight

4. Any weight

Question 23. Do you think eating unhealthy and junk food is associated with PCOS?

1. Yes

2. No

Question 24. Do you think PCOS has any problem in future childbearing?

1. Yes

2. No

Question 25. Do you think PCOS can lead to pregnancy loss?

1. Yes

2. No

Question 26. Do you have PCOS and can have any risk of deranged sugars or diabetes in the future?

1. Yes

2. No

Question 27. Do you think PCOS can have the risk of hypertension in the future?

1. Yes

2. No

Question 28. Do you think PCOS can be associated risk Cardiovascular Disorder?

1. Yes

2. No

Question 29. Do you think PCOS can be associated risk of cancer?

1. Yes

2. No

Question 30. Do you think PCOS can lead to psychological problems like depression, anxiety, and sleep disturbances?

1. Yes

2. No

Question 31. Do you think weight-changing management can help women with PCOS?

1. Yes

2. No

Question 32. Do you think exercise can help in PCOS?

1. Yes

2. No

Question 33. Do you think eating healthy and avoiding junk food can help women with PCOS?

1. Yes

2. No

Question 34. Do you think stress-relieving activities can help women with PCOS?

1. Yes

2. No

Question 35. Do you think medication is the only cure for PCOS?

1. Yes

2. No

Question 36. Do you think Surgery is the only cure?

1. Yes

2. No

Question 37. Do you exercise regularly?

1. Yes

2. No

Question 38. What kind of exercise do you do?

1. Regular walk

2. Swimming

3. Aerobic

4. Weight Training

5. Yoga

7. Other

6. None

Question 39. Do you practice any kind of meditation?

1. Yes

2. No

Question 40. How often do you eat junk food?

1. Very Often

2. Sometimes

3. Rarely

Behavioural Hypochondriacs and Life Style Management in PCOS: A Review

Vrunda Vyas

School Of Biosciences and Technology

Vellore Institute of Technology, Vellore Tamil Nadu, India

Abstract:- Polycystic ovary syndrome (PCOS) is habitually linked with psychological and physiological anguish. Etiology of PCOS still remains unclear. It is mainly associated with obesity. Women with PCOS endure from pregnancy complications during their reproductive age. Several reviews and studies suggest that women suffering from PCOS can develop mental distress like depression, anxiety, body dissatisfaction, Food and eating habits and Disaffection about their sexual life. These all factors are key factors for behavioral hypochondriacs as it increases stress, anxiety and depression in women with PCOS. There are several evidences that appropriate weight management strategies and modification in lifestyle is helpful for the women with PCOS for to improve the hormonal imbalance, infertility and obesity. It is also helpful to reduce symptoms for PCOS. This literature review is about effect of PCOS on behavioral hypochondriacs and how a little modification in life style management will positively affect the women with PCOS.

Keywords:- PCOS, Depression, Hirsutism, Life Style Management, Pregnancy, Infertility, Hypochondriacs.

I. INTRODUCTION

Polycystic ovary syndrome is an endocrine disorder which mainly affects the women with reproductive age. First case for PCOS was observed in 1976. PCOS affects the 5-10% of all women. Irregular menstrual cycle, biochemical hyper androgenism and presence of polycystic ovaries on ultrasound are clinical and diagnostic feature of PCOS. This also have reproductive and metabolic (insulin resistance) malfunction. 50% are the women with obesity. As the amount of adipose tissue increases it results in various abnormalities of sex steroid metabolism as increase in amount of androgen and repression of globulin which bind to sex hormones. It can also give rise to severe infertility and an-ovulation. Furthermore it also causes breast cancer, cardiovascular disease, endometrial cancer, type 2 diabetes etc. They are more vulnerable to coronary artery disease and hypertension. So these were the physical consequences which are observed in women with PCOS but in spite of these some behavioral hypochondriacs which includes anxiety, depressed mood, body shaming, sleep disturbance, low appetite, negative thoughts, less self confidence etc. Depression among women with PCOS very high which varies between 28% to 64%. Sometimes it leads to suicide case also. Hirsutism and skin acne problem is also a major

factor for depression in women with PCOS. As above mentioned 50% of girls are obese in PCOS that's why various study has undertaken that how life style management and weight management will help in PCOS. Objective of this literature review is to understand that how PCOS affects behaviour of a patient and how lifestyle management will help to reduce symptoms of PCOS.

II. MATERIALS AND METHOD

Literature review was conducted by reviewing different research articles and review articles. The papers were collected from various online sources like GOOGLE SCHOLAR, SCIENCE DIRECT, PUBMED, WILEY, SPRINGER, ELISVERE. Keywords used to search this research and review article were PCOS, infertility, depression, life style management etc. Papers that show relation of PCOS with behavioral change and life style management were also taken.

III. RESULTS AND DISCUSSION

- **Behavioural Hypochondriacs:-**

Hypochondriac are a condition in which patients lives in a fear of having some serious illness, and is also known as illness anxiety disorder. This kind of condition is often seen in patients with PCOS. It is commonly due to having insecurity of infertility, hirsutism, body dissatisfaction, difficulty in pregnancy, obesity, eating disorder, bipolar disorder etc. Women.

Infertility is common cause in women with PCOS due to anovulation which is a cause of hypochondriacs, but it is curable. Hormonal imbalance and high amount of estrogens leads to poor growth and release of egg from ovules and results in deficient ovulation. When ovulation does not occur, it increase amount of testosterone and as a result it affects the egg quality and lead to insulin resistance. There are some other factors which can also negatively affect the fertility. Despite of this Women with PCOS suffer with body shaming which causes depression, frustration and difficulty in self acceptance. A persuasion of own self acceptance leads to unsatisfaction with sex life especially in women with obesity and hirsutism. Another reason for infertility is “infertility stress” which includes lose of interest in daily activities, difficulty in maintaining interpersonal relationship, depression and high level of anxiety. Moreover infertility stress leads to sleep disorder, a feeling of helpless,

guilt and lose of concentration and attention. Women with PCOS can also get pregnant with appropriate treatment. First step to get rid of infertility is modification in life style management and daily exercise. Another step is to provide some fertility medications which are estrogens receptor modulators. Sometimes fertility injections (Follistim®, Gonal-F®, Bravelle®, and Menopur®) are also required to release eggs.

Hirsutism is another cause of behavioral hypochondriacs. It is a condition in which PCOS patients slowly results in excess hair growth. 70-80% of women with PCOS shows symptoms of hirsutism. It is because of excess level of androgen. It is related with appearance like "male pattern" appearance like acne, excess hair at chest, abdomen, face, arms, increase in body weight, loss of menstruation cycle, baldness etc. Moreover this can cause psychotic symptoms which includes high level of anxiety and tension. They are more susceptible to social phobia and insecure about their body appearance. They often have feeling of shame, loneliness Hyperandrogenism. Various short term treatments can be used for hirsutism like use of chemical depilatories or bleaching cream, plucking of hair. For long term treatment electrolysis and laser can be used. Eflornithine cream can be used for slow down the topical hair growth.

Body image distress is most commonly seen in women with PCOS. It is mainly because of the obesity. To maintain a ideal body weight is another reason for anxiety and depression on women with PCOS. Obesity give rise to decreased self confidence and negative thoughts and often looks for strict dieting which can put additional stress on person. Eventually this can cause eating disorder in women. This all parameters can lead to hypochondriacs.

➤ Life style management

Obesity is a major challenge for clinicians in women with PCOS. Health risk of obesity cannot be ignored that why it is important to maintain healthy weight which needs a slight change in daily lifestyle. It includes an extra 2000-3000 steps per day, regular 30 mins physical activity, replacement of artificial sweetened drinks and sugars with health options, having cereals for breakfast. Overall reduction of calories is more important in weight loss. It needs a long term practice otherwise after short time of physical activity one may starts to gain weight again. Diet with high fibre content and low carbohydrate is recommended. Food with low glycemic index like cereals, soy, lentils can be included in diet. This can be accomplished by daily exercise or physical activity. Exercise in combination with diet will reduce muscle mass and, exercise with muscle strengthning will improve insulin activity.

IV. CONCLUSION

Preceding literature review on various parameters for behavioral hypochondriacs indicates that a little support from society and changed perspective to consequences of PCOS can improve the psychotic symptoms of stress, anxiety and depression. According to a cross sectional survey lifestyle management awareness is well recognized by women but awareness about psychological distress is not recognized well. In rural areas, awareness about PCOS is not well acknowledged. Hirsutism, obesity, infertility is not accepted by the community which is the main reason for depression and excess level of anxiety. PCOS is not a severe condition but it can be controlled by various awareness programmes for PCOS, nutrition and exercise counselling, prescribed medication for hormonal imbalance etc.

Clinical and Biochemical Features of Polycystic Ovarian Disease

JOSEPH W. GOLDZIEHER, M.D., and LEONARD R. AXELROD, Ph.D.

THE EXISTENCE of bilateral polycystic ovarian disease and its occasional improvement following cuneiform ovarian resection was known before the turn of the century.¹⁻⁴ Additional clinical and surgical observations were reported sporadically in the ensuing years,⁵⁻⁸ but a broad interest in this disorder did not develop until 1935 when an associated syndrome consisting of "menstrual irregularity featuring amenorrhea, a history of sterility, masculine type hirsutism, and less consistently retarded breast development and obesity" was described.⁹ Excellent therapeutic results following wedge resection were reported by these authors over a span of many years; their results, however, have never been duplicated in any other substantial series of cases. In the eyes of many investigators, the clinical features of this syndrome were neither definitive nor satisfactory, and additional criteria such as a normal urinary 17-ketosteroid excretion¹⁰ were employed in an effort to improve diagnostic accuracy and the consistency of surgical results. With time, increasing numbers of patients with polycystic ovarian disease and atypical clinical findings were observed,¹¹ and in a significant number of even these cases, a normalization of function followed wedge resection. Netter *et al.*¹² in typical Gallic style, remarked that: "the syndrome of Stein is a fugitive syndrome, with limits less well defined than those of the Sahara or the Sudan." In England, Roberts and Haines¹³ studied 14 cases and entitled their report, "Is there a Stein-Leventhal syndrome?" It is noteworthy that these questions were raised from a clinical point of view and not because of the superficial resemblance of polycystic ovaries to the ovarian

This paper was presented at the 19th Annual Meeting of the American Society for the Study of Sterility, New York, N. Y., Apr. 19-21, 1963.

We wish to express our gratitude to Dr. Anna Southam for access to her reference file and for many fruitful discussions, and to Dr. C. W. Lloyd for providing the persistent-estrus rats used in one of our studies.

sclerosis and other pathology which is known to accompany androgenic^{14, 15} or Cushingoid¹⁶ adrenocortical hyperfunction.

Since there appeared to be growing doubt as to the existence of a clinical syndrome associated with sclerocystic ovaries, we undertook a survey of the world literature in a search for the incidence of certain signs and symptoms in patients who were found at operation to have polycystic ovarian disease. A total of 187 pertinent references yielded acceptable information from 1097 cases, as shown in Table 1. Amenorrhea was observed in only half of the patients, and the per cent of frequency with which this symptom occurred in different series varied tremendously—from 15 to 77%. On the other hand, cyclic menses were noted in a significant number of patients (12%), and functional bleeding was exceedingly common (65%) in some series. The incidence of infertility also varied widely, ranging from 35 to 94% with an over-all average of 74%. However, since infertility is one of the major reasons why patients consult a physician in the first place, the figures probably have a positive bias. By contrast, there appeared to be unequivocal evidence of ovulation in patients with polycystic ovaries as shown by reports of primary dysmenorrhea, by biphasic basal temperature curves in 12–40% of subjects, and finally by the finding of corpora lutea in an average of 22% of the cases where the presence or absence of this feature was specifically mentioned. Hirsutism was observed in an average of 69% of the subjects, but again the incidence varied widely. Virilization appeared with some frequency. Taken together, these statistics make it most difficult to accept as a distinct entity a group of symptoms of which only two nonspecific ones (hirsutism, infertility) are present much more than half the time, where cyclic menses or functional uterine bleeding occur nearly as often as the supposedly important amenorrhea, and where positive evidence contradicts

TABLE 1. Signs and Symptoms Associated with Polycystic Ovarian Disease

<i>Symptom</i>	<i>Usable No. cases</i>	<i>Incidence (%)</i>	
		<i>Mean</i>	<i>Range</i>
Obesity	600	41	16–49
Hirsutism	819	69	17–83
Virilization	431	21	0–28

Infertility	596	74	35–94

Data tabulated from 187 references with a total of 1079 cases.

the postulated anovulation which is thought to cause the infertility. As a matter of fact, in a study of the gross appearance of the ovary in a series of 12,160 gynecological laparotomies, 170 instances (1.4%) of polycystic ovaries were observed.¹⁷ It is difficult to avoid the conclusion that Stein and Leventhal's symptomatology calls attention to a small and perhaps not especially unique fraction of polycystic ovarian disease. It has been claimed in rebuttal that these clinical variations are simply different stages of an evolving disease process. We have indicated elsewhere¹⁵ that this explanation is unsupported by positive findings, and that there is no detectable association between the duration of the disease and the "completeness" of the alleged syndrome.

The success of wedge resection in correcting the infertility and menstrual disorders associated with polycystic ovaries has been in large measure responsible for the wide and continued interest in this disease. Examination of the literature, however, indicates that success is by no means uniform. Where published data are adequate for evaluation, as seen in Table 2, regular cycles are re-established in an average of 80% of operated patients, but in some hands, the rate of success is as low as 6%; results in terms of pregnancies are also most unpredictable, ranging from 13 to 89%. It is quite evident that the clinical material which forms the basis of these studies is inhomogeneous, and that criteria for the selection of candidates for wedge resection are neither uniform nor adequate. In our experience, there has been no difference in the results of wedge resection whether the urinary 17-ketosteroids were normal or elevated; as a matter of fact, the elevated steroid excretion was unaltered by surgery in two-thirds of the patients. The corticosteroid suppression test (see below) has not been helpful, nor has ovarian size, since normal-sized ovaries have responded at about the same rate as enlarged ovaries. One correlation, apparently valid but extremely difficult to evaluate quantitatively, was suggested to us by Southam:¹⁸ the more estrogenic activity and the less androgenic activity there is, the better the results of wedge resection are likely to be.

Efforts to find additional clinical signs and symptoms which would im-

TABLE 2. Results of Wedge Resection in Patients with Polycystic Ovarian Disease

prove the diagnostic and therapeutic "score" have not met with much success, and investigators have turned to cytological and biochemical studies for help. There have been a number of recent reports¹⁹⁻²¹ of chromosomal anomalies associated with polycystic ovarian disease. This unexpected finding awaits confirmation and correlation. The occurrence of polycystic ovaries in sisters^{15, 22, 23} may be mere coincidence or another intimation of genetic involvement.

Criteria of classic morphology have not provided much assistance, and indeed there is controversy at the present time whether any of the histological changes observed in polycystic ovaries are at all specific^{15, 24} or whether they can be observed with frequency in other clinically unrelated conditions. From the practical point of view, Plate²⁵ has shown that the presence or absence of hyperthecosis was not significantly correlated with the results of wedge resection.

Biochemical studies until very recently were confined to analysis of urinary steroid metabolites. The extensive literature dealing with this aspect of the problem has been reviewed elsewhere.²⁶ For the enormous amount of effort expended in this direction, the results have been disappointingly meager. Our improved understanding of ovarian and adrenal steroidogenesis goes a long way to explain some of these difficulties. Elevated excretion of urinary 17-ketosteroids has been observed by many investigators, while others rule out the diagnosis of "Stein-Leventhal syndrome" in the face of elevated excretion. Figure 1 shows the ranges of values of total urinary 17-ketosteroids and 17-hydroxycorticoids observed by us in a series of patients with polycystic ovaries. It is evident that there is a diffuse spread of values which does not permit the categorization of these patients into distinct sub-

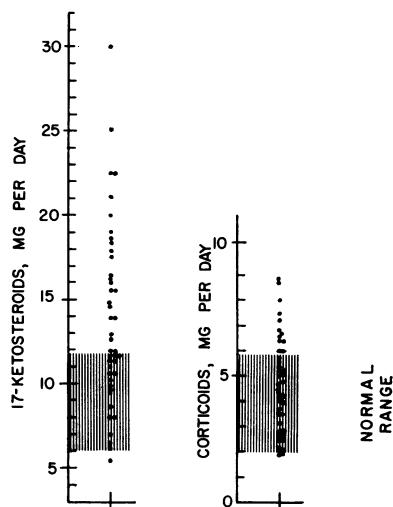

Fig. 1. Urinary excretion of total 17-ketosteroids and 17-hydroxycorticoids in patients with polycystic ovarian disease.

groups. Some of the 17-hydroxycorticoid values significantly exceed our normal range and suggest that certain patients may have had adrenocortical hyperfunction. It should be noted that these elevated values were not associated with extreme obesity, which would tend to increase the level of urinary excretion.²⁷

Important methodological difficulties²⁸ stand in the way of correct interpretation of "total 17-ketosteroid" excretion. Chromatographic separation and measurement of the individual 17-ketosteroids has not been particularly helpful, since both ovarian and adrenal ketosteroids are metabolized to the same excretory products (androsterone and etiocholanolone), and since dehydroepiandrosterone, the major "adrenal" ketosteroid, is now known to be produced by the ovary as well.²⁹⁻³¹ As a consequence, dynamic tests of steroid metabolism have been developed in an attempt to distinguish the ovarian contribution from that of the adrenal. In an early study, we examined the effects of adrenal suppression by a small dose of prednisolone (2.5 mg., t.i.d.) given over a period of 10 days. There appeared to be a significant difference in the response of normal women vs. women with hirsutism but without menstrual disorders (Fig. 2). The higher the initial

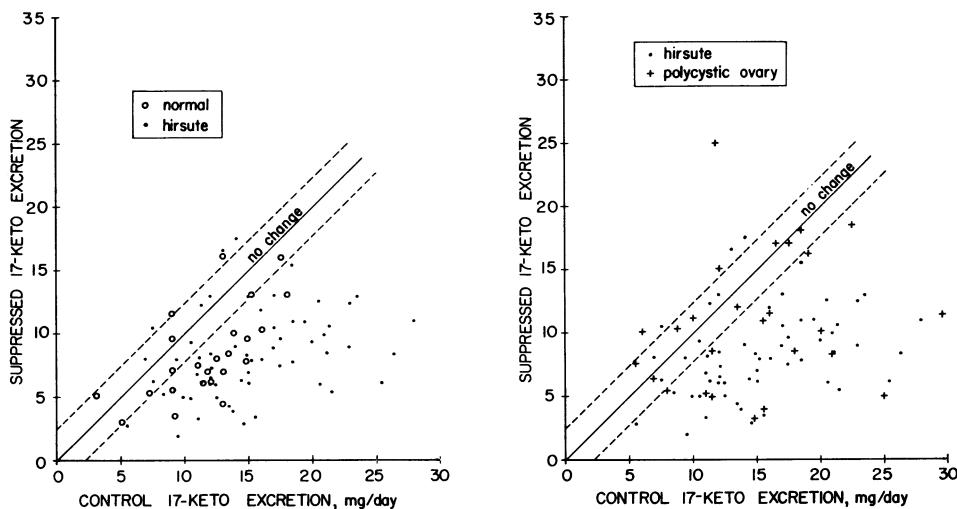

Fig. 2 (left). Urinary 17-ketosteroid excretion before and after minimal adrenal suppression. No change in excretion would yield points lying along diagonal line \pm the error of measurement. Values below diagonal line indicate degree of suppression. Results were obtained in normal vs. cyclic, but hirsute, women. **Fig. 3 (right).** Urinary 17-ketosteroid excretion before and after minimal adrenal suppression. No change in excretion would yield points lying along diagonal line \pm the error of measurement. Values below diagonal line indicate degree of suppression. Results are from hirsute cyclic women vs. patients with polycystic ovaries.

17-ketosteroid excretion in the hirsutism cases, the greater was the decrease following adrenal suppression. We interpreted these findings as indicating a hyperresponsiveness of the pituitary-adrenal axis in certain cases of hirsutism.³² When the situation was examined in women with polycystic ovaries, Fig. 3, some were found to show the minimal response seen in normals or certain hypertrichotic women, while others showed the pattern which we interpreted as pituitary-adrenal hyperresponsiveness. This might possibly be an indication of a role of the adrenal cortex in certain cases, but the evidence was equivocal and at any rate offered no clearcut, useful diagnostic index. Netter and others³³⁻³⁵ have developed dynamic tests involving the use of dexamethasone for adrenal suppression and an estimation of urinary steroid changes following the superimposed administration of large doses of chorionic gonadotropin. Some interesting differences in the excretion of neutral and phenolic steroids have been noted, but the acid test of broad clinical application, especially in diagnostically difficult situations, remains to be carried out.

On the basis of so much work and so little yield in the attempt to distinguish ovarian from adrenal factors, one might well begin to wonder if there is not indeed an adrenocortical component in some cases of polycystic ovarian disease. Sherman³⁶ has found increased excretion of 11-ketopregnanetriol, undoubtedly an adrenal metabolite, in 16 cases. Wedge resection of the ovaries has frequently failed to alter an elevated excretion of urinary 17-ketosteroids,^{26, 37, 38} which could be decreased promptly upon adrenal suppression with corticosteroids. Moreover, in some therapeutic failures of wedge resection, satisfactory results have been achieved subsequently with corticosteroid treatment. On the other hand, there is no reason to believe that adrenal hyperfunction is inevitably associated with polycystic ovarian disease, hence the finding of histologically normal adrenal tissue in a few instances³⁹ comes as no surprise. It is known, furthermore, that histologic normalcy is no indication of normal function: the adrenals may appear quite unremarkable in full-blown cases of Cushing's syndrome.

There are many indications that the pituitary-adrenal and pituitary-ovarian circuits are not completely isolated from each other, but that there is a good deal of functional "crosstalk" which can be demonstrated in a variety of ways. Some years ago Sohval and Soffer⁴⁰ demonstrated that the administration of corticosteroids or ACTH can cause an increase in urinary gonadotropin excretion. In chickens, even ovulation can be triggered by this procedure.⁴¹ Clinically, the occasional appearance of uterine bleeding after administration of ACTH is well known. Looking at the other side of the relationship, it has been shown that estrogenic compounds which are potent gonadotropin inhibitors significantly alter cortisol and aldosterone

secretion rates.⁴² Gemzell *et al.*⁴³ noted in one unusual patient with hirsutism and elevated 17-ketosteroids that the administration of gonadotropin not only increased urinary estrogens but also tripled the 17-ketosteroids and corticoids, suggesting an action of pituitary gonadotropin on the adrenal. Finally, in rats the production of persistent estrus and polycystic ovaries by hypothalamic injury is associated with adrenal hypertrophy,⁴⁴ an observation we feel to be of considerable theoretical importance.

The co-existence of adrenal and ovarian disturbances is therefore not entirely unexpected. This complicates the question of the pathogenesis of polycystic ovarian disease, and it becomes necessary to delve more deeply into ovarian endocrine function in an effort to understand the physiologic problems involved.

OVARIAN STEROIDOGENESIS

While the main elements of steroid biosynthesis in adrenal tissue were fairly well clarified 10 years ago, it has been only recently that an equivalent understanding of ovarian steroidogenesis has been achieved. The cyclic nature of ovarian function clearly makes the problem more difficult than with the adrenal. The ovary stores very little steroid material, thus increasing the problems of detecting steroids in its tissue. Even the secreted quantities of ovarian estrogens and androgens are so small that actual isolation (to say nothing of definitive identification) of the compounds strains the reliability of the best methods available. New technics involving the determination of secretion rates by isotope dilution are beginning to yield more precise and meaningful information.

In view of these difficulties, the majority of efforts to establish the steroid biosynthetic pathways have relied on the incubation of precursor substances with ovarian tissue and the isolation and identification of the resulting products. Many of these investigations yielded only tentative identification of the metabolites and were therefore of limited value, but definitive identification of all the steroid intermediates between cholesterol and the estrogens has finally been achieved.²⁹ In 1962 definitive identification of the complete series of steps from pregnenolone to estrogen in single samples of ovarian tissue was accomplished.²⁹

A diagrammatic outline of the ovarian biosynthetic mechanism is shown in Fig. 4. Using readily available cholesterol, the ovarian enzymes first cleave the side chain, yielding Δ^5 -pregnenolone. This compound then undergoes hydroxylation to 17-hydroxypregnenolone. Another side-chain-cleaving enzyme system removes the rest of the side chain, leaving the 17-ketosteroid dehydroepiandrosterone. During all this time, an enzyme system

called 3β -ol dehydrogenase has been actively switching the position of a certain double bond (Fig. 5), converting pregnenolone to progesterone, dehydroepiandrosterone to androstenedione, and probably acting at all the intermediate stages as well. Progesterone itself also undergoes the same trans-

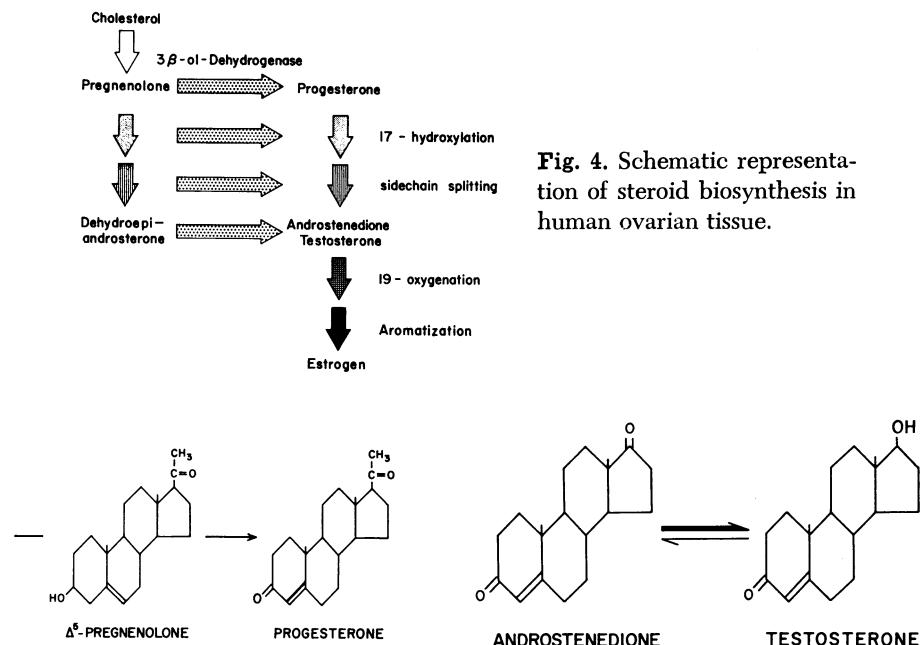

Fig. 4. Schematic representation of steroid biosynthesis in human ovarian tissue.

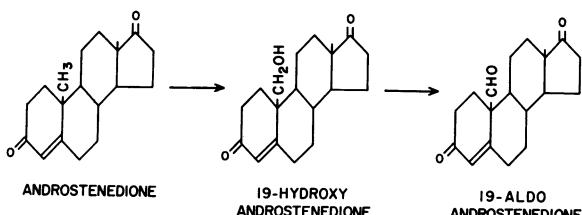

Fig. 5 (left). Conversion of Δ^5 -pregnenolone to progesterone by 3β -ol dehydrogenase system. **Fig. 6 (right).** Conversion of androstenedione to testosterone by 17-reductase enzyme system.

formations of 17-hydroxylation and side-chain cleavage to form androstenedione. Thus parallel biosynthetic pathways, with interactions at each stage, are formed. It is important to recognize at this point what the ovarian biosynthetic mechanism has accomplished: *pregnenolone and progesterone formed from still earlier precursors, have been transformed into 17-ketosteroids (dehydroepiandrosterone and androstenedione)*. Both are relatively weak androgens, but androstenedione is readily convertible to testosterone (Fig. 6) by a reductase which is present in ovarian tissue and blood and in peripheral tissues as well. Thus, the formation of testosterone by the ovary, long suspected on the basis of circumstantial evidence,* was finally proved in definitive fashion.⁴⁶ Biosynthesis of these 17-ketosteroids has been amply confirmed in both normal and polycystic ovaries.^{31, 47-51}

*See Parkes⁴⁵ for a masterful review.

Studies of ovarian venous blood^{52, 53} have demonstrated the presence of 17-ketosteroids, and elevated levels of blood testosterone have been observed in virilized patients with polycystic ovaries.^{54, 55} Thus, there is no longer any doubt as to the existence and identity of the ovarian androgens. These

Fig. 7. Progressive oxidation of 19-methyl group of andro-
stenedione.

findings explain the different levels of urinary 17-ketosteroid excretion associated with adrenal vs. ovarian virilization. Since the major adrenal steroid is dehydroepiandrosterone (apparently little or no testosterone is produced by the adrenal), it requires large quantities of this weak androgen to bring about pronounced clinical manifestations, and this elevated output is reflected in a high level of urinary 17-ketosteroids. The ovary, on the other hand, produces testosterone, a much more potent androgen, and consequently extreme degrees of virilization (as with arrhenoblastomas) may be the result of quantitatively much smaller production of steroid, causing little or no elevation of urinary 17-ketosteroids.

Before turning to a consideration of abnormalities of ovarian androgen production, it is necessary to complete the discussion of ovarian steroidogenesis by examining the mechanism which transforms these various androgens into the natural estrogens. This transformation takes place in two major stages. The first stage consists of an oxidative attack on the C-19 methyl group, which sticks out at right angles from the front face of the steroid molecule. This methyl group is first oxidized to an alcohol (forming 19-hydroxyandrostenedione or testosterone), then to an aldehyde (19-aldo-androstenedione or testosterone), Fig. 7. These intermediates have been identified in biosynthetic experiments with normal and polycystic ovarian tissue.²⁹ The second stage which involves aromatization of ring A begins by an enzymatic removal of the oxidized methyl group together with a nearby hydrogen atom. This results in an unstable intermediate which spontaneously rearranges to form the phenolic ring-A characteristic of the natural estrogens (Fig. 8). Evidence in support of this mechanism has been presented elsewhere.⁵⁶ By this route, therefore, androstenedione is converted to estrone, testosterone into estradiol. It is interesting to note that in our biosynthetic studies with normal or polycystic ovarian tissue, estradiol has always been the predominant estrogen formed.

Biosynthetic experiments in vitro reveal the potentialities of tissue under the given conditions, and presumably this reflects the activity of the organ in vivo; however, the relationship between in vitro and in vivo conditions is in need of further study. This question involves some surprising complications. Falck⁵⁷ in a technical *tour de force* transplanted vaginal epithelium and small nests of ovarian cells side by side in the anterior chamber of the eye of experimental animals, and showed that no single cell type produced cornification of the adjacent vaginal epithelium. When two types of ovarian cells in various combinations (theca interna or interstitial cells combined with granulosa or corpus luteum cells) were transplanted, however, cornification (i.e., estrogen production) occurred. In rabbits, it has been found that the interstitial tissue can produce as much progestagen as control ovaries with intact follicles,⁵⁸ and in humans, the medullary portion of polycystic ovaries is as active as the cortical zone in steroidogenesis.⁵⁹ Some workers have chosen to examine the steroid content of ovarian tissue in an effort to find correlations with the functional state of the ovary. Some of the data on tissue steroid concentration are summarized in Table 3.^{30, 60-65} It is

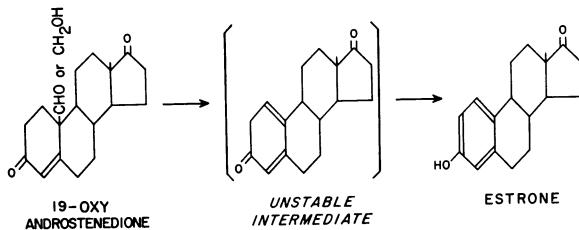

Fig. 8. Conversion of 19-oxygenated 17-ketosteroid into estrogen ("aromatization").

TABLE 3. Concentration of Steroids in Ovarian Tissue

<i>Steroid</i>	<i>Concentration (μg./gm.)</i>	
	<i>Normal</i>	<i>Poly cystic</i>
Progesterone	0-90	
17-hydroxypregnenolone	0	0-4.5
17-hydroxyprogesterone	0-1.7	3-6
"20-hydroxyprogesterone"	0-19	
Δ ⁴ -androstenedione	0.6	0-15
Testosterone	<0.3	
Dehydroepiandrosterone	0-1	0-7
Estrone	0.07-2	0.3-1.5
Estradiol	0.01-0.9	1.1-2.5
Estriol	0-0.6	0-0.9

Summary of results by various authors. Since different technics were used, the results are not necessarily comparable.

evident that ovarian tissue does not store appreciable quantities of steroids; indeed, the levels are so low in most instances as to be at the limit of detectability (to say nothing of reliability) of current technics. This approach to the problem therefore presents formidable difficulties. Moreover, since little is known of the relationship of tissue storage to the level of hormonal activity of the organ, the results are difficult to relate to ovarian function.

The escape of some of the intermediate steroid compounds from the ovarian biosynthetic "factory" into the peripheral circulation and hence into the urine might theoretically prove of value as an index of ovarian activity. Indeed, urinary excretion of Δ^5 -pregnenetriol,^{66, 67} pregnanetriol,⁶⁸ and other metabolites has been examined with this aspect in mind, but as with the urinary 17-ketosteroids, the contribution from the adrenal confuses the findings.

The technic of determining steroid secretory rates by isotope dilution has been widely employed in studies of adrenal function where determinations of cortisol or aldosterone secretory rates are fairly routine research procedures. It is only recently, however, that this methodology has been applied to the androgens,⁶⁹ estrogens,⁷⁰ and progesterone. Dominguez *et al.*⁷¹ have found a progesterone secretory rate of 2.5–5.4 mg./day in the preovulatory phase, rising to 22–43 mg./day during the postovulatory phase. At the ovulatory peak, estradiol secretory rates of 0.2–0.5 mg./day have been observed.⁷⁰ Important studies in normal and hirsute patients have been carried out by MacDonald *et al.*³¹ using dual-label technics to overcome the difficulty presented by the fact that both dehydroepiandrosterone and testosterone (or androstenedione) are metabolized to the same urinary excretory products. Normal ovaries were estimated to produce 1–2 mg. dehydroepiandrosterone and up to 1.6 mg. testosterone+androstenedione per day. By comparison, the adult testis produces 4–5 mg. dehydroepiandrosterone and 2.8–4.5 mg. testosterone+androstenedione per day. In hirsute women with normal 17-ketosteroid excretion and in some instances with polycystic ovaries, secretory rates were determined with the adrenals suppressed by dexamethasone. Under these conditions, increased secretion of dehydroepiandrosterone and/or testosterone+androstenedione was demonstrated. In one instance the ovaries produced 16 mg. dehydroepiandrosterone (but no testosterone+androstenedione) per day, while in another instance 4.5 mg. dehydroepiandrosterone and 5.6 mg. testosterone+androstenedione were produced—a rate comparable to that of the normal testis. Suppression of the pituitary gonadotropic stimulus with norethindrone acetate invariably resulted in a prompt drop of ketosteroid secretion, thus further confirming their ovarian origin. Studies such as these are time-consuming and require highly sophisticated technics, and when complications such as the secretion

of conjugated dehydroepiandrosterone by the adrenal are taken into consideration the mathematics become quite complex. There is also the important possibility that the state of the pituitary-ovarian axis may be altered by the dexamethasone used for adrenal suppression during these studies. Nevertheless, it will require methods such as these to provide fundamental information about the *in vivo* activity of the ovaries.

To explore these and other areas of endocrine abnormality in polycystic ovaries, many investigators, including ourselves, have concentrated on the information to be gained by examining the *in vitro* biosynthetic potential of polycystic ovarian tissue. Table 4 shows a comparison of the definitively identified metabolites from incubations of normal and polycystic ovarian tissue with progesterone and pregnenolone. The normal ovarian tissue is seen to metabolize all but 10.7% of the starting material at the end of 2 hr., the majority of the metabolites being in the form of 17- and/or 20-hydroxyprogesterones. Formation of androstenedione and testosterone is found; there is of course no dehydroepiandrosterone since the precursor was progesterone. There are considerable quantities of 19-oxygenated steroids and 4.8% conversion of the starting material to estradiol. No estrone or estriol was detected. The polycystic ovaries A and B also incubated with radioprogesterone were, if anything, even more active than the normal ovary, since they metabolized 99 and 100% of the starting material, and since much less 17- and/or 20-hydroxylated progesterone was left. However, a

TABLE 4. Steroids Produced by the Incubation of Normal and Polycystic Ovarian Tissue with Various Precursors

Steroid	Normal ovary with progesterone	% conversion		
		Polycystic ovary		
		With progesterone		With pregnenolone
		A	B	
Unconverted substrate	10.7	0.9	0.0	63.9
17- and/or 20-hydroxylated metabolites	78.2	43.1	46.8	6.1
Androstenedione	1.1	22.6	25.1	1.9
Testosterone	0.4	2.2	3.4	9.1
Dehydroepiandrosterone				15.1
19-oxygenated androstenedione or testosterone	3.9	31.3	24.4	3.5
Estrone	0.0	0.0	0.0	0.0
Estradiol	4.8	0.0	0.0	0.0

tremendous quantity of androstenedione (22.6 and 25.1%) and testosterone (2.2 and 3.4%) accumulated. Equally impressive is the conversion to 19-oxygenated steroids, being 6 to 10 times as great as that seen in the normal. However, no detectable estrogen was formed by these particular ovaries, immediately suggesting that the aromatizing mechanism which converts 19-oxygenated compounds to estrogens was defective and that the accumulation of androgens and 19-oxy compounds represents a "backing up" of steroid material behind the roadblock.

In the polycystic ovary incubated with pregnenolone, there is a very poor conversion of the starting material and also an accumulation of dehydroepiandrosterone, in addition to the abnormalities already seen in polycystic ovaries A and B. This would suggest an inadequacy of the 3β -ol dehydrogenase system in this particular ovary, as well as the aromatizing defect, which is clearly present in view of the 3.5% conversion to 19-oxygenated steroids with no detectable conversion to estrogen. These findings are entirely consistent with secretion rate studies of MacDonald *et al.*³¹ described above.

Such observations do not imply the uniform existence of invariable, all-or-none enzyme defects in polycystic ovarian tissue. The very fact that measurable urinary estrogen excretion along with more or less cornification of the vaginal epithelium does occur proves that in certain cases and at certain times biosynthesis can go on to aromatization. (In one polycystic ovary incubated with radiotestosterone, we have observed 10.1% conversion to estradiol and 3.2% conversion to estrone.) It appears, however, that there is still some obstruction to aromatization in these cases, as shown by the disproportionately large ratio of androstenedione and testosterone to estrogen formed. To put it another way, in the process of producing a particular amount of estrogen, the ovary is forced to synthesize and therefore secrete excessive amounts of androgen. Short and London⁷² have examined cyst fluid from human ovaries, and in "Stein-Leventhal" instances found an increased content of androstenedione and an absence of estrogens. On this basis, they also concluded that there was a defect in estrogen synthesis of polycystic ovaries. Confirmatory results by means of tissue incubation have been reported although unfortunately the necessary technical details were lacking.⁵³

It would appear incontrovertible then, that the androgenic manifestations associated with polycystic ovaries are in part due to an overproduction of ovarian androgens as a consequence of variable enzymatic defects in the aromatizing mechanism, the 3β -ol dehydrogenase system, and possibly other enzyme functions as well. That these defects do *not* define a clinical entity is shown by consideration of the cases which provided incubations A and

B in Table 4. The biosynthetic pattern of these two tissues is virtually identical. Clinically, however, "polycystic ovary A" presented a typical picture of androgenic adrenal hyperfunction (adrenogenital syndrome) without obesity or amenorrhea. Virilization and infertility were present; the 17-ketosteroid excretion ranged from 19 to 23 mg/day and was readily suppressed by minimal corticosteroid therapy, and a corpus luteum was found at wedge resection of the slightly enlarged, polycystic ovaries. "Polycystic ovary B" had all the symptoms associated with the "Stein-Leventhal syndrome." The urinary 17-ketosteroids ranged from 18 to 27 mg. per day and were not diminished by the standard corticosteroid suppression test. No corpus luteum was found on wedging the polycystic ovaries. It is paradoxical that the patient with the adrenal disorder became pregnant after wedging, whereas the "Stein-Leventhal" did not. Findings such as these, together with the established fact that surgical damage of the ovaries normalizes their function in a significant per cent of cases, indicate that the enzymatic defects found in polycystic ovaries are not irreversible, and that they may be the consequence of still more recondite influences which initiated the ovarian pathology. A search for these factors leads to the hypothalamic-pituitary mechanism which largely governs ovarian activity.

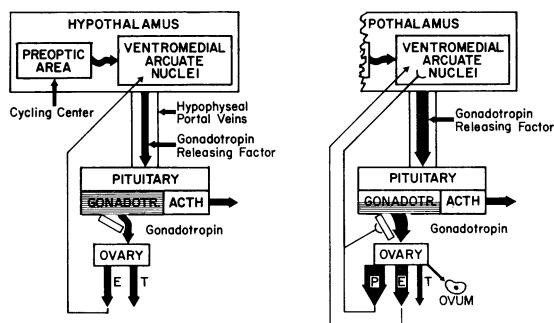

HYPOTHALAMIC-PITUITARY-OVARIAN RELATIONSHIPS

Our knowledge of hypothalamic regulation of the menstrual cycle in primates and especially in humans is far less advanced than one might suppose. Most of the information available has been derived from studies of rodents, particularly those having an estrus cycle.⁷³ It is usually assumed that the basic features of the estrus cycle are comparable to those of the primate menstrual cycle, but there is reason to believe that future research will show important fallacies in this assumption. Nevertheless, one must deal with the information at hand, recognizing its tentative and very possibly species-specific character.

Our current concept of the neural-pituitary-ovarian circuit is diagrammed in Fig. 9. A region in the preoptic area of the hypothalamus, possibly the suprachiasmatic nucleus, appears to act as a biological "clock," imparting a cyclic character to the rest of the mechanism and thus accounting for the estrus cycle and the menstrual rhythm. These neural impulses are registered in the region of the median eminence of the hypothalamus, probably the ventromedial and arcuate nuclei.⁷⁴ These centers produce a neurohormone⁷⁵ which has been called the gonadotropin-releasing factor (GRF). GRF is transported by means of the hypophyseal portal veins (note the similarity to the role of corticotrophin-releasing polypeptide in the pituitary-adrenal axis)

to the adenohypophysis, where it causes a synthesis and release of pituitary gonadotropin. Thus, the median eminence area of the hypothalamus exerts a tonic stimulation on the pituitary, and the preoptic area superimposes a cyclic variation on this mechanism. The released gonadotropin (whatever its

Fig. 9. Hypothalamic-pituitary-ovarian mechanism. At left, preovulatory relationships; At right, post-ovulatory relationships. E = estrogens; T = testosterone (androgens); P = progesterone.

true qualitative character may be) stimulates the ovary to secrete androgens and estrogens approximately in the ratio of 7:1. The estrogens released into the circulation have a stimulatory effect on the nuclei near the median eminence (a "positive feedback" effect), causing increased secretion of GRF, which in turn increases gonadotropin secretion, and so on. At a certain point, the rising estrogen output triggers ovulation.⁷⁶ With the occurrence of ovulation and the production of an egg, dramatic changes in the ovarian steroid output occur. In addition to estrogen, there is now a tremendous output of progesterone (milligrams of progesterone as compared to micrograms of estrogens). Progesterone inhibits the release (but not the formation) of pituitary gonadotropins^{77, 78} (Fig. 9), and also has an inhibitory effect on the hypothalamic centers. This "negative feedback" mechanism serves to diminish the gonadotropic stimulus of the ovary, and together with the waning phase of the preoptic "cycling" center brings about the termination of the cycle.

The mechanism permits an interpretation of some remarkable experiments based on the rediscovery of certain simple methods for producing persistent estrus in rats.⁷⁹ Electrolytic lesions or single massive injections of steroids in the first few days of life apparently damage the cycling center of the rat hypothalamus; the results are shown in Fig. 10. There is now a *tonic* discharge of GRF from the ventromedial and arcuate nuclei, causing a continuous release of pituitary gonadotropin. The resulting tonic secretion of estrogen and positive feedback turn this into a situation where the pituitary never gets a chance to pause and store up gonadotropin for the large burst needed in the process of ovulation. Thus an anovulatory mechanism is set up, with a continuous low-level stimulation of the ovary. As these

rats grow to maturity, the ovaries become enlarged and polycystic, and there also occurs a hypertrophy of the adrenals.

Under these conditions of continuous, noncyclic ovarian stimulation it is conceivable that changes in the ovarian steroid biosynthetic mechanism might occur. For this reason, we incubated a number of such enlarged, polycystic rat ovaries in the same manner as used for the studies on human ovaries. The results of one such experiment are shown in Table 5. Keeping in mind the possibility of species-specific differences in ovarian steroidogenesis,^{80, 81} one fact emerges with great clarity: *although there is ample conversion of the pregnenolone to androgens, no aromatization to estrogens is detectable*. The similarity to one of the enzymatic abnormalities observed in human polycystic ovaries is apparent. It is possible that experimental modifications which take into account the fact that rat tissue metabolizes much faster than human tissue (a cycle is complete in 4 days vs. 28 days for man) might have demonstrated the presence of other intermediates such as 19-oxygenated compounds. It is also evident from the fact that these animals are in persistent estrus that *some* estrogen is being formed (although other steroids are known to be able to produce vaginal cornification),⁸²⁻⁸⁴ but the important fact, as seen with human tissue also, is that the ratio of androgen to estrogen formed must be extremely high. This overproduction of androgen, now observed in both rat and man, might have some bearing on the formation of capsular fibrosis in human polycystic ovarian disease, since the

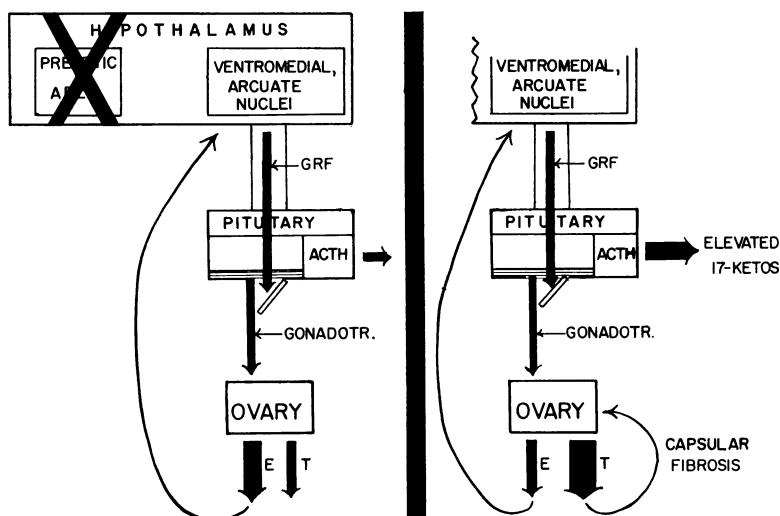

Fig. 10. Genesis of polycystic ovaries. Disruption of hypothalamic-pituitary-ovarian mechanism in persistent-estrus rat. At left, early stage; At right, breakdown of enzyme systems and possible cause of ovarian fibrosis seen in human disease.

TABLE 5. Steroidogenesis in Ovarian Tissue of Persistent-Estrus Rats

<i>Metabolite</i>	<i>Substrate: pregnenolone-4-C-14</i>	<i>Total DPM</i>
Unconverted pregnenolone		391,540

Testosterone		12,470
Estrogens		None

administration of androgens to primates for prolonged periods of time has been shown to cause such a lesion.⁸⁵ This is shown diagrammatically in Fig. 10.

There are other important experiments which have been performed with these persistent-estrus rats. If the estrogenic "positive feedback" mechanism is interrupted by removing one ovary and resecting most of the second (or inactivating its hormones by transplanting it to the portal circulation), the character of pituitary function changes and luteinization of the remaining ovary occurs.^{86, 87} Still another experiment affirms this line of thought: Electrical stimulation of the hypothalamus of persistent-estrus rats fails to produce ovulation unless the animals are pretreated with large doses of progesterone (causing a storage of pituitary gonadotropin).⁷⁴

These experiments may well suggest an answer to the perpetual question, why wedge resection restores cyclic function in some women with polycystic ovaries. By analogy with these rodent experiments, consider the endocrine situation which may develop in certain instances of human polycystic ovarian disease. Characteristically, menarche occurs at about the normal age and there is some menstrual function for a time. The histories often suggest that this phase of early ovarian function is anovulatory. If, for some reason, the human hypothalamic "cycling center" does not straighten matters out, the ovary remains exposed to a more or less tonic gonadotropic stimulus, without the beneficial gonadotropin-accumulating influence of progesterone. Thus the vicious circle of noncyclic GRF secretion, noncyclic and possibly qualitatively abnormal gonadotropin secretion, and finally uninterrupted estrogenic positive-feedback develops. Ultimately certain ovarian steroid-biosynthetic enzymes become exhausted. (In this connection it is worth noting that the testis, under its *noncyclic* gonadotropic control biosynthesizes androgens physiologically. When the ovary is exposed to noncyclic gonadotropic influences, its production of female hormones breaks down and it

reverts to a testicular pattern of steroidogenesis.) Chronic exposure of the ovary to these gonadotropic stimuli produces cystic changes, and the constant presence of high local concentrations of androgens may account for the ovarian fibrosis. Now, the surgeon inflicts a major trauma on the ovary, especially if he follows the customary recommendations to resect a *generous* portion of tissue and to extend his incision *well down into the hilus*, where the major blood supply is found. This procedure so affects the ovary that its steroid production is greatly reduced or perhaps even interrupted for a time. Positive feedback and the vicious circle are broken; secretion of gonadotropin is slowed or halted and accumulation can occur; the exhausted ovarian steroidogenic enzymes may be able to recover. If the cycling center is intact, it may be able to take over and initiate a rhythm which the rested pituitary and ovary may be able to follow. The fact that infertility is corrected less often than the menstrual rhythm may be due to mechanical problems, irreversible pathology of the ovary, or to as yet unknown factors. Leclercq⁸⁸ examined a successfully resected polycystic ovary some years later and described its appearance as "entirely normal." Others, including ourselves, have observed recurrence of the symptoms and again a typical gross pathology at the time of the second wedging. Whether these changes persisted or recurred is impossible to say.

There are, of course, many additional and perhaps very important factors which this tentative working hypothesis has not included. Puzzling instances of unilateral polycystic disease have been reported.⁸⁹⁻⁹¹ There is the question of the intrinsic responsiveness of the ovarian tissue to gonadotropin. Many animal experiments have shown that the administration of gonadotropin will produce a type of polycystic ovary in the hypothyroid animal, whereas that same treatment will be ineffective in euthyroid controls.^{92, 93} The excessive enlargement of human polycystic ovaries in response to gonadotropin^{94, 95} or clomiphene is an observation which requires further clarification. Taymor and Barnard⁹⁶ have recently supported the observations of Ingersoll and McArthur⁹⁷ of an intermittent elevation of urinary LH in some patients with polycystic ovaries and found these changes in patients with both normal-sized and enlarged ovaries. Many technical difficulties as well as troublesome day-to-day variation in gonadotropin output beset these investigations; improved methods and additional studies may explain the "normal" results and hopefully provide correlations with the neurohypophyseal studies in rodents.

At all events, these advances in ovarian biochemistry and neurohypophyseal relationships have suggested new approaches for research on the polycystic ovary problem and a working diagram which can be tested and will no doubt be modified, perhaps greatly, by future observations. The clinical

implications of the findings we have summarized are equally important. A more flexible attitude and a critical re-examination of our diagnostic criteria is evidently needed. Which cases of "secondary amenorrhea" or "functional uterine bleeding" might be associated with polycystic ovaries? What functional or in vitro studies will improve our ability to select those cases most likely to benefit from wedge resection, and what factors are present in those cases where surgery fails? Would the action of progesterone in the persistent-estrus rat be duplicated in the human—i.e., would there be a beneficial result from giving large doses of progesterone postoperatively to promote storage of gonadotropin in the pituitary? These and many other vital questions await further research in polycystic ovarian disease.

Abstract

Polycystic ovary syndrome predisposes alterations which contribute to the reduction of quality of life. This randomized controlled clinical trial study was to evaluate the effect of two protocols of aerobic exercise on quality of life in women with polycystic ovary syndrome. Women were allocated to three groups: continuous aerobic training ($n=28$), intermittent aerobic training ($n=29$), and control group (no training; $n=30$). Testosterone levels, body composition indices, and quality of life were assessed at baseline and after 16 weeks of intervention. Both protocols were effective to improve testosterone levels, anthropometric indices, and quality of life in polycystic ovary syndrome women. Thus, these protocols should be included in the clinical environment to improve clinical parameters psychological, biological and social health to this population.

Keywords

aerobic exercise, anthropometric indices, polycystic ovary syndrome, quality of life, testosterone

Introduction

Polycystic ovary syndrome (PCOS) affects 5%–16% of women of reproductive age (Ding et al., 2017) and is characterized by the presence of at least two of the following factors: clinical and biochemical hyperandrogenism, polycystic ovaries, and oligomenorrhea or anovulation (Consensus Amsterdam, 2012; Consensus Rotterdam, 2004). PCOS is marked by hormonal and anthropometric changes, as well as by metabolic disorders, which increase

the risk of cardiovascular disease (Alves et al., 2017; Anagnostis et al., 2018; Consensus Rotterdam, 2004; Ribeiro et al., 2016). Furthermore, all of these changes and disorders associated with PCOS culminate in an increased risk of sexual dysfunction, reduced quality of life (QoL), and altered emotional state for those affected by this syndrome (Borghi et al., 2018; Elsenbruch et al., 2003; Lopes et al., 2018; Shafti and Shahbazi, 2016; Stapinska-Syniee et al. 2018).

Previous evaluations of QoL through the use of the 36-Item Short-Form Health Survey (SF-36) in women with PCOS have shown differences in the domains of social functioning, vitality, emotional functioning, and sexual dysfunction (Aliasghari et al., 2017; Elsenbruch et al., 2003; Panico et al., 2017). Possibly, an increase in body mass index (BMI) and hirsutism are factors that interfere with these QoL scores (Aliasghari et al., 2017; Jones et al., 2011; Shishehgar et al., 2016), since these characteristics may cause self-image distortion, leading to a negative self-assessment with implications on the psychological condition of women with and without PCOS (Becker et al., 2017; Campbell and Hausenblas, 2009; Hahn et al., 2005; Kowalczyk et al., 2012). Furthermore, it has been shown that many of the characteristics associated with PCOS contribute to lower self-esteem with negative impact on QoL (Benetti-Pinto et al., 2015; Hahn et al., 2005; Panico et al., 2017; Shishehgar et al., 2016).

Isolated pharmacological treatment has been found to be ineffective in controlling the clinical condition of PCOS, and complementary measures such as lifestyle changes and exercise are recommended (Costa et al., 2018; Kogure et al., 2016; Lara et al., 2015; Lopes et al., 2018; Ribeiro et al., 2016; Thomson et al., 2010). Previous studies conducted by our research group have demonstrated the positive effects of physical strength training on QoL (Ramos et al., 2016), while in another study, the benefits of aerobic exercise in PCOS were demonstrated (Costa et al., 2018). Relatedly, the positive effects of exercise on QoL have been demonstrated in different clinical conditions and different populations (Brown et al.,

2018; Hayashino et al., 2018; Vasiliadis and Bélanger, 2018). However, there is a lack of research comparing different protocols of exercise to discriminate which is more effective in improving the QoL of women with specific clinical conditions such as PCOS. This information is relevant as there are indications that intermittent aerobic exercise is associated with greater satisfaction for those performing the exercise, which favors adherence to the exercise program (Thum et al., 2017). Thus, identifying the best exercise protocol is essential for the development of care programs for women with PCOS. Therefore, this study aimed to verify and compare the effects of continuous aerobic exercise and intermittent aerobic exercise protocols on the QoL of women with PCOS.

Methods

Study design and participants

This study was registered in ISRCTN10416750 and approved by the Institutional Review Board of the University Hospital, Ribeirão Preto Medical School, University of São Paulo (protocol no. 9640/2014).

This study was designed as a randomized controlled clinical trial in which women with a diagnosis of PCOS, based on the Rotterdam criteria (Consensus Rotterdam, 2004), were recruited as participants. Advertisements in the city newspaper and on the university website were used to recruit participants for the study.

The women selected as participants were invited to follow up at the Gynecological Endocrinology Outpatient Clinic of the Human Reproduction Sector of the Department of Gynecology and Obstetrics of the Ribeirão Preto Medical School, University of São Paulo, the setting for this study. All participants signed an informed consent form prior to being allowed to participate in the study.

Exclusion criteria were age less than 18 years and greater than 39 years, BMI less than 18 and greater than 39.9 kg/m^2 , women using drugs that interfered with the hypothalamic-pituitary hormone function (i.e. hormonal contraceptives,

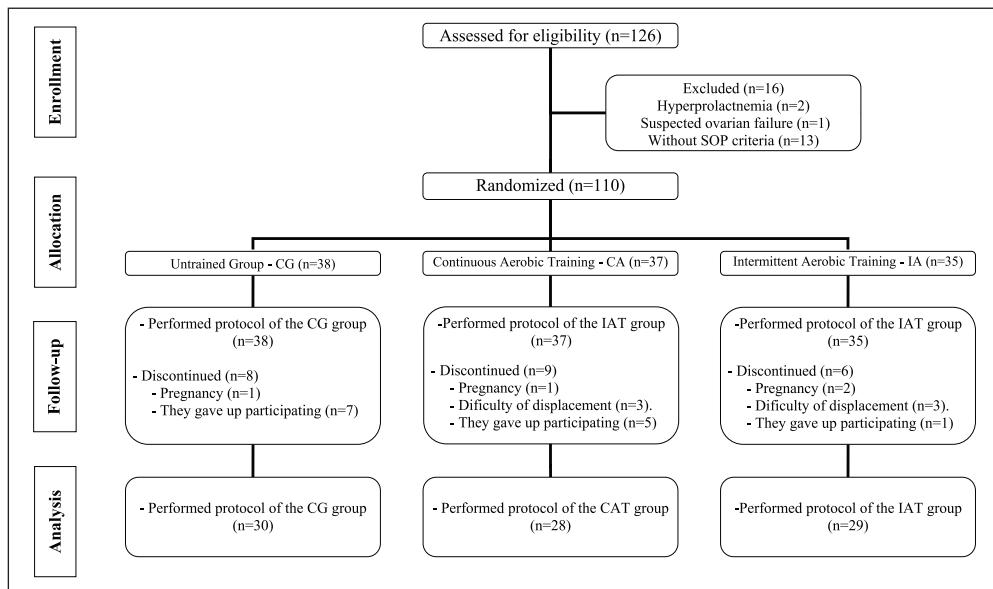

Figure 1. Selection of participants.

estrogen and progestin drugs, hormone therapy, gonadotropin-releasing hormone (GnRH) analogues and antagonists), pregnant women, smokers, and women with diabetes, congenital adrenal hyperplasia, thyroid diseases, hyperprolactinemia, Cushing's syndrome, or musculoskeletal disorders.

In this study, 126 volunteers were recruited. Of these, 16 were excluded during the initial evaluations. Thus, the remaining 110 started the physical training protocols. Of these, 23 were lost in the course of the study and 87 completed the study which were divided into continuous aerobic training (CAT; $n=28$), intermittent aerobic training (IAT; $n=29$), and control group without training (CG; $n=30$). The reasons for exclusions and withdrawals are described in Figure 1.

Randomization

The sample was randomly allocated by placing written assignments in sequentially numbered, sealed, opaque envelopes that were grouped in blocks of 15 participants, with five blocks for each group. The envelopes were consecutively

and separately collected, depending on each participant's BMI at the time of inclusion. A list of random numbers was generated by a computer and, after the participant consented to participate, the envelope was opened, and the participant was allocated into one of the three groups, according to the contents of the envelope. The generation of the random sequence was performed by a researcher and the sealing of the envelopes was performed by an assistant, neither of whom participated in the recruitment nor the allocation of the participants. Another researcher recruited and allocated participants to the groups.

Intervention and evaluation

Before and after the intervention, measurements were conducted, with all post-exercise intervention assessments occurring 72 hours after the last exercise training session. The first part of the evaluation included anthropometric measurements. Waist circumference (WC) was measured with the participant in the standing position, with arms at the side of the body, feet together, and with a relaxed abdomen. For WC, a horizontal measurement was obtained on the

CA: continuous aerobic; IA: intermittent aerobic; HR: heart rate.

Added 5 minutes of heating and 5 minutes of cool down.

narrower part of the dorsum (above the navel and below the xiphoid process; Ciconelli et al., 1997). Hip circumference (HC) was measured using the same positioning, as the region with the largest circumference of the buttocks (American College of Sports Medicine (ACSM), 2014). Waist-to-hip ratio (WHR) was measured by dividing the WC value by the HC value (ACSM, 2014).

Testosterone was measured before and after the intervention, through the use of the chemiluminescence method (Immulite 1000, Siemens). Prolactin, thyroid stimulating hormone (TSH), and 17-hydroxyprogesterone (17-OHP) were measured before the intervention using the chemiluminescence method (Immulite 2000, Siemens XPI). For these measurements, 20 mL of whole blood was collected until the eighth day of the menstrual cycle (early follicular phase), or any day if the patient was in amenorrhea. Ovary morphology was assessed by ultrasound, using the Voluson E8 Expert (GE

HealthCare, Zipf, Austria) equipped with a 5–9 MHz vaginal probe (RIC5-9D).

QoL was assessed by the validated Portuguese version of the self-reported MOS SF-36, which consists of eight subscales: (1) Physical Role Function, (2) Physical Functioning, (3) Bodily Pain, (4) General Health Perception, (5) Vitality, (6) Social Role Functioning, (7) Emotional Role Functioning, and (8) Mental Health. Subscale scores range from 0 to 100, with a lower score indicating lower QoL for that subscale (Ciconelli et al., 1997; Martinez et al., 2004).

Participants were instructed to maintain the same daily diet for the duration of the study. Using Embreex 570-L and Embreex 570-Pro treadmills, the two protocols of aerobic training were performed: Continuous and intermittent aerobic exercise. The duration of the exercise intervention was 16 weeks, with three sessions per week (Table 1). The intensity of the training was monitored by a heart rate monitor (Polar RS810). To ensure equivalent training volume

for both protocols, heart rate percentage was multiplied by the session duration (in minutes; ACSM, 2014). To calculate intensity, a formula of [maximum heart rate (HR_{max}) \times % intensity] was used (ACSM, 2014). The training protocol included a 5-minute warm up and a 5-minute cool down between 50% and 60% of the maximum heart rate. The target intensity areas of training followed the recommendations of ACSM (2014). The IAT and CAT protocols were performed in the Cardiovascular Physiology and Physiotherapy Laboratory. Participants' adherence to the training intensity was monitored by a team of personal trainers and physiotherapists.

Sample size

The sample size was calculated using the GPower program, version 3.1.92 (see <https://pt.freedownloadmanager.org/Windows-PC/GPower-GRATUITO.html>). The sample size was obtained considering a Cohen's d effect size of 0.6, a significance level of 5%, and a test power of 80%. According to Cohen's agreement, 24 patients are necessary to achieve a moderate difference between groups (CAT, IAT, and CG). The final sample was increased by to cover the losses (Figure 1; Miot, 2011).

Statistical analyses

Means and standard deviations were calculated for all variables and included a 95% confidence interval (CI), where appropriate. Anthropometric and laboratory measurements, as well as scores on the SF-36 were compared using a planned orthogonal contrast in the mixed effects linear regression model. Repeated measures from the same participant were considered as random effects (i.e. more than one measurement for the same participant). Age, group, time, BMI, WHR, testosterone, and interaction between group and time were examined as covariates for all analyses to evaluate the training effects both within and between groups. All statistical analyses were performed using SAS® Software Version 9.4 (SAS Institute Inc., University of

North Carolina, Chapel Hill), with $p < 0.05$ considered to be statistically significant.

Results

Anthropometric and laboratory data

Upon examination of the baseline measurements, no significant differences were found between the three groups with regard to age, height, and levels of prolactin, 17-OHP, and TSH. The groups were also homogeneous with regard to the BMI, WC, and WHR variables. However, the CAT showed significantly higher values of testosterone in relation to the CG ($p = 0.014$) in the baseline measurement (Table 2).

Following the intervention, a significant reduction in WC was found in the CAT ($p = 0.045$) and IAT ($p = 0.049$) groups. Conversely, a significant increase in WC was found in the CG group ($p = 0.014$). HC was significantly reduced in the CAT group ($p = 0.032$). Furthermore, there was a significant reduction of WHR in the IAT group ($p = 0.012$). Finally, testosterone levels in the CAT ($p < 0.001$) and IAT ($p = 0.019$) groups were significantly lowered (Table 2).

QOL—SF-36 scores

At baseline, there was no significant difference between the three groups regarding SF-36 scores. Following the 16-week intervention period, there were no significant differences found in the CG when compared with baseline scores. However, with regard to the CAT group, there was a significant increase in Physical Functioning ($p = 0.022$), Physical Role Functioning ($p < 0.001$), General Health Perception ($p < 0.001$), Vitality ($p < 0.001$), Social Role Functioning ($p < 0.001$), Emotional Role Functioning ($p < 0.001$), and Mental Health ($p = 0.001$). For the IAT group, significant increases were found in Physical Functioning ($p < 0.001$), Physical Role Functioning ($p = 0.027$), General Health Perception ($p < 0.001$), Vitality ($p < 0.001$), Social Role Functioning ($p < 0.001$), Emotional Role Functioning ($p = 0.011$), and Mental Health ($p < 0.001$) (Table 3).

Discussion

This study aimed to evaluate the effects of continuous and intermittent aerobic exercise protocols on QoL in women with PCOS. Both protocols were found to be effective in improving physical, emotional, and social functioning as well as vitality, mental health, and the perception of general health, as indicated by increased scores on the SF-36, a measure of QoL. In addition, there was a reduction of WC, HC, and testosterone in the CAT group and WC, WHR, and testosterone in the IAT group. Furthermore, there was an increase in WC in the CG group.

Based on a review of related research, it appears that this is the first study to compare the effects of two aerobic exercise protocols on QoL in women with PCOS, making this study particularly relevant to improving care for this population. Although there was no improvement in BMI as previously demonstrated (Frène et al., 2015; Stener-Victorin et al., 2013), this study provided evidence of various benefits from physical exercise. Consistent with the results of this study, a recent study evidenced the effectiveness of a lifestyle and physical exercise program in promoting QoL in women with PCOS, even without improvement in BMI (Frène et al., 2015). Similarly, another study provided evidence of improved depression and QoL in women who were identified as overweight or obese (Thomson et al., 2010).

Different protocols have been used to prove the beneficial effects of exercise on QoL in other populations such as older persons and individuals with cancer and type II diabetes (Brown et al., 2018; Hayashino et al., 2018; Vasiliadis and Bélanger, 2018). In studying women with PCOS, the most recent protocols have involved physical strength training and aerobic exercise (Costa et al., 2018; Ramos et al., 2016). A study by Ramos et al. (2016) included a protocol of progressive intensity with a frequency of three times per week, over a 16-week period. The results of the study showed improvement in the Physical Role Functioning score of the SF-36 and a reduction

Table 3. Comparison of the SF-36 questionnaire scores of women with PCOS before and after the period without training (CG) or 16-week physical training.

of WC in this population (Ramos et al., 2016). Similarly, Costa et al. (2018) used a three times per week, 16-week, open-field aerobic exercise protocol which evidenced the improvement of the Physical Role Functioning, General Health Perception, and Mental Health domains of the SF-36 questionnaire. In this study, which included a larger sample size, all of the SF-36 questionnaire scores were increased, with the exception of the Bodily Pain subscale, both in the intermittent and continuous training protocols, thus demonstrating improvement across a broader span of variables related to QoL.

Women with PCOS are frequently dissatisfied with their body image (Micskei et al., 2014). This study found a significant reduction in the anthropometric indices following the exercise protocols, which may have contributed to the improved perception of body image as evidenced by an improvement in QoL scores, mainly with regard to physical and emotional perceptions (Micskei et al., 2014). In addition, there was a significant reduction in the serum concentration of testosterone following both protocols, which may have also contributed to the improvement of QoL scores. Therefore, it is possible that the reduction of testosterone, as observed in this study, may be a predictive factor of improvement in QoL, mainly with regard to emotional functioning and overall general health status. Furthermore, aerobic physical exercise has been found to promote an adjustment in cortisol levels and increase levels of anandamide and serotonin which, together, promote the improvement of mood (Heijnen et al., 2015; Park et al., 2017). Similarly, treadmill exercise has been shown to improve serotonergic function by reducing depressive symptoms (Shin et al., 2017). Previous research has shown that improvements in mood and depressive symptoms may lead to an improved QoL (Böttcher et al., 2018; Wright et al., 2013).

Care was taken in the design of the protocols used in this study to avoid injuries by standardizing the same training volume and duration of the sessions, both for the CAT and IAT interventions. Previous studies have demonstrated that intermittent aerobic exercise allows individuals to perform the same volume as continuous exercise training but with a shorter duration, which

seems to favor greater adherence to the exercise program (Thum et al., 2017). In this study, the same training volume intensity and duration of sessions were maintained in order to compare the efficacy of the continuous and intermittent protocols. Furthermore, the intensity of the training was diluted throughout the sessions to avoid injuries, which allowed the training of individuals with a large variation in BMI (18–39.9 kg/m²), without any cases of orthopedic injury. Although there were cases of participant withdrawal throughout the study for various reasons, there was considerable permanence in the groups trained in both protocols (Figure 1). It is possible that the inclusion of group exercises favored the creation of bonds between the participants, which may have been a stimulus for adherence to the program, as previously demonstrated (Thum et al., 2017).

Strengths and limitations

The main strengths of this study are that this was a randomized clinical trial, and the structure of the two different training protocols was well defined. However, one limitation was the lack of menstrual cycle control and hirsutism observed in some participants after training, which may have directly interfered with the QoL results. In addition, the sample of participants in the training groups did not reach the desired quantitative goal of 30 per group.

Future research

For future research, an objective evaluation of hirsutism through the use of the Ferriman–Gallwey Scale (Ferriman and Gallwey, 1961) after the end of the exercise and control period is suggested in order to control for this variable, which is known to interfere with self-image (Morotti et al., 2013) and may influence the evaluation of QoL of women with PCOS.

Conclusion

Continuous and intermittent aerobic exercise protocols were found to be equally effective in reducing anthropometric indices and hyperandrogenism,

and in the improvement of QoL in women with PCOS. Thus, these protocols should be included in the clinical environment to improve clinical parameters psychological, biological and social health to this population.

Acknowledgements

We thank all the participants who volunteered for this study. We appreciate their willingness to exercise with unwavering intensity and to sacrifice many of their normal activities to adhere to the described protocol. We also thank the members of the Centre of Physical Education, Recreation, and Sports at the University of São Paulo and members of the Department of Obstetrics and Gynecology (FMRPUSP), and the sector of assisted human reproduction, especially Océlia de Vasconcelos and Maria Aparecida Vasconcelos for blood collection and Cristiana Carolina Padovan for technical support.

Availability of data and materials

Data sets generated during and/or analyzed during this study are available to the corresponding author upon reasonable request, subject to the privacy of the participants.

Declaration of conflicting interests

The author(s) declared no potential conflicts of interest with respect to the research, authorship, and/or publication of this article.

Funding

The author(s) disclosed receipt of the following financial support for the research, authorship, and/or publication of this article: This research was supported by the São Paulo State Research Foundation (FAPESP—process 2015/14031-0) and scholarships by National Council for Scientific and Technological Development (CNPQ) and Coordination for the Improvement of Higher Education Personnel (CAPES)—Finance Code 001.

DEVELOPMENT OF KAP TOOL AND ITS APPLICATION IN ASSESSMENT OF YOUNG FEMALES WITH PCOS.

Mrs. Shubhi Agarwal*	M.Sc.NET, PhD scholar, Dept. of Food and Nutrition and Research Centre, Smt.V.H.D.Central institute of Home science. Assistant professor ,Mount Carmel College, Autonomous, Bengaluru.*Corresponding Author
Dr.Usha Devi C	PhD, Associate professor, Head of the Dept. of Food and Nutrition and Research Centre, Smt.V.H.D.Central institute of Home science, Bengaluru, Bengaluru

ABSTRACT **BACKGROUND:** Polycystic ovary syndrome (PCOS) is the most common endocrine disorder amongst women of reproductive age associated with various clinical and psychological manifestations. Promoting awareness and lifestyle modifications is essential to empower the female PCOS population to take health care decisions for the treatment and management. **OBJECTIVE:** Assessment of knowledge, attitude and practice(KAP) among PCOS population is significant in behavioral and lifestyle modification. Thus, the present study was undertaken to develop a KAP tool. **METHODS:**An observational, non-controlled study was conducted using random sampling in the age range of 15-25 years. A total of 600 subjects were screened with the help of a standardized screening questionnaire and the presence of PCOS was confirmed using the Rotterdam criteria (2003).A KAP tool validated by an expert panel was given to the subjects confirmed for PCOS to assess knowledge, attitude and practices. The validity was assessed using exploratory factor analysis. The Spearman-Brown correlation coefficients helped to assess reliability for knowledge, attitude and practice domains, which were found to be 0.83, 0.63 and 0.47 respectively. **RESULTS:** Significant knowledge was found among confirmed PCOS subjects, but had low attitudes and their practices did not commensurate with their knowledge about PCOS and Nutrition. **CONCLUSION:** The present research contributes to the understanding of a growing PCOS epidemic in urban India and document the need to screen knowledge, attitude and practice, to develop supportive interventions addressing quality of life issues to reduce the distress among women with PCOS.

KEYWORDS : PCOS; Rotterdam Criteria; glucose tolerance; insulin resistance; KAP; lifestyle modification; development; validation; reliability

INTRODUCTION

Polycystic ovary syndrome (PCOS) is one of the commonest endocrine disorders seen in young women characterized by three classic symptoms: Irregular menstrual periods ,excessive hair growth and or Polycystic ovaries.[1]

In a survey, it was found to be 9.13% prevalent among south Indian adolescent girls.[2] World Health Organization (WHO) indicated that PCOS affected 116 million (3.4%) of women worldwide.[3]

Women with PCOS are also at an increased risk of psychological implications. Lifestyle management is currently advised as the first line management strategy for PCOS. Therefore, assessment of knowledge, attitude and practice is significant in behavioral and lifestyle modification.

OBJECTIVES

The study aimed at assessing the knowledge, attitude and practices among subjects confirmed for PCOS.

2. MATERIAL AND METHODS

Sample size and Selection of subjects:

Random sampling technique was used to select subjects .Screening questionnaire was distributed to 600 subjects. Responses were received from 521 subjects. Based on the inclusion criteria, 56 subjects were considered for the study. Average age of the selected subjects was 21.5 years.

INCLUSION CRITERIA:

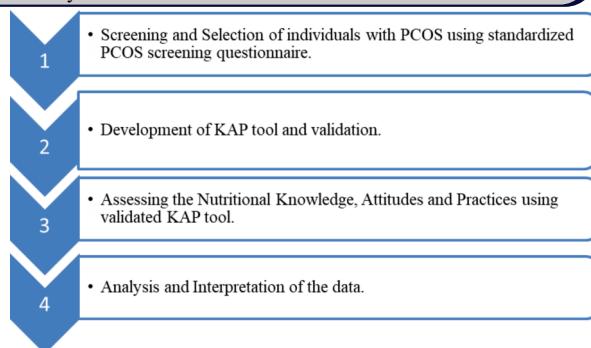

Females aged between 15-25 years of age.

- Confirmed cases of PCOS based on Rotterdam Criteria which requires the presence of any two of the following:
- Oligo/anovulation
- Clinical or biochemical signs of hyperandrogenism
- Polycystic Ovaries on Ultrasound
- Subjects willing to be a part of the study.

EXCLUSION CRITERIA:

- Subjects beyond the required age group.
- Individuals with congenital adrenal hyperplasia, androgen secreting tumors, Cushing syndrome, thyroid dysfunction and hyperprolactinemia as mentioned in the Rotterdam criteria of PCOS diagnosis.

Research Design

EVALUATION TOOLS

a) SCREENING QUESTIONNAIRE

A pre-developed screening questionnaire was used to screen and identify women with PCOS. The questions were based on Awareness, Diagnosis, symptoms of PCOS and presence of any psychological conditions such as stress, depression, body image issues etc.

b) KAP questionnaire- KAP questionnaire was constructed and validated with the aim of assessing knowledge, attitudes and practice of the subjects.

Knowledge, attitude and practice play main roles in the Knowledge-Attitude-Practice (KAP) model, which proposes that accumulated knowledge in a health aspect initiates changes in attitude, and results in gradual behavior change.[4]

Development - The aim was to develop and examine the validity and reliability of the KAP questionnaire towards the syndrome among PCOS women aged 15-25 years. Various literatures were reviewed using journal databases, existing reports, books, opinion from the experts and inputs from the diagnosed PCOS cases. The retrieved information was included in knowledge, attitude and practice domains.

Validation-Validity has been described as the agreement between a test score or measure and the quality it is believed to measure. [5]

Face validity- The retrieved information was included in knowledge, attitude and practice domains. Following this, a guided self-administered questionnaire was developed which comprised 25

knowledge items, 19 attitude items and 27 practice items. Items were generated with emphasis on features of PCOS.

Content validity- Content validity refers to the extent to which the items on a measure assess the same content .[6] Content Validity is based on the extent to which a measurement reflects the specific intended domain of content.[7]It refers to the conceptualization of the statements for developing the scale for the study. The developed KAP questionnaire was reviewed by a panel of 12 experts including registered dietician, academicians, gynecologist, psychologist and confirmed PCOS cases. The experts reviewed each item of the questionnaire based on content relevance, clarity, simplicity and ambiguity and rated each question on the following scale of 5[8]

- Not necessary
- Less than average
- Average
- Significant
- Most significant

The comments from content and face validation were considered and items were either edited, removed or remain unchanged with the help of factor analysis.

Factor analysis - It assesses the degree to which the individual items on a scale truly cluster around one or more concepts. Items designed to measure the same concept should load on the same factor. .

Reliability- reliability is the extent to which the instrument yields the same results on repeated measures. It is concerned with consistency, accuracy, precision, stability and homogeneity.

Assessment of knowledge, attitude and practice

In diagnosed and confirmed cases knowledge, attitudes and practices were assessed based on their awareness about the disease, symptoms, consequences, personal experience and concern towards the disease and their adopted lifestyle modifications.

This was followed by Statistical interpretation of the data.

Ethical considerations

The protocol was approved by the institutional human ethical committee-Nutri-Explore ethics committee (NEEC BU 012).An approved consent was also obtained from the study participants.

RESULTS

Screening questionnaire

General information of the subjects

It was observed that the 67% of the subjects were in the age group of 15 – 18 years, 30% and 3% of the subjects were between 19 – 22 and 27-30 years of age respectively.

99% of the subjects were single whereas 1% of the population was married.

Table 1. Menstruation related symptoms

Average age of menarche in the study population was found to be 12.7 years.

	Number	Percentage
Occurrence of regular menstruation		
Yes	384	74
No	56	11
Sometimes	81	15
Total	521	100
Frequency of occurrence of menstrual cycle	Number	Percentage
Less than 25 days	58	11
Every 25 th day	200	38
More than 30 days	110	21
Variable days	153	30
Total	521	100
Time of noticing irregular menstrual cycle	Number	Percentage
No irregularity	189	36
A year after attaining puberty	178	34
Two years later	40	8
After more than two years	114	22
Total	521	100
Observation during menstruation	Number	Percentage

Heavy bleeding	82	16
Moderate bleeding	373	72
Spotting	11	2
Blood clots	55	10
Total	521	100

It can be observed from the above table that 26% of these subjects showed irregularity in the menstruation. For 11% of the subjects, the duration of menstrual cycle was found to be less than 25 days, 34% of the subjects noticed irregularity in menstruation a year after attaining puberty and 16% of the subjects had heavy bleeding during menstruation.

Table 2 Diagnosis and Clinical signs of PCOS among the subjects.

Subjects diagnosed with PCOS	Number	Percentage
	Yes	11
	No	89
Specific test done by the subjects for the diagnosis of PCOS	Total	100
	Yes	12
	No	88
Excess of hair growth on face	Total	100
	Yes	11
	No	89
Presence of coarse hair growth at 3 or more sites	Total	100
	Yes	17
	No	83
	Total	100

The above table shows that among the study population 11% of the subjects were diagnosed with PCOS. Though from the same study it was found 26% of the study population was at risk of PCOS.

It was also observed that 12% of the subjects got specific test done for the diagnosis of PCOS and 11% of the subjects were found to have excess hair growth on the face whereas 17% of the subjects had coarse hair growth at 3 or more site.

Table 3. Correlation between PCOS and menstruation Irregularity

Undergone tests to confirm PCOS	Notice of irregular Menstrual cycle				Significance of Chi square test
	No irregularity	A year after attaining puberty	Two years later	After more than two years	
Yes(56)	1	24	10	21	18.2345**
No(465)	188	154	30	93	

** Significant at 1% level

The above table suggests that confirmation of PCOS had significantly higher association with irregularity of menstrual cycle with the chi square value being 18.2345.

Table 4 Correlation between PCOS and clinical sign

Undergone tests to confirm PCOS	Excess growth of hair on face		Significance of Chi square test
	Yes	No	
Yes	21	35	21.1607**
No	37	428	
** Significant at 1% level			
Undergone tests to confirm PCOS	Coarse hair growth at 3 or more sites		Significance of Chi square test
	Yes	No	
Yes	20	36	16.3090**
No	67	398	
** Significant at 1% level			

It can be concluded from table 4 that there was a significant association seen between confirmation of PCOS and coarse hair growth at 3 or more sites and the chi square value was found to be 16.3090.

KAP Questionnaire

Content validity

For the content validation, the KAP questionnaire was given to the

expert panel. Several suggestions and feedbacks were received related to the framing of questions and every item in the questionnaire was rated as adequately relevant, clear, simple and non- ambiguous. With this, the tool was made adequate for the present study.

Construct validity

Based on the comments provided by the expert panel, factor analysis was done to assess construct validity which helped to check the importance of each questions. It was found that knowledge section of the instrument had 25 questions initially. Among 25 questions, factor analysis showed 7 components with cumulative percentage variance of 94% which were later plotted on scree plot to derive eigen values. These component matrix were then rotated with the Varimax with Kaiser Normalization method in which question no. 9 and 24 were discarded and rest 23 were selected for the further study.

Attitude section had 19 questions initially among which factor analysis showed 6 components with cumulative percentage variance of 89% which were later plotted on scree plot to derive eigen values. These component matrix were then rotated with the Varimax with Kaiser Normalization method in which question no. 12, 14, 15 and 17 were discarded and rest 15 were selected.

Practice section had 25 questions initially among which factor analysis showed 7 components with cumulative percentage variance of 94.6% which were later plotted on scree plot to derive eigen values. These component matrix were then rotated with the Varimax with Kaiser Normalization method in which question no. 11, 21 and 24 were discarded and rest 23 were selected for the further study.

Reliability

Reliability analysis was done to assess the reliability of the instrument. For this, split of reliability was worked out to find the correlation

Table 5. Reliability analysis

	Reliability	Cronbach's Alpha I	Cronbach's Alpha II
Knowledge	0.83 (83%)	.712	.301
Attitude	0.63 (63%)	.481	.272
Practice	0.48 (48%)	.630	.810

The Knowledge tool had an association (Correlation) of 83%. Higher the value of reliability coefficient, higher will be the correlation i.e. the instrument was found to be more reliable for further use.

The Cronbach's Alpha for part I and part II gives the strength when the items are divided in two parts. (Split half) The significance of reliability coefficient is not tested.

Assessment of knowledge, attitudes and practices

The analysis of validated KAP questionnaire showed that knowledge scores among the subjects (n=40) was found to be 80.5 ± 15.02 , attitude scores was 43.95 ± 6.61 and practice score was found to be 60.10 ± 6.86

Table 6. Correlation between Knowledge, Attitude and Practice among subjects

	Knowledge	Attitude	Practice
Knowledge	1.0000		
Attitude	0.7356**	1.0000	
Practice	0.5249**	0.5693**	1.0000

** Significant at 1% level

The above table shows that there was a significant correlation between Knowledge and Attitude (0.7356). A significant correlation also exists between Knowledge and Practice (0.5249) and Attitude and Practice (0.5693) among the subjects.

DISCUSSION

The conducted study showed that PCOS has a great association with menstrual irregularity and facial hair growth.

In one of the study conducted it was observed that the prevalence of Polycystic Ovaries increased significantly with the irregularity of the menstrual cycle pattern. [9]

Similar findings were reported where it was observed that the excess amount of androgens production in PCOS women prevents ovulation, may cause infertility, acne and abnormal hair growth, such as excess facial hair or male pattern baldness.[10]

In another study conducted in New Delhi to study the clinical manifestations in PCOS women it was found that the prevalence of menstrual irregularities, clinical hyperandrogenism, endometrial hyperplasia (EH), and type 2 diabetes mellitus was significantly higher in the PCOS women.[11]

There is an escalation in the prevalence of PCOS due to the nutritional transitions of developing countries towards obesogenic lifestyle. The rising incidence coupled with the etiological complexity of PCOS calls for the effective management of this condition to improve the quality of life.

The Developed KAP Questionnaire helped in acquiring the information regarding Knowledge, Attitude and Practices of the selected subjects pertaining to Nutrition and PCOS .It was clearly evident that the subjects had low attitude and their practices were not commensurate with the knowledge they had about PCOS and Nutrition. Contrasting results were observed in one of the study conducted by Patel et al ,2018 in young central Indian Population, where among 400 participants, only 41% of the women were aware of the term PCOS and very few young women understood the earliest symptoms that should alarm them to consult a physician.

Another study observed that most of the subjects in the study had poor knowledge regarding polycystic ovarian syndrome. After the educational sessions there was enhancement of knowledge score on polycystic ovarian syndrome. [12]

Similar findings were obtained in one more study where nutrition education improved KAP scores significantly and Ninety-seven per cent of the participants rated the overall intervention and its delivery as 'very good to excellent', reporting that they would recommend this educational intervention to colleagues.[13]

CONCLUSION

The study is helpful in addressing the gaps in knowledge, attitudes and practices and encourage females to consult health professionals for effective management of PCOS .The study also paves the way for the development of nutrition education material and initiation of awareness generation programs for PCOS.

Many studies have shown that Educational program conducted regarding PCOS, Diet and Lifestyle intervention have improved the knowledge, attitudes and practices among women with PCOS. The developed questionnaire can be used to identify the gaps among the target population and would further help in designing the various awareness and educational programs for PCOS population.

ACKNOWLEDGEMENT: The authors are thankful to the subjects for eliciting information and helping in the successful conduction of the study.

ABSTRACT

Objective: To estimate the incidence and prevalence of polycystic ovary syndrome (PCOS) in UK primary care and investigate prescribing patterns before and after a PCOS diagnosis.

Design: Retrospective cohort study.

Setting: UK primary care (2004–2014).

Participants: Women aged 15–45 years.

Primary and secondary outcome measures: The incidence and prevalence of diagnosed PCOS and probable PCOS (ie, those without a confirmed diagnosis but with at least 2 PCOS features recorded within 3 years). Among women with diagnosed or probable PCOS, the prevalence of prescribing of drugs typically used to treat PCOS was calculated prior to and in the 24 months after the diagnosis of PCOS.

Results: We identified 7233 women with PCOS diagnoses and 7057 women with records suggestive of probable PCOS, corresponding to incidence rates of 0.93 and 0.91 per 1000 person-years at risk (PYAR) and an overall rate of 1.84 per 1000 PYAR. Women aged 20–24 years and women living in deprived areas had the highest incidence of PCOS. The prevalence of PCOS in 2014 was ~2%. The proportion of women with a prescription in the 24 months after their PCOS index date varied by drug type: 10.2% metformin, 15.2% combined oral contraceptives, 18.8% acne-related treatments, 1.93% clomiphene, 1.0% spironolactone, 0.28% cyproterone and 3.11% eflornithine. Acne-related treatments were more commonly used to treat probable (28.3%) than diagnosed (12.3%) cases, while metformin was prescribed much more commonly in diagnosed cases.

Conclusions: In conclusion, compared to rates estimated in community samples, the incidence and prevalence of women presenting in primary care with PCOS diagnoses and features are low, indicating that PCOS is an under-recognised condition. Although considerable variation is observed in treatments prescribed to women with PCOS, the treatments initiated following a confirmed diagnosis generally reflect the long-term prognostic concerns raised in PCOS consensuses.

BACKGROUND

Polycystic ovary syndrome (PCOS) is associated with a wide range of reproductive,

Strengths and limitations of this study

- The current study is the first to investigate the incidence and prevalence of polycystic ovary syndrome (PCOS) in the primary care setting in the UK and the longitudinal nature of the database allowed us to examine trends over a long time period, which has not been captured by previous epidemiological studies.
- Underdiagnosis was the main concern for the current study as only data considered relevant at the time of a consultation are recorded by clinicians although we attempted to include women with two or more features of PCOS as potential cases.
- Our study investigated the prescribing patterns of PCOS in the UK primary care, which has not been well explored in previous studies. These findings reflected the current management of PCOS in the clinical practices and provide important indications for general practitioners.

cardiometabolic and dermatological abnormalities. One of the most prominent symptoms in patients with PCOS is oligomenorrhea. Consequently, women with PCOS are highly likely to be infertile and potentially develop endometrial hyperplasia due to continuing secretion of oestrogen without ovulation.^{1 2} Furthermore, emerging evidence has suggested that ~50–70% of patients with PCOS have insulin resistance regardless of their body weight or body mass index.³ Consequently, women with PCOS are at an elevated risk of developing various common metabolic disorders compared with the general population.⁴ In addition, many patients with PCOS are observed to have an elevated androgen level, which leads to hirsutism, alopecia and acne.¹

While the epidemiology of PCOS in the community has been well studied,^{5–8} the proportion of women who present in routine clinical practice with PCOS features and the extent to which these women are subsequently diagnosed are less clear. Similarly,

while a range of treatments have been suggested for the management of PCOS,⁹ there is very little information regarding which of these drugs are actually prescribed in routine clinical practice. Such 'real-world evidence' can help identify priority areas for research, training and health promotion efforts. The current study sought to provide such evidence by investigating the recording of PCOS features and diagnoses in UK general practice between 2004 and 2014 and the subsequent prescribing of pharmacological treatments.

METHODS

Data source

The Health Improvement Network (THIN) is one of the largest primary care data sources in the UK, including data from over 500 general practices, covering ~6.2% of the total population in the UK. Available data include patient demographics, medical history, test results, drug prescriptions and social deprivation as measured by quintiles of the Townsend score.¹⁰ Symptoms and diagnoses are recorded using a hierarchical clinical coding system (Read codes),¹¹ with additional information recorded as unstructured text. The information stored as unstructured text was not available in this study. Notably, as the data are collected in routine clinical practice, only information deemed clinically relevant is entered in a patient's record.

In our study, data were included from each practice that met minimum quality criteria, for example, acceptable computer usage (a time point when a practice is considered to use their computer system adequately, ie, at least one medical record, one additional health data record such as body mass index, laboratory test results and two therapy records are computerised annually for a practice) and acceptable mortality reporting (a time point which the observed death rates for a practice reach the standard predicted numbers of deaths derived from National statistics given the practice's demographics).^{12–14}

Study population

Women aged 15–45 years, who were permanently registered for at least 1 year, were included in the study population. Women with conditions that can cause similar symptoms to PCOS were identified and excluded. These conditions include prolactinoma, Cushing's syndrome, Nelson's syndrome, adrenal-related disorders (ie, adrenal tumours, adrenal hyperplasia) and pituitary disorders.

Case definition

PCOS cases were identified using two methods. First, Read codes for 'polycystic ovary syndrome' (C165.00), 'Stein-Leventhal syndrome' (C164.12) and 'endoscopic drilling of ovary' (7E25300) were used to identify those women who had been clinically diagnosed as PCOS cases (diagnosed cases). Women with two or more Read

codes indicative of PCOS features (menstrual/ovarian dysfunction, clinical and biochemical hyperandrogenism, polycystic ovaries) recorded in a 3-year period were then selected and we considered these as probable cases. These women were considered as those who were likely to meet at least one of the three major definitions of PCOS^{15–18} but who may not have been clinically diagnosed as having the condition. The index date for probable cases was considered to be the date the second PCOS feature was recorded. A full list of the codes used to define cases is provided in online supplementary table SI.

Covariates and prescription indicators

We extracted data on each woman's year of birth, ethnicity and deprivation level of the area in which the woman lived;¹⁰ data on prescriptions of interest (ie, combined oral contraceptives (COCs), progestin oral contraceptives (POCs), intrauterine devices, clomiphene, metformin, spironolactone, gonadotrophins, cyproterone, flutamide, eflofene, weight control/loss drugs, lipid regulators and acne-related drugs) were also included and information on prescribing of these drugs before and in the 24 months after each PCOS case index data was extracted.

Statistical analysis

For incidence estimation, the rate was computed as the total number of new PCOS cases recorded between 2004 and 2014 divided by the total number of person-years of follow-up. Person-time for the denominator was estimated by summing each woman's follow-up from the latest among (1) their 15th birthday, (2) 1 year after registration, (3) the date at which their practice met minimum quality criteria and (4) the 1 January 2004, to the earliest of the date among (1) their first incident diagnosis, (2) their date of death, (3) the date they left the practice, (4) the date data were last collected from their practice and (5) the 31 December 2014. All incidence rates were reported per 1000 person-years at risk (PYAR).

Hierarchical (patients were considered to be nested in each practice) multivariate Poisson regression models were used to estimate incidence rate ratios and 95% CIs comparing the incidence of first PCOS diagnoses across 5-year age bands, Townsend score quintiles and calendar period (ie, 2004–2007, 2008–2011 and 2012–2014).

The period prevalence of the diagnosis of PCOS was evaluated for the calendar year 2014. The denominator for the prevalence calculation consisted of any women with at least 1 year of postregistration follow-up, of which at least 6 months must have occurred in 2014. The prevalence of PCOS was also estimated within 5-year age bands. Secondary analysis was carried out to assess the sensitivity of the prevalence estimate to the length of the postregistration period (ie, 1 year, 2 years) and the minimum period registered within 2014 (ie, 3, 6 and 9 months).

Among the women with a diagnosis of PCOS, we calculated the number and proportion with a prescription for one of the drugs of interest at any point prior to their PCOS index date. Among the women without prescription for each drug of interest prior to the index date, we then calculated the proportion of women with a prescription for that drug within 2 years after the PCOS index date. We used cumulative incidence plots to describe how the proportion initiating different drugs increased over the 2 years following the PCOS index date for the time period 2004–2012.

All analyses were performed using STATA V.13.0 and were carried out for all PCOS cases and stratified by case definition (diagnosed PCOS vs probable PCOS).

RESULTS

In total, 7233 diagnosed and 7057 probable PCOS cases were identified among 2 087 107 female individuals aged 15–45 years old between 2004 and 2014. Table 1 describes the number of PCOS features identified in each group. The incidence rate of diagnosed PCOS cases was 0.93 per 1000 PYAR (95% CI 0.91 to 0.96), whereas the rate for probable cases was 0.91 per 1000 PYAR (95% CI 0.89 to 0.93). This equated to an overall combined incidence rate of 1.84 PYAR (95% CI 1.81 to 1.87).

The overall incidence of PCOS increased from 1.67 (95% CI 1.58 to 1.77) per 1000 PYAR in 2004 to 2.00 (95% CI 1.89 to 2.10) per 1000 PYAR in 2010, after which the rate remained relatively constant at ~2 per 1000 PYAR (figure 1). The incidence was the highest for those in the 20–24 year age group (3.59 per 1000 PYAR, 95% CI 3.47 to 3.70), whereas the 40–44 year age group had the lowest incidence (0.62 per 1000 PYAR, 95% CI 0.58 to 0.66). The age-specific trend of PCOS diagnoses was similar for diagnosed and probable cases. After adjusting for the effects of year and social deprivation, significant differences still remained in the incidence of PCOS (table 2). In terms of social deprivation, the incidence of PCOS for individuals who were least deprived was 1.59 (95% CI 1.53 to 1.65) per 1000 PYAR, whereas among the most deprived, a rate of 2.23 (95% CI 2.15 to 2.32) per 1000 PYAR was estimated. This difference in

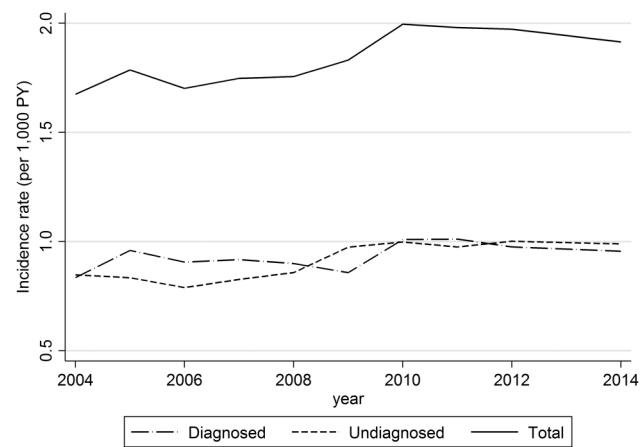

Figure 1 Time trends in PCOS diagnosis recorded (for diagnosed, probable and total cases). PCOS, polycystic ovary syndrome.

rates remained statistically significant after adjusting for effects of other covariates (ie, age and year) and after stratifying by case definition (table 2).

The overall prevalence of PCOS in 2014 was ~2.27% (95% CI 2.23% to 2.31%), with a prevalence of 1.34% and 0.93% in diagnosed and probable cases, respectively. The age-specific prevalence peaked in the 30–34 year age group, and decreased for older age groups. Prevalence estimates were not sensitive to varying the postregistration period and the time period registered within 2014, remaining consistently ~2%.

The proportion of women using one of the PCOS-related drugs before or after their index date varied widely across drugs groups (see table 3). At the time of their PCOS index date, over 40% of women had previously been prescribed COC, ~30% had been prescribed acne-related drugs before diagnosis, >18% had been prescribed POCs and ~18% had previously been prescribed at least one of the other drugs (table 3). Acne-related drugs, COC and metformin were the most commonly used drugs in the 24 months after a PCOS record (table 3). Plots describing the cumulative incidence of women with a prescription for each drug type over the 24 months following their index date are provided in online supplementary figure SI. The plots show that while all drugs show an initial surge in prescribing on or just after the PCOS index date, this is greater for some drugs (eg, metformin, acne-related drugs) than for others (COCs and POCs).

Prescription results stratified according to whether PCOS cases were diagnosed or probable are provided in online supplementary table SII. These results indicate that acne-related treatments and POCs were more commonly used to treat probable than diagnosed cases, while COCs, metformin, clomiphene, cyproterone, eflornithine and weight loss drugs were prescribed more commonly in diagnosed than probable cases. Cumulative incidence plots stratified according to whether a case was diagnosed or probable illustrate the

Table 1 Number and proportion of diagnosed and probable cases with major PCOS features

Features	Diagnosed cases (n=7233)	Probable cases (n=7057)
Menstrual dysfunction	2055 (28.4)	6265 (88.8)
Hyperandrogenism	2836 (39.2)	6221 (88.2)
PCO	199 (2.8)	1636 (23.2)
Two or more features	597 (8.3)	7057 (100)

Values are represented as n (%).

differences listed in online supplementary table SII and further to this show that these differences are typically established on or immediately after the index date (figure 2).

DISCUSSION

Summary

We present data on >14 000 potential PCOS cases among women aged 15–45 years in primary care across the UK between 2004 and 2014. 51.2% of these women had a PCOS diagnosis recorded, while 49.9% did not, corresponding to incidence rates of 0.93 per 1000 PYAR (95% CI 0.91 to 0.96) and 0.91 per 1000 PYAR (95% CI 0.89 to 0.93), respectively. The prevalence of PCOS in 2014 was ~2.27%. There was a considerable variation in the type of drug prescribed on the day of, or in the 24 months after, a PCOS diagnosis and prescribing differed between diagnosed and probable cases.

Strengths and limitations

To the best of our knowledge, this study is the first to investigate the diagnosis and management of PCOS in the primary care setting in the UK. As THIN contains over 10 million patient records, our study is robust in terms of sample size. The longitudinal nature of the database also allowed us to examine trends over a 10-year study period, which has not been captured by previous epidemiological studies where individuals were often sampled at a single time point.

As our data were collected in routine clinical practice, our results reflect the true burden of PCOS on the healthcare system. However, this also means that only data considered relevant at the time of a consultation are recorded by clinicians. Consequently, it is unsurprising that only 8% of diagnosed cases had two or more PCOS features recorded as, while the initial feature

prompting referral is likely to be noted by the general practitioner (GP), once a PCOS diagnosis has been made by a specialist a GP is unlikely to record anything other than the confirmed diagnosis in the coded record. The routine nature of data collection also meant that underdiagnosis was a concern in the current study and underestimation of PCOS rates was anticipated. We attempted to address under-reporting by allowing women with two or more features of PCOS (interfeature period within 3 years) to count as a PCOS case. However, the inclusion of probable cases may introduce case misclassification as some probable cases may not be true PCOS cases. For example, while we considered women with a raised testosterone level to have hyperandrogenism, there are concerns surrounding the accuracy of testosterone testing.¹⁹ On the contrary, it is also possible that many probable cases are true cases but do not have a diagnosis recorded in their medical records for some reason.

Incomplete patient history is a concern as women with prevalent PCOS diagnoses at the time of registration with a practice may not be identified, resulting in the underestimation of prevalence rates and the overestimation of incidence rates. Additionally, the lack of information on ethnicity is also an issue as the trends in incidence observed over age, deprivation and calendar year categories may be influenced by unobserved differences in ethnicity distributions across these covariates.

As we lack information on the indication for prescriptions, we cannot be certain that prescriptions issued after, or even on, the date of a PCOS record were prescribed for the treatment of PCOS. For example, ~30% of the PCOS cases prescribed metformin had a prior diagnosis of type 2 diabetes, the approved indication for this drug. However, by excluding those ever prescribed metformin prior to their PCOS diagnosis from our calculations, we can be relatively confident that prescriptions for

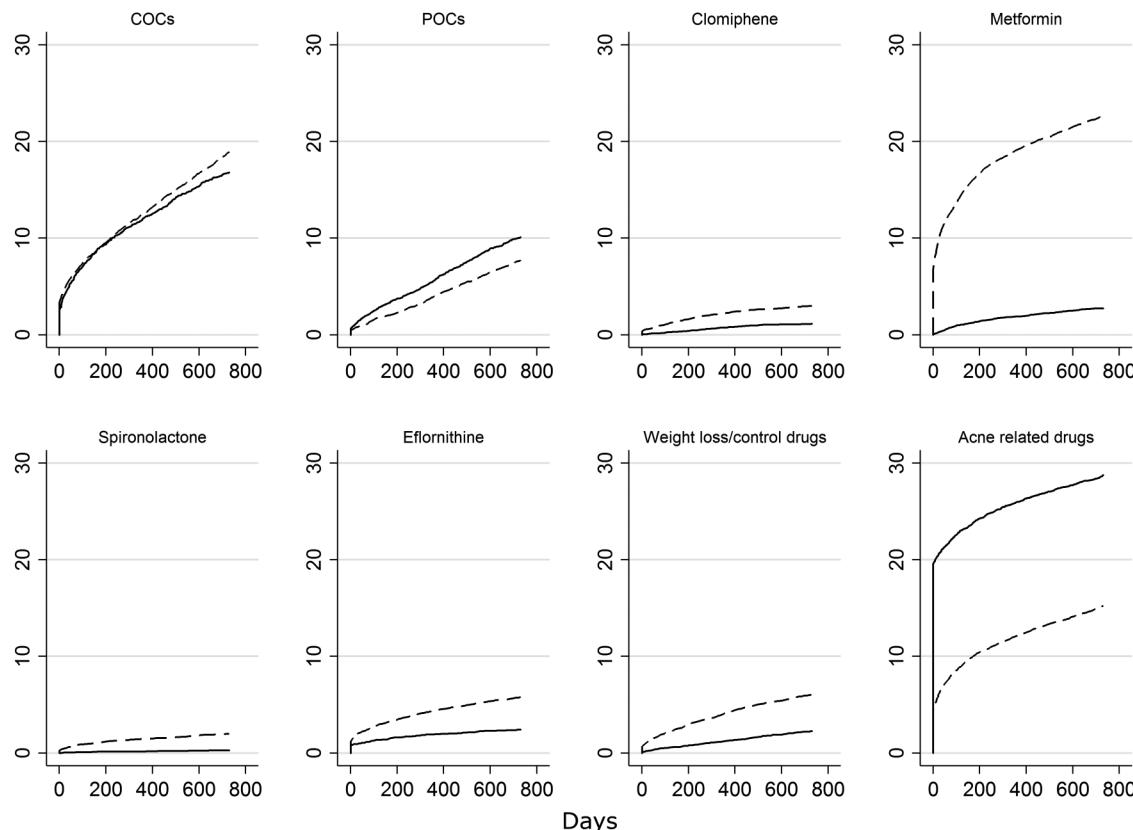

Figure 2 Plots describing the cumulative incidence of women with a prescription for each drug type over the 24 months following their index date stratified according to whether the case was diagnosed (dashed line) or probable (solid line). Results shown for the eight most commonly prescribed drugs. COC, combined oral contraceptive; POC, progestin oral contraceptive.

metformin issued on the date of a PCOS diagnosis are likely to be at least partly for the treatment of PCOS. Our confidence that the drug was prescribed for PCOS then decreases with increasing time after the PCOS diagnosis such that we expect the proportion of diagnosed cases prescribed metformin for PCOS to lie somewhere between the 8% with a prescription on the date of diagnosis and the 20% with a prescription on or in the 24 months after the date of diagnosis.

While we lacked information on prescribing outside primary care, the responsibility for prescribing treatments which have been initiated by specialists is likely to be transferred to an individual's GP a number of months after diagnosis. The use of a 24-month window to assess prescribing therefore allowed us to capture initiation of drugs prescribed in secondary care. This is reflected in the cumulative incidence curves shown in online supplementary figure S1 where the drugs that are commonly initiated outside primary care (eg, spironolactone and clomiphene) are initiated further after the index date than the drugs typically initiated in primary care (eg, COCs and acne drugs). However, prescribing rates may be underestimated if care is not transferred to the GP within 24 months (eg, for budgetary reasons).

The proportion of women with PCOS who had been prescribed COCs before their PCOS diagnosis is similar to that reported by other studies.^{20 21} The proportion of

women with PCOS who initiated metformin after their diagnosis in our study (over 10%) is comparable to that of a Danish study where 11.8% of the women with PCOS were identified as having received metformin.²¹ These comparisons support the validity of our prescribing data.

Interpretation

The prevalence of recorded PCOS in UK primary care in 2014 is comparable to that obtained from studies using databases in the USA (0.56–2.22%).^{22–24} However, the rates are significantly lower than those from epidemiological surveys in the Europe where systematic screening was often provided to identify cases from selected populations.^{25–28} This gap highlights the importance for improving public and GPs' awareness of PCOS.

The incidence of PCOS increased slightly over the study period; however, no significant changes in yearly rates were observed. This might reflect the increasing awareness of the syndrome after the establishment of the Rotterdam and Androgen Excess Society criteria during the study period. However, it could also be due to the improvement of the database, that is, the completeness of medical recordings has improved over time.

It should be noted that the Townsend score represents the deprivation level of the area in which a woman lives. Women who lived in more deprived areas had a higher

incidence of PCOS than those living in the less deprived areas. A possible explanation is that obesity (a factor strongly associated with PCOS) is more prevalent among women living in more deprived areas. Alternatively, these women may consult their GP more frequently than those in less deprived areas, for other morbidities (ie, type 2 diabetes), and therefore have more opportunity for PCOS to be diagnosed and recorded.

The fact that the incidence of probable PCOS cases was as high as the incidence of diagnosed cases indicates that there is a large group of women who present in primary care exhibiting two features of PCOS within a 3-year period but who do not have a subsequent PCOS diagnosis. While for some of these probable cases a PCOS diagnosis may not be relevant, it is likely that a considerable proportion of the women may meet the diagnostic criteria for PCOS and should therefore be referred for further assessment. Failure to refer such women may mean that they are not offered the lifestyle advice or medications that could reduce their risk of long-term PCOS-related complications.

Variation was observed in the treatments prescribed to diagnosed and probable PCOS cases; in particular, a greater proportion of diagnosed women received metformin prescriptions, while a greater proportion of the probable cases received treatment for the PCOS feature they presented with. This suggests that the diagnosed and probable cases are indeed receiving different care for their condition, with some probable cases not receiving potentially effective treatments such as metformin. The wide variation in prescribing patterns may also be due to the varied nature of clinical presentations of PCOS not only by individuals and also by age. For example, young women consulting their GPs are more likely to ask for drugs to regulate their menses or to treat acne, whereas more elderly women may initiate antidiabetic drugs to prevent rapid conversion to diabetes.

Metformin and oral contraceptives were the two drugs most commonly initiated in women with diagnosed PCOS, possibly reflecting the major concerns of long-term metabolic risks of this syndrome stated by the three PCOS consensuses. However, it is notable that even among the diagnosed PCOS cases, there is some variation in treatments prescribed following a diagnosis. This suggests that there may be a lack of consensus on the ideal treatment for the condition. This is supported by a recent survey of European endocrinologists which found variation in the treatments most commonly prescribed for PCOS.²⁹ Further research into the comparative efficacy and effectiveness of the various PCOS treatment options may therefore be warranted.

Conclusions

In conclusion, compared to rates estimated in community samples, the incidence of women presenting in primary care with PCOS diagnoses and features is low compared with most epidemiological surveys. Among

the women who present, only 50% were observed to have a PCOS diagnosis recorded. Further work is therefore needed to inform women and healthcare professionals about the condition to avoid any worsening of the disease or rapid conversion into other metabolic disorders considering the relatively low cost of diagnosis and high cost of care for the associated diseases suggested by Azziz *et al.*³⁰ There is much potential for these treatments to prove cost-effective alternatives, which should be carefully considered by public healthcare providers, such as the National Health Service in the UK.

Although there is much variation in the treatments prescribed following a PCOS diagnosis, the widespread prescribing of oral contraceptives and metformin generally reflects the prognostic concerns raised in PCOS consensuses, aiming to reduce the future metabolic risks of patients with PCOS or patients who are undergoing treatment for PCOS and may already have developed metabolic disorders. Further work is needed to identify the most effective treatment for the condition.

Contributors TD, CS and IP were involved in the design of the study. TD and CS performed the analysis, and GB, IP and PJH helped with the interpretation. TD prepared the manuscript, and CS, GB, IP and PJH revised it as needed. All authors have read and approved the final manuscript.

Funding This research received no specific grant from any funding agency in the public, commercial or not-for-profit sectors.

Diagnosis and management of polycystic ovarian syndrome

Ebernella Shirin Dason MD, Alexandra Koshkina MD MSc, Crystal Chan MD MSc, Mara Sobel MD MSc

■ Cite as: CMAJ 2024 January 29;196:E85-94. doi: 10.1503/cmaj.231251

Polycystic ovarian syndrome (PCOS) causes irregular menstrual cycles and symptoms of hyperandrogenism and affects 10% of females (Figure 1).¹ Symptoms most often begin between the ages of 18 and 39 years, but diagnosis and treatment of PCOS are often delayed or patients remain undiagnosed.^{1,2} People with PCOS are more likely to be overweight or obese (53%–74%) than those without the condition, and higher body mass index (BMI) is associated with more severe symptoms of PCOS.^{3–5} Patients with PCOS also have higher rates of adverse reproductive, cardiovascular, psychological, metabolic and neoplastic outcomes than the general female population.^{3,6} Early diagnosis of PCOS allows for identification and treatment of associated conditions such as hypertension, diabetes, obstructive sleep apnea, depression and anxiety. We review evidence on the pathophysiology, diagnosis and management of PCOS from guidelines and other relevant articles (Box 1).

What is the pathophysiology of PCOS?

The pathophysiology of PCOS is complex and poorly understood. Hyperandrogenism and hyperinsulinemia underpin the clinical symptoms, diagnosis and treatment targets of PCOS. Clinical phenotypes vary widely. Whether the presence of immature ovarian follicles, characteristic of PCOS, precedes hyperandrogenism, hyperinsulinemia and their associated clinical symptoms or vice versa remains unclear (Figure 2).⁸

Two theories for why hyperandrogenism occurs in PCOS have been proposed.⁸ The first theory, called the altered gonadotropin secretion theory, postulates that increased gonadotropin-releasing hormone (GnRH) pulse frequency leads to excessive levels of luteinizing hormone (LH) and slightly elevated levels of follicle-stimulating hormone (FSH).^{9–11} Elevated LH stimulates androgen production from theca cells, while elevated FSH stimulates follicular development and excess estrogen production.^{10,11} The second theory, called the functional ovarian or adrenal hyperandrogenism theory, postulates that hyperandrogenism originates from dysregulated steroidogenesis at the level of the ovary or adrenal gland.⁸

Elevated androgens support follicular recruitment while also inducing follicular atresia.^{8,10,12} This ultimately leads to the classic appearance of multifollicular ovaries (or polycystic ovaries) on transvaginal ultrasonography.

Key points

- Polycystic ovarian syndrome (PCOS) is a chronic disorder associated with infertility; miscarriage; adverse pregnancy outcomes; and cardiovascular, metabolic, psychological and neoplastic risks.
- Diagnosis of PCOS can be made based on the presence of any 2 of menstrual irregularities, clinical or biochemical hyperandrogenism or polycystic ovarian morphology on transvaginal ultrasonography.
- Treatment of PCOS may target anovulation, androgen excess, hyperinsulinemia and weight management.
- Patients with PCOS should have regular monitoring of their body mass index, blood pressure and metabolic parameters, and should be regularly screened for depression, anxiety and obstructive sleep apnea.

Hyperinsulinemia is thought to have multiple effects including elevating LH, decreasing sex hormone-binding globulin (SHBG), increasing conversion of androstenedione to testosterone and reducing LH desensitization at the level of the ovary.^{9,10} Hyperinsulinemia leads to an increase in visceral adipose tissue deposition and hypertrophy. Hyperandrogenism may also lead to increased visceral adiposity. Obesity worsens symptoms of PCOS but the prevalence of PCOS rises only slightly with increasing BMI, suggesting it is not the main cause of PCOS.^{5,10,13}

What symptoms do patients with PCOS describe?

Patients with PCOS often have menstrual cycle irregularities with or without features of hyperandrogenism, which include hirsutism, acne and female-pattern alopecia (overall thinning with maintenance of hairline).¹ Before a diagnosis of PCOS can be made, other causes for these phenomena must be excluded. These alternative causes include hyperprolactinemia, thyroid dysfunction, non-classic congenital adrenal hyperplasia, Cushing syndrome, ovarian tumours or adrenal tumours. A detailed history is the first step to differentiating among potential causes of a patient's symptoms.

Symptoms suggestive of PCOS

Patients with PCOS typically present with irregularities in the frequency of their menstrual cycle, suggestive of anovulation.

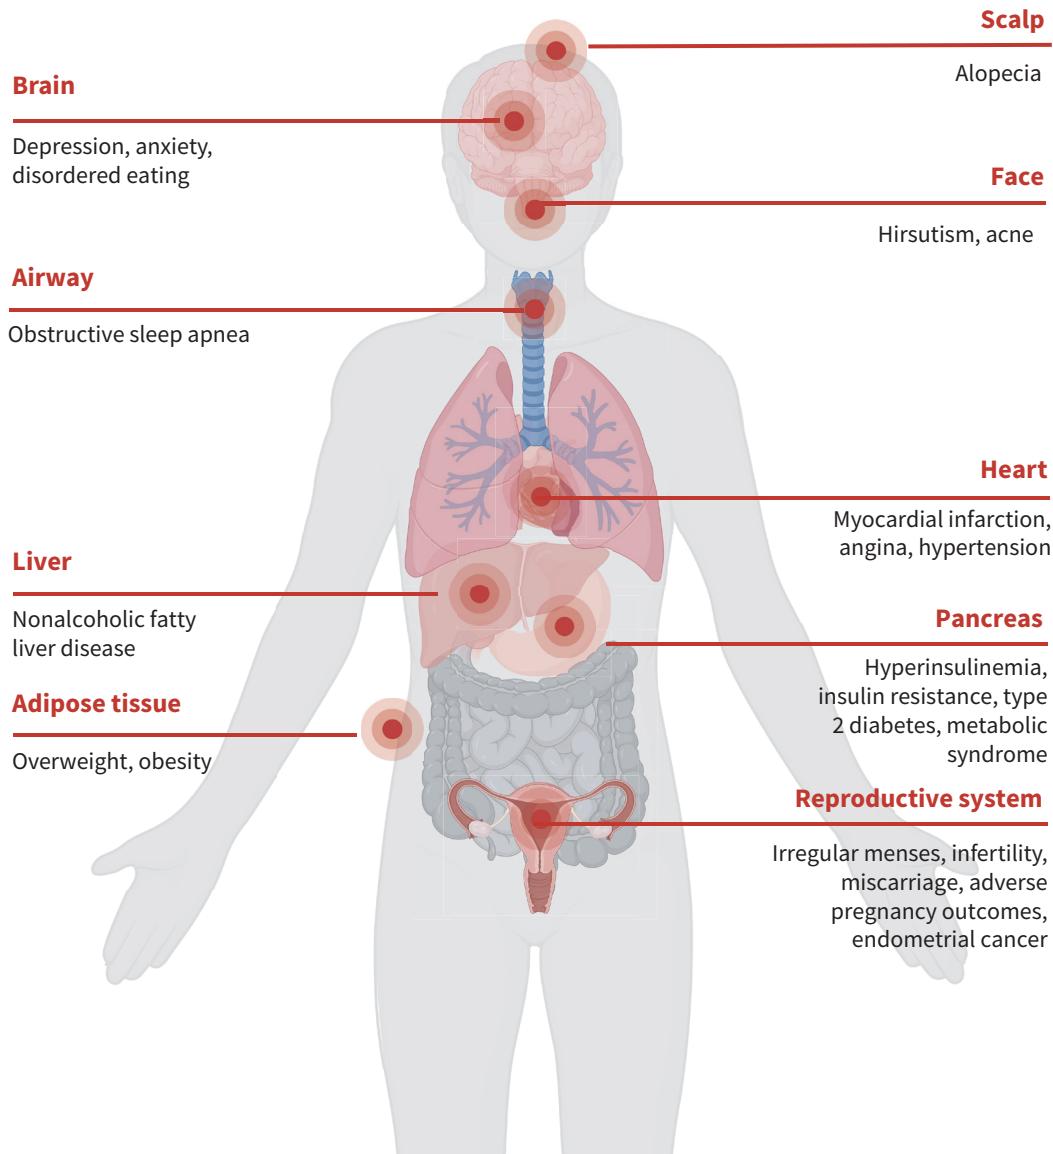

Figure 1: Health impacts associated with polycystic ovarian syndrome. Created with BioRender.com.

Box 1: Evidence used in this review

We drew on the international guideline on the management of polycystic ovarian syndrome (PCOS) published by the European Society of Human Reproduction and Embryology and the American Society for Reproductive Medicine in 2023 and the hirsutism guideline published by the Endocrine Society in 2018.^{1,3,7} We also searched articles in PubMed from 2018–2023 using the terms “PCOS,” and “polycystic ovarian syndrome.” We considered all articles and further searched reference lists of relevant articles to find other articles of interest.

Menstrual cycle patterns among patients with PCOS can fluctuate through a patient’s lifetime, ranging from amenorrhea to regular

ovulatory cycles. Clinicians should determine whether the patient has a family history of PCOS, dyslipidemia, hypertension or diabetes, as PCOS has a heritable component.³

The androgenic symptoms of PCOS — such as acne, hirsutism and female-pattern alopecia — develop gradually. Hirsutism, which is the symptom most predictive of biochemical hyperandrogenism, can be assessed objectively using the Ferriman-Gallwey score, although the clinical utility of this scoring system is limited as patients will often engage in hair removal before assessment.¹ Thus, subjectively distressing hair growth can be adequate to consider treatment.¹

Clinical features suggestive of other diagnoses

Other causes of both hyperandrogenism and menstrual cycle irregularities that can mimic PCOS include non-classic congenital adrenal hyperplasia and Cushing syndrome. Although non-classic congenital adrenal hyperplasia is clinically indistinguishable

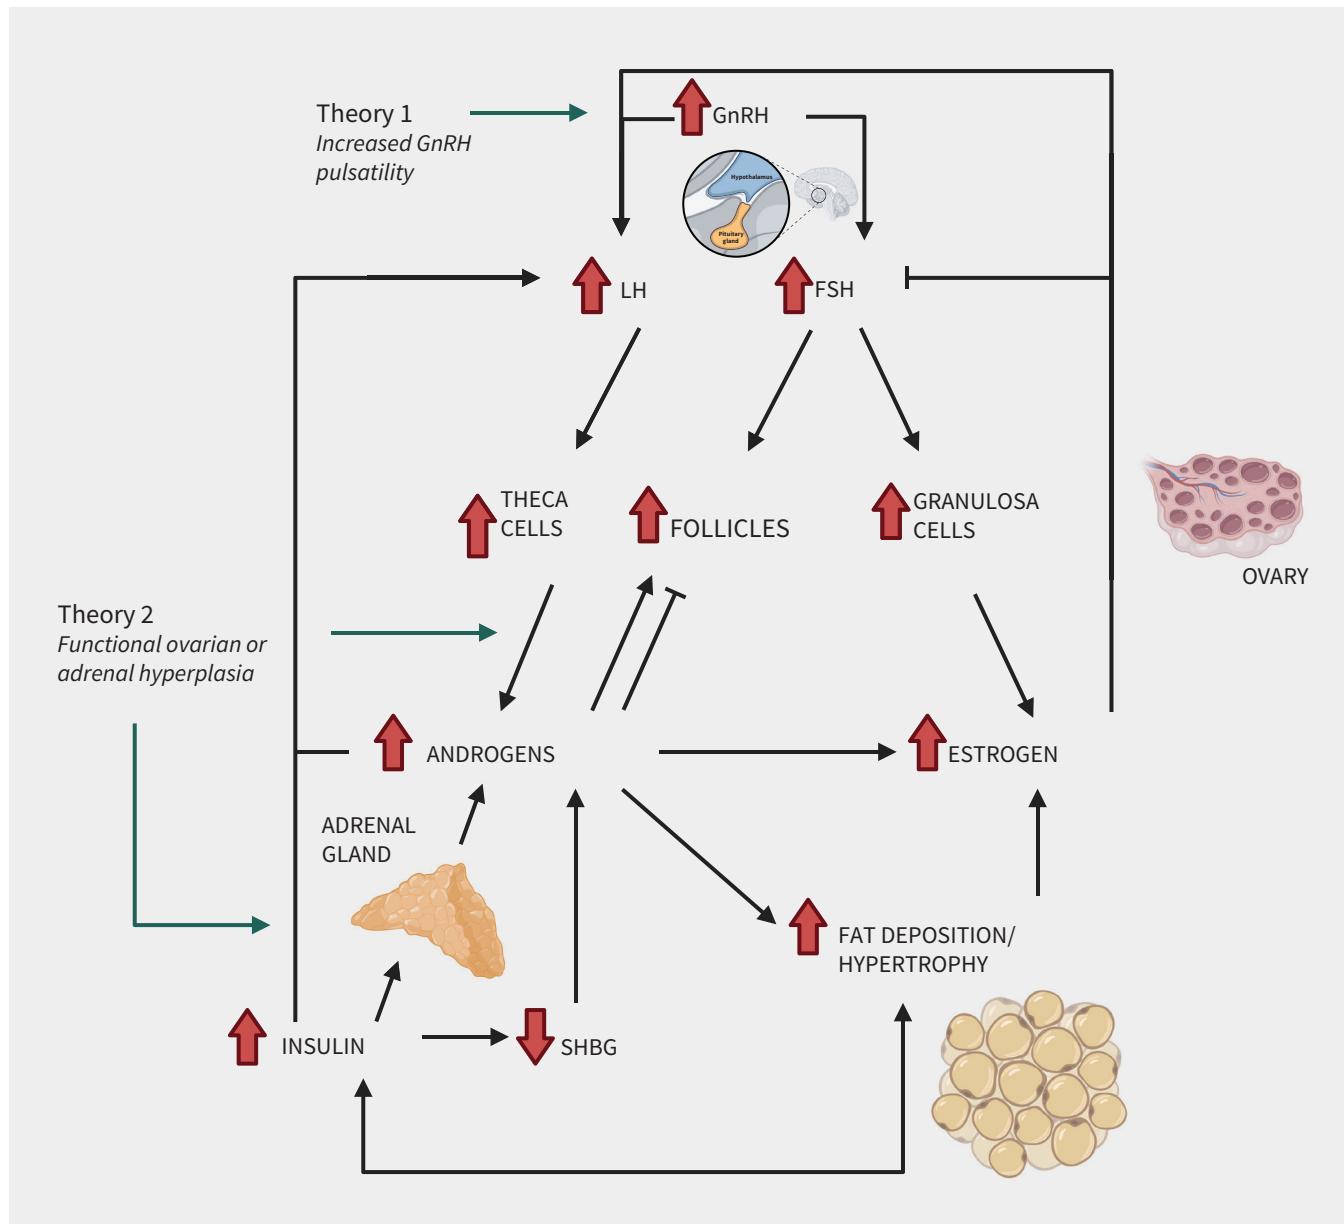

Figure 2: Two theories of the pathophysiology of polycystic ovarian syndrome (PCOS). The 2 main defining pathophysiological mechanisms of PCOS are hyperandrogenism and hyperinsulinemia; this relationship has been described and one perpetuates the other, but the exact mechanisms are not fully elucidated. The 2 main theories that are postulated include increased gonadotropin-releasing hormone (GnRH) pulse frequency (theory 1) and functional ovarian or adrenal hyperandrogenism (theory 2). Gonadotropin-releasing hormone stimulates release of follicle-stimulating hormone (FSH) and luteinizing hormone (LH) from the anterior pituitary. At the ovary, LH acts on theca cells to produce androgens; FSH acts on granulosa to produce estrogens. Estrogen has negative feedback mechanisms to FSH production. Both androgens and estrogen stimulate LH production. Ovarian release of androgens may also be functional. Hyperandrogenism, as well as FSH and LH stimulation, stimulates both follicular development and atresia leading to the classic multifollicular appearance of the ovaries on ultrasonography. Androgens may also be overproduced by the adrenal glands, which may be further driven by insulin. Both hyperinsulinemia and hyperandrogenism are postulated to be worsened by and drive adipose tissue deposition. Created with BioRender.com.

from PCOS, many patients with Cushing syndrome will have other features such as violaceous striae, weight gain with central fat deposition and dorsal fat pad, easy bruising and proximal muscle weakness.

Intermenstrual bleeding and heavy regular menstrual bleeding are not usually associated with PCOS; infectious or structural causes of heavy bleeding such as fibroids, polyps or adenomyosis should be considered. Associated symptoms, such as hot

flashes presenting in the context of new menstrual cycle irregularities, are more suggestive of premature ovarian insufficiency.

Patients with thyroid dysfunction and hyperprolactinemia may have additional symptoms; skin or hair changes or hot or cold sensitivity often accompany thyroid dysfunction, and galactorrhea, headaches, visual changes are features of hyperprolactinemia. A thorough review of medications that may cause hyperprolactinemia or hyperandrogenism should also be undertaken. Severe, sudden onset of

Box 2: Rotterdam criteria¹

Polycystic ovarian syndrome is diagnosed when 2 out of 3 of the following criteria are met and other diagnoses are excluded:

- Irregular cycles (if > 3 yr post-menarche, > 35 d apart or < 21 d apart; < 8 menstrual cycles per year; or > 90 d for any 1 menstrual cycle)
- Clinical hyperandrogenism (acne, hirsutism, alopecia) or biochemical hyperandrogenism
- Polycystic ovarian morphology on transvaginal ultrasonography or high antimüllerian hormone*

*Only applicable if patient is at least 8 years from menarche.

Box 3: Suggested initial investigations for patients presenting with menstrual irregularities or clinical hyperandrogenism

Tests should be completed in early follicular phase (day 2–4) in non-amenorrheic patients

- Prolactin
- Thyroid-stimulating hormone
- Luteinizing hormone, follicle-stimulating hormone and estradiol
- β-human chorionic gonadotropin (β-hCG)
- 17-hydroxyprogesterone (17-OHP)
- Total testosterone, calculated free testosterone or free androgen index with or without androstenedione, dehydroepiandrosterone sulfate
- Transvaginal ultrasonography or antimüllerian hormone*

*Optional if clinical criteria are not met; antimüllerian hormone used as an alternative to transvaginal ultrasonography, but should not be used in adolescents.

virilizing symptoms (e.g., clitoromegaly, voice deepening, male-pattern balding) are more suggestive of an androgen-secreting tumour originating from the adrenal glands or ovaries.⁷

How is PCOS diagnosed?

The Rotterdam criteria are the most widely accepted criteria for diagnosis of PCOS (Box 2).¹ As PCOS is considered a diagnosis of exclusion, diagnostic testing is required for patients presenting with symptoms, although the results of this testing may be normal. Suggested investigations are included in Box 3. An interpretation of test findings can be found in Table 1. If a patient has a concomitant disorder, such as hypothyroidism, the concomitant disorder should be treated and the patient should be reassessed to determine whether the patient has PCOS.

Biochemical hyperandrogenism is found in 60% of patients with PCOS and can be assessed using total testosterone, calculated free testosterone, dehydroepiandrosterone sulfate (DHEA-S) and androstenedione.¹ If feasible, testing for these androgens should be done in a step-wise fashion, with total testosterone and calculated free testosterone or the free androgen index evaluated first. If these initial investigations are normal, then DHEA-S and androstenedione levels should be tested.¹ Androgen

levels are only marginally elevated in PCOS; marked elevations should prompt further investigation for androgen-secreting tumours.¹ Androgen levels cannot be measured reliably while a patient is on combined hormonal contraceptives (CHCs) because of the elevation in SHBG and altered gonadotropin-dependent androgen production, resulting in falsely lowered values.¹ If a patient meets 2 of 3 Rotterdam criteria, this satisfies criteria for PCOS diagnosis without need for laboratory confirmation of elevated androgens. If laboratory confirmation is necessary, CHCs must be stopped for 3 months before measuring androgens.¹⁶

Polycystic ovarian morphology on transvaginal ultrasonography (≥ 20 follicles or an ovarian volume ≥ 10 mL in at least 1 ovary) may be an additional criterion if clinical or laboratory criteria are not met.^{1,12,17} Transabdominal ultrasonography can be used as an alternative with different thresholds (≥ 10 follicles or an ovarian volume ≥ 10 mL in at least 1 ovary).¹ The requisition should indicate the clinical concern for PCOS so that an antral follicle count is performed. Normal follicle numbers per ovary can overlap based on age and polycystic ovarian morphology; the normal mean follicle number is 8 among reproductive-aged females, with a mean volume of 6.1 mL.^{1,18} Polycystic ovarian morphology may be present in as many as 25% of healthy females and is considered a variant of normal.¹⁹ Patients should be counselled that cysts are immature follicles, which is a normal finding in all ovaries; the number of follicles is what indicates polycystic ovarian morphology. An incidental finding of polycystic ovarian morphology should prompt the clinician to inquire about irregular menstruation, acne, hirsutism and alopecia, and targeted laboratory evaluation for biochemical hyperandrogenism can also be considered.

The serum anti-müllerian hormone level is also a marker of follicle number. A recent meta-analysis suggests an appropriate threshold for PCOS diagnosis may be an anti-müllerian level of 34.2 pmol/L.¹⁵ Values and thresholds are highly dependent on age and laboratory measurement.¹ Although the anti-müllerian hormone level can be used as an alternative to transvaginal ultrasonography, it is not widely available in laboratories in Canada and is not covered by most provincial health plans.

How are the clinical manifestations of PCOS managed?

Patients with PCOS often request treatment for cycle irregularity, heavy bleeding, acne or hirsutism, and weight management (Table 2).

Weight loss

Among patients who are overweight or obese, weight loss of 5%–10% can help to reduce the severity of symptoms, including menstrual cycle irregularity, acne, hirsutism and alopecia.^{16,22} No specific diet or exercise recommendations for PCOS are available, and clinicians should be particularly sensitive to weight stigma as patients with PCOS are at risk of dysmorphic body image and disordered eating.¹

Combined hormonal contraceptives

Combined hormonal contraceptives are first-line medical treatment options for cycle regulation and hirsutism or acne. No evidence

Table 1: Initial investigations and differential diagnoses for polycystic ovarian syndrome

Test	Results				Next steps
	Expected results for patient with PCOS	Results for a patient with an alternative diagnosis	Alternative diagnoses		
Prolactin	Normal	Markedly elevated	Pituitary tumour	<ul style="list-style-type: none"> Repeat early morning, fasting prolactin Test macroprolactin Consider pituitary MRI Referral to endocrinology

		Low	Age-related decline in ovarian reserve		

Note: CT = computed tomography, FSH = follicle-stimulating hormone, LH = luteinizing hormone, MRI = magnetic resonance imaging, PCOM = polycystic ovarian morphology, PCOS = polycystic ovarian syndrome, POI = premature ovarian insufficiency, TSH = thyroid-stimulating hormone, 17-OHP = 17-hydroxyprogesterone, β-hcg = β-human chorionic gonadotropin.

demonstrates the superiority of 1 form of CHC over another in minimizing symptoms and, thus, guidelines cannot recommend which to choose.^{1,7} Several mechanisms are involved when treating hyperandrogenism with CHCs; the estrogenic component increases SHBG, which decreases the amount of free testosterone, and both the estrogen and progestin provide nega-

tive feedback mechanisms to pituitary LH production and thus decrease production of LH-induced ovarian androgen.²³

Many patients specifically desire cycle regularity, although this is not medically necessary provided cycles are fewer than 90 days apart. Cycle irregularity may be associated with heavy bleeding. Combined hormonal contraceptives are first-line

Table 2 (part 1 of 2): Management options for polycystic ovarian syndrome according to symptoms^{1,20}

Symptom	Treatment	Dosing or recommendation	Clinical considerations
Menstrual irregularity, heavy bleeding	First-line		
	Lifestyle interventions	Diet and exercise aimed at weight reduction by 5%–10% or prevention of excess weight gain	<ul style="list-style-type: none"> Be aware of weight stigma and increased risk for disordered eating
	CHCs	Any form	
	Progestins		
	Oral medroxyprogesterone	5–10 mg for 5–10 d every 30–90 d	
	Oral norethindrone acetate	5 mg daily for 7 d every 30–90 d or 5 mg daily for 3 wk on, 1 wk off	
	Oral drospirenone	4 mg 24 d, 4 d placebo	
	Oral dienogest	2 mg daily	<ul style="list-style-type: none"> May cause breakthrough bleeding
	Levonorgestrel intrauterine device	52 mg released over 5 yr	<ul style="list-style-type: none"> Patients may continue to have irregular, although lighter, bleeding
	Etonogestrel subdermal implant	68 mg released over 3 yr	<ul style="list-style-type: none"> Patients may continue to have irregular, although lighter, bleeding
	Intramuscular medroxyprogesterone acetate	150 mg intramuscularly every 3 mo	
Acne, hirsutism or alopecia	Alternative options		
	Metformin	1500–2000 mg daily in divided doses	<ul style="list-style-type: none"> Start at 500 mg and increase by 500 mg every 1–2 wk Cannot be used for endometrial protection in the event of amenorrhea but may help induce regular ovulation
	Inositol	Dosing varies 4 g of myo-inositol with a 40:1 ratio between myo-inositol and D-chiro-inositol daily ²¹	<ul style="list-style-type: none"> Cannot be used for endometrial protection in the event of amenorrhea but may help induce regular ovulation
Acne, hirsutism or alopecia	First-line		
	CHCs	Any form	
	Topical hirsutism treatment	13.0% eflornithine	<ul style="list-style-type: none"> Can be used during or before external hair removal methods
	Minoxidil (for alopecia)	2% twice daily	
	Topical or oral acne treatments	According to general guidelines	
	External hair removal methods	Mechanical laser and light therapy	
	Alternative options		
	Spironolactone	50–100 mg twice daily	<ul style="list-style-type: none"> Must be used with effective contraception given teratogenicity (i.e., CHCs or progestin-based contraception if CHCs are contraindicated) Do not use in combination with CHC containing drospirenone Requires monitoring with electrolytes 3 mo after starting and then annually and with dose adjustments
	Finasteride	5 mg daily	<ul style="list-style-type: none"> Must be used with effective contraception given teratogenicity (i.e., CHCs or progestin-based contraception if CHCs contraindicated)

agents that provide predictable bleeding patterns. When estrogen is contraindicated or not tolerated, progestin-only methods include oral and injectable progestins, the levonorgestrel intrauterine device and the etonogestrel subdermal implant.

Oral progestins can be used cyclically (i.e., 3 wk on and 1 wk off) or in rescue fashion (i.e., short course taken after > 90 d amenorrhea) to induce regular withdrawal bleeding. Continuous use of progestins will likely result in amenorrhea. Patients should

Table 2 (part 2 of 2): Management options for polycystic ovarian syndrome according to symptoms^{1,20}

Symptom	Treatment	Dosing or recommendation	Clinical considerations
Overweight or obesity	First-line		
	Lifestyle interventions	Diet and exercise aimed at weight reduction by 5%–10% or prevention of excess weight gain	<ul style="list-style-type: none"> Be aware of weight stigma and increased risk for disordered eating

	Letrozole	2.5 mg–7.5 mg for 5 d	<ul style="list-style-type: none"> Although considered first-line by many guidelines, still considered as off-label use in Canada If cycling regularly, start on day 2–5 If irregular cycles, can start randomly after negative home pregnancy test or medroxyprogesterone-induced withdrawal bleed Consider measuring serum progesterone level 3 wk after starting letrozole to confirm ovulation
	Alternative options		
	Inositol	Dosing varies; 4 g of myo-inositol with a 40:1 ratio between myo-inositol and D-chiro-inositol daily ²¹	
	Referral to gynecologist or reproductive endocrinologist and infertility specialist		

Note: CHC = combined hormonal contraceptive.

be reassured that this is a normal outcome with this medication and should not be confused with oligomenorrhea in untreated PCOS. The levonorgestrel intrauterine device and the etonogestrel subdermal implant may provide patients with endometrial protection, as well as less menstrual pain and bleeding, but may not allow for predictability in menstrual bleeding. Many progestins have high androgenic activity and may worsen clinical hyperandrogenism.⁷

When amenorrhea exceeds 90 days, endometrial protection is critical. The risk of endometrial cancer is 2–6 times higher among people with PCOS than the general population and often presents before menopause.¹ Patients with prolonged amenorrhea should be offered CHCs or progestins to maintain a nonproliferative endometrial lining (Table 2). An endometrial biopsy should

be considered for all patients with amenorrhea exceeding 90 days, especially if this occurs frequently.²⁴

Nonhormonal medications

Some patients are not candidates for CHCs or prefer not to be on a hormonal medication. Metformin, an insulin sensitizer, can be used as a nonhormonal alternative for PCOS by promoting modest weight loss and reducing insulin levels, which may subsequently have an impact on cycle regularity and hyperandrogenism.¹ A meta-analysis of 22 randomized control trials (RCTs) of metformin for treatment of PCOS found a reduction in BMI (-0.53), testosterone (-13.36 ng/dL) and fasting glucose (-2.39 mg/dL).¹ Subgroup analyses demonstrated that metformin lowered BMI, fasting glucose and total and low-density lipoprotein cholesterol

among patients with BMI greater than 25, while the free androgen index and fasting insulin were lowered among patients with a BMI less than or equal to 25.¹ The efficacy of metformin in reducing clinical features of PCOS remains uncertain. However, given the improvements in metabolic markers, metformin should be considered in patients with PCOS and a BMI greater than 25.¹

Metformin has been compared with CHCs in 22 RCTs.¹ Between the 2 treatments, no statistically significant differences were shown for weight, BMI or hirsutism, with very low certainty of evidence. Compared with metformin, CHCs did significantly improve menstrual irregularities, with moderate certainty of evidence. Compared with CHCs, insulin and cholesterol levels were improved with metformin with low to very low certainty of evidence.¹ The addition of metformin to CHCs can be considered in patients with PCOS in high metabolic risk groups, which includes those with a BMI greater than 30, those with impaired glucose tolerance, ethnic groups with high metabolic risk factors and those with other diabetes risk factors.¹

Inositol is an over-the-counter supplement that can be considered in management of PCOS. It belongs to the vitamin B complex group and is involved in many signalling cascades, including downstream of FSH and insulin. It may have a role in improving insulin sensitivity.^{1,20} A recent meta-analysis showed that inositol, in particular myo-inositol, reduced BMI (mean difference 0.45 kg/m²) compared with placebo.²⁰ Cycle normalization was higher in the inositol group (relative risk [RR] 1.79). Myo-inositol has minimal adverse effects, although more studies are needed to further support this. Furthermore, as inositol is a supplement, there is no regulation of what is commercially available to consumers and thus it must be used with caution.^{1,20}

Anti-androgen agents

Anti-androgen agents can be considered for patients with clinical hyperandrogenism after 6 months of CHCs with no improvement or in those with contraindications for CHCs. Medical treatment of hirsutism can reduce new hair growth but cannot reverse hair growth that was previously established.⁷ Only external hair removal techniques such as mechanical laser and light therapy (i.e., laser removal) can be used for previous hair growth. Addition of topical eflornithine may improve outcomes of mechanical laser and light therapy.⁷

Metformin and inositol may also indirectly reduce androgen levels, although their specific effect on the clinical reduction of hirsutism and acne has not been shown.¹ Anti-androgen agents such as spironolactone, cyproterone acetate and finasteride must be used with effective contraception given their teratogenicity; evidence also supports the reduction of hirsutism with the addition of an anti-androgen to CHCs.¹

What are the fertility and pregnancy considerations for patients with PCOS?

If a patient intends to conceive, clinicians should communicate that irregular or prolonged (> 35 d) cycles may still be sporadically ovulatory.²⁵ Conversely, contraception is needed if pregnancy is not desired. Time to pregnancy is longer on average; a

large population-based study in Sweden observed that spontaneous conception took an average of 2 years longer among patients with PCOS.²⁶ Ovulatory function and, thus, cycle regularity tend to improve as patients age, although all patients are subject to age-related fertility decline regardless of PCOS.²⁷

In the population-based study from Sweden, the cumulative probability of childbirth after spontaneous conception was 55% among patients with PCOS, compared with 73.8% among women without PCOS.²⁶ With assisted reproduction, the cumulative probability of childbirth was the same among both patients with PCOS (80%) and those without (78%).²⁶ First-line options for management of return of ovulatory cycles that can be initiated by primary care physicians include weight loss of 5%–10% for patients with overweight or obesity, metformin, inositol or letrozole.¹ It is reasonable to trial these methods for 6–12 months in patients younger than 35 years. Metformin and inositol are safe in pregnancy; however, unless the patient has concurrent type 2 diabetes, no convincing evidence supports continuing these medications in pregnancy. Referral to a fertility specialist for ovulation induction with letrozole, gonadotropins or laparoscopic ovarian drilling (i.e., use of a monopolar needle to puncture the ovarian cortex) can be considered at any time.¹

Pregnant patients with PCOS are at increased risk of miscarriage, gestational weight gain, gestational diabetes, hypertension, preeclampsia, intrauterine growth restriction, preterm delivery and cesarean delivery; some of the risks may be mitigated by maintenance of a normal BMI.¹ Given the known contribution of PCOS to impaired glycemic status, screening for impaired fasting glucose or impaired glucose tolerance with a 75-g oral glucose tolerance test should be considered before conception.³ When not completed before conception, it should be performed at the first prenatal visit before 20 weeks' gestation and again at 24–28 weeks' gestation.¹ Although the quality of evidence is low, an oral glucose tolerance test is the preferred method for identification of insulin resistance among patients with PCOS.¹

What are the long-term health complications associated with PCOS?

Long-term complications such as hypertension, impaired glucose tolerance, type 2 diabetes, metabolic syndrome, non-alcoholic fatty liver disease, depression, anxiety, obstructive sleep apnea and cardiovascular disease (i.e., ischemic heart disease, myocardial infarction and cardiovascular mortality) have all been associated with PCOS.¹⁶ These conditions tend to present earlier among people with PCOS than age-matched controls.²⁷ People with PCOS and a BMI greater than 25 are at higher risk of long-term health complications than patients with PCOS and a BMI of 25 or less. Ongoing care for patients can often be fragmented as the emphasis in PCOS can be overly focused on reproduction rather than long-term sequelae.²⁸ Baseline and follow-up assessments, as outlined in Box 4, should be performed for all patients with PCOS.

Polycystic ovarian syndrome may be associated with hypertension. A recent meta-analysis showed that the risk of hypertension was increased only among patients of reproductive age (pooled RR 1.72, 95% confidence interval [CI] 1.43–2.07) but not

Box 4: Baseline and annual health assessment in all patients with PCOS

- Measurement of height, weight and body mass index
- Measurement of blood pressure
- Cardiovascular risk assessment including cigarette smoking, physical activity and family history of premature cardiovascular disease.
- Assessment of lipid profile (cholesterol, low-density lipoprotein cholesterol, high-density lipoprotein cholesterol and triglycerides)
- Assessment of glycemic status, ideally with oral glucose tolerance test
- Assessment for obstructive sleep apnea symptoms (i.e., snoring with waking unrefreshed, daytime sleepiness or fatigue)
- Screening for depression and anxiety
- Screening for amenorrhea exceeding 90 d

among menopausal patients who had PCOS during their reproductive years (pooled RR 1.26, 95% CI 0.95–1.67).²⁹ As such, patients with PCOS should have blood pressure measurements annually and at any time when fertility is desired since patients are at increased risk of hypertensive disorders in pregnancy.¹

Data on cardiovascular risk outcomes show inconsistent findings, although this is likely owing to the low event rate of major adverse cardiovascular events among premenopausal women.²⁸ Recently, several meta-analyses have suggested with very low to low certainty that females with PCOS have higher ORs or incidence rate ratios for composite cardiovascular disease, composite ischemic heart disease, myocardial infarction, stroke and cardiovascular mortality.¹ Thus, monitoring of cardiovascular risk profiles, including lipid profiles, should be undertaken both at baseline and on an ongoing basis for all patients with PCOS.¹

Polycystic ovarian syndrome is also related to hyperinsulinemia, impaired glucose intolerance and type 2 diabetes.^{9,16,22} A meta-analysis of 41 studies indicated an increased risk of type 2 diabetes among patients with PCOS compared with those without PCOS (OR 2.87, 95% CI 1.37–6.01).¹ Hyperinsulinemia is present in 75% of patients with PCOS and a BMI of 25 or less and 95% of patients with a BMI greater than 25.¹

Polycystic ovarian syndrome is associated with a higher risk of obstructive sleep apnea, independent of BMI. In a recent meta-analysis of 8 studies, those with PCOS had a 10 times higher chance of obstructive sleep apnea than those without PCOS, with an odds ratio (OR) of 9.52 (95% CI 3.90–23.26).³ Patients with PCOS should be assessed for symptoms of obstructive sleep apnea, screened using appropriate tools (e.g., Berlin Questionnaire) and directed for a sleep study and treatment if obstructive sleep apnea is identified.³

Patients with PCOS also have a high prevalence of depression and anxiety. In a meta-analysis of 47 studies, depression was more likely among patients with PCOS than those without PCOS (OR 2.59, 95% CI 2.11–3.16).¹ In a meta-analysis of 27 studies reporting on anxiety, patients with PCOS had a higher risk of anxiety than those without, with an OR of 2.68 (95% CI 2.08–3.44).¹ Polycystic ovarian syndrome can have a negative impact

on body image and self-esteem, and is also associated with a higher rate of disordered eating.¹

Conclusion

Polycystic ovarian syndrome, a common endocrinological disorder among reproductive-aged females, presents with menstrual irregularities, hyperandrogenism and polycystic ovarian morphology. It is associated with important long-term health consequences such as hypertension, neoplastic risks, metabolic consequences, adverse cardiovascular outcomes, psychological impacts and adverse reproductive outcomes. Early diagnosis can allow for improvement in symptoms and mitigation of long-term health complications.

Abstract

Polycystic ovary syndrome (PCOS) is a complex multisystem condition associated with life-long reproductive, metabolic, and psychological symptoms. Individuals with PCOS are at an increased risk of cardiovascular disease and type 2 diabetes, with approximately 70% of all PCOS cases presenting with insulin resistance. Lifestyle interventions have historically been recommended as first-line therapies for the management of PCOS-related cardiometabolic disorders. The term “lifestyle management” incorporates a multifaceted approach to dietary, exercise, and behavioral strategies, aiming to promote a healthy lifestyle. This approach has been commonly employed in practice, in particular through exercise and dietary modulation, due to its effect on cardiometabolic outcomes as well as its tolerability. Furthermore, there is evidence to suggest that combining dietary change with exercise may yield the greatest improvements in clinical outcomes. However, such practices require careful consideration and coordination, as there are instances where certain exercise and/or dietary prescriptions may compromise the effectiveness of the respective interventions. Thus, this review aims to provide practical guidance on diet and exercise planning in the routine care of PCOS. Such recommendations include emphasizing realistic and achievable goals, as well as minimizing barriers to lifestyle changes in order to increase the long-term sustainability of this treatment strategy.

- realistic medicine

Polycystic ovary syndrome (PCOS) is the most common endocrine disorder in females during reproductive years, affecting 2 to 20% of this population.^{1,2} This condition is associated with life-long metabolic (impaired glucose tolerance, insulin resistance, type 2 diabetes mellitus, cardiovascular disease risk), reproductive (infertility, hirsutism,

hyperandrogenism), and psychological symptoms (anxiety, depression, and worse health-related quality of life).³ The updated 2023 International Evidence-based Guideline for the assessment and management of PCOS recommends the use of the revised Rotterdam criteria for the diagnosis of PCOS in adults: the presence of two of (1) clinical/

biochemical hyperandrogenism, (2) ovulatory dysfunction, and (3) polycystic ovaries on ultrasound or elevated anti-mullerian hormone (AMH) levels.^{4,5} In adolescents, the diagnosis is made in the presence of hyperandrogenism and ovulatory dysfunction, with ultrasound and AMH levels not recommended.^{4,5} A key characteristic of PCOS is insulin resistance, which affects 60 to 95% of individuals with the condition.⁶ Beyond pathogenesis related to excess adiposity, it is thought that insulin resistance is exacerbated through interactions with hyperandrogenism.^{7,8} In fact, hyperandrogenic PCOS phenotypes have the highest prevalence of insulin resistance: 80% in PCOS phenotypes with hyperandrogenism and oligomenorrhea and 65% in phenotypes with hyperandrogenism and polycystic ovaries, compared to 38% in normoandrogenic PCOS phenotypes.⁹

Lifestyle interventions, including dietary modulation and exercise, have historically been considered first-line therapies for the management of cardiometabolic risk factors in PCOS.^{10,11} In this narrative review, we aim to provide practical guidance on nutrition and exercise planning in the routine care of PCOS, with an emphasis on realistic and achievable goals. While examining the evidence base underlying these management strategies, we present practical considerations for person-centered care, including identifying and minimizing barriers to lifestyle changes in order to increase the long-term sustainability of this treatment strategy.

Lifestyle Intervention: An Overview

Among the general population and those with metabolic disorders, exercise is critical for the prevention and treatment of chronic disease,¹² as well as for improving in quality of life.¹³ In individuals with PCOS, exercise improves cardiorespiratory fitness, lowers central obesity,¹⁴ increases insulin sensitivity,^{10,15,16} and ameliorates psychological distress.¹⁷ While intricately connected to the condition itself, insulin resistance, hyperinsulinemia, and central obesity have been shown to exacerbate the clinical manifestations of PCOS.^{3,18} As a result, the current international evidence-based guidelines for exercise intervention in the management of PCOS specifically

recommend a minimum of two sessions of muscle-strengthening activities and 150 to 300 minutes of moderate-intensity exercise per week or 75 to 150 minutes of vigorous exercise per week, aiming for 30 active minutes daily, for the prevention of weight gain and maintenance of overall well-being.^{4,5} When aiming for weight loss or central obesity reduction, the guidelines recommend a minimum of 250 minutes per week of moderate-intensity exercise or 150 minutes per week of vigorous exercise, in addition to muscle-strengthening activities.^{4,5} Additionally, limiting sedentary time is advised.^{4,5} Given the lack of available evidence, the guidelines were unable to recommend one form of exercise training over another (►Table 1).^{4,5,19} Furthermore, it is important to consider that these recommendations act as benchmarks and clinicians should consider an individualized exercise prescription, rather than a “one-size-fits-most” approach.

Currently, there is no evidence that a specific dietary composition is superior to others in individuals with PCOS.^{4,5} The International Evidence-based Guideline for the assessment and management of PCOS recommends general healthy eating principles that tailor dietary recommendations to the individual in order to meet personal goals and PCOS presentation.^{4,5} Although not highlighted in the guidelines, the evidence does show an anti-inflammatory nutrition pattern such as the Mediterranean diet may be effective in reducing chronic low-grade inflammation and the health problems that this induces in PCOS.²⁰ For instance, diets that follow anti-inflammatory principles are mostly plants and limit processed foods. Nevertheless, dietary modifications should be personalized to the individual according to personal goals and PCOS presentation. In some instances, an energy deficit of 30% or 500 to 750 kcal/day may be beneficial in individuals who are wanting to achieve weight loss (body mass index [BMI] $\geq 25 \text{ kg/m}^2$). Clinicians should consider the appropriateness of the prescription as patients with a history or risk of disordered eating and an unhealthy relationship with self and body may require a focus on behaviour-change goals as an alternative to a weight loss focus.^{4,5,21,22} The input of a registered or accredited practicing dietitian, as part of the multidisciplinary team, may be helpful for the implementation of dietary changes.

Table 1 General exercise recommendations based on the 2023 International Guideline for all people with PCOS^{4,5}

Recommendation	Frequency and duration	Examples
Moderate intensity exercise	For the prevention of weight gain and maintenance of health: 150–300 min/wk	A brisk walk, cycling with light effort, playing tennis, mowing the lawn
	For modest weight loss and the prevention of weight re-gain: >250 min/wk	
Vigorous intensity exercise	For the prevention of weight gain and maintenance of health: 75–150 min/wk	Jogging, cycling fast, an exercise class at your local gym (e.g., circuits, spinning), playing soccer/basketball
	For modest weight loss and the prevention of weight re-gain: >150 min/wk	
Resistance training	Twice weekly	Bodyweight exercises (e.g., squats, lunges, push-ups, plank), free weights, pilates, plyometrics

Abbreviation: PCOS, polycystic ovary syndrome.

As a complex and multifaceted condition, the management of PCOS often relies on the multidisciplinary team.²³ While many healthcare professionals play an important role in the multidisciplinary management of PCOS, primary care providers are the first point of contact for an individual with PCOS,²⁴ and may take on a leadership role, particularly in contexts with limited resources, where balancing perspectives regarding allied health involvement could be considered.

Evidence-based practice involves considering the latest available evidence, the capacity and expertise of the clinician, and the individual desires and preferences to achieve optimal goals.²⁵ This approach will often involve using SMART goals (Specific, Measurable, Achievable, Relevant, and Time-Bound),²⁶ self-monitoring, problem-solving, and focusing on stimulus control, among other interventions.¹¹ However, it is important to note that while evidence-based practice involves using the guidelines and recommendations as a structured and evidence-based treatment framework, individual preferences should be taken into account to create a personalized and sustainable approach that leads to long-term behavior change.¹¹

Body Composition in PCOS

Individuals with PCOS are at higher risk of weight gain compared to the general population, as demonstrated in multiple longitudinal studies.^{27–29} Indeed, 40 to 60% of individuals with PCOS are classified as overweight or obese.³⁰ Despite adjusting for lifestyle and psychosocial factors, participants in a 19-year longitudinal study gained an excess of 4.62 kg compared to controls, suggesting an underlying cause of weight gain unrelated to these factors.²⁸ The driver of this disproportionate weight gain is unclear, but a greater daily energy intake and lower physical activity in individuals with PCOS may contribute.³¹ Whether the weight gain results from physiological or psychological consequences of the conditions remains unclear. However, there is some evidence to suggest that postprandial thermogenesis, a reduced resting metabolic rate, and increased subjective hunger levels may contribute to this finding.^{32–34}

Appetite regulation may be affected by PCOS, as previous reports have shown impaired levels of appetite hormones, including cholecystokinin and ghrelin, in people with this condition.^{35,36} Other intrinsic hormonal abnormalities, including insulin resistance and hyperandrogenism, may contribute to the increased levels of adiposity in this group, as evidenced by a large population-based cohort study that found that these features were not related to adverse lifestyle behaviors such as poor dietary quality or a lack of physical exercise.³¹

Lifestyle Intervention: Important with or without Medical Therapy

The term “lifestyle management” incorporates a multifaceted approach to dietary, exercise, and behavioral strategies, aiming to promote a healthy lifestyle. This approach is recommended for all individuals diagnosed with PCOS due to its positive effects on metabolic health, quality of life,

weight management, and body composition.^{4,5} Higher weight exacerbates clinical features of PCOS, while weight loss ameliorates symptoms.²⁹ A 5% reduction in body weight is considered clinically significant weight loss; however, there is a significant variation in weight between individuals with different anthropometric parameters.³⁷ For the average Australian woman who is 161.8 cm tall and weighs 71.1 kg,³⁸ a clinically significant weight loss would be 3.5 kg. It has been suggested that this modest initial loss provides the greatest effect on the restoration of ovulation and fertility in obese individuals with PCOS,³⁹ and allows achievable and realistic goals to be set. Furthermore, the initial amount of weight lost by individuals does not affect the maintenance of weight loss long-term; the mean percentage of weight loss maintenance 1 year post-intervention was found to be 54% regardless of the initial weight loss.⁴⁰ Therefore, an approach balancing dietary modulation and exercise, perhaps at the expense of a greater initial weight loss, is beneficial in the long term. The approach to weight management should be determined in partnership with the individual, discussing whether they are interested in weight loss and avoiding weight stigma in the clinical setting.

The available evidence suggests that in the pursuit of weight loss, the greatest results are from the synergistic effects of dietary changes combined with exercise intervention.^{10,12} A period of intense exercise is followed by a perceived decrease in appetite, and the energy expended by physical activity is not compensated by a change in dietary intake.⁴¹ While exercise alone can elicit weight loss, this is seldom achieved without high volumes of exercise which may be unattainable for the average person⁴²; however, when added to a low-calorie diet, it induces greater fat loss while preserving lean body mass.⁴³ Due to its weight loss-independent effects on metabolic health, physical capacity,^{12,44–46} and psychological outcomes,¹⁷ exercise is considered a cornerstone therapy for PCOS management. Among individuals with PCOS, exercise has been reported to improve cardiometabolic outcomes, including lipid profile,^{47,48} fasting glucose levels,⁴⁷ systolic blood pressure,⁴⁷ and insulin sensitivity.^{12,18,48} Body composition is also improved, with reduced waist circumference,^{12,14,47,48} body fat percentage,⁴⁸ and improved cardiorespiratory fitness,^{12,14,48} a clinical vital sign⁴⁹ associated with cardiometabolic health.⁵⁰ The greatest improvement in these anthropometric and metabolic outcomes is seen in individuals with PCOS who have a higher weight, compared to individuals with a BMI below 25 kg/m².^{18,48} Exercise may also be beneficial for reproductive outcomes, including hormone profiles,^{12,18,47} but the evidence on this is limited to a few small studies with heterogeneous methodologies and varying magnitudes of effect.

When considering dietary interventions, no one dietary composition is superior to another for the management of PCOS.¹¹ However, a range of dietary patterns underpinned by general healthy eating principles are beneficial for PCOS management, independent of weight change.^{51,52} The benefits are potentially due to the effects on the chronic low-grade inflammatory environment of PCOS, which is mediated by higher fat mass, insulin resistance, and high androgen concentration.⁵³ For example, the Mediterranean Diet (MedDiet) has

been found to be beneficial in PCOS populations,^{20,54,55} as it reduces inflammatory markers, testosterone, and Ferriman-Gallwey score and improves insulin resistance and hyperandrogenemia.⁵⁶ Furthermore, adequate intake of omega-3 fatty acids may reduce liver fat concentrations and oxidative stress, and optimize lipid profiles and overall metabolic measures,^{57–59} although not specifically recommended by the International Evidence-based Guideline for the assessment and management of PCOS.^{4,5} Similarly, the use of probiotics for 8 to 12 weeks has been shown to decrease weight, improve insulin markers and lipid profiles, reduce inflammatory markers, and favor hormone changes and hirsutism scores in individuals diagnosed with PCOS,^{60–62} but the evidence is limited to studies with small numbers of participants and therefore should be interpreted with caution.

Apart from their efficacy, lifestyle interventions are recommended for PCOS because of their tolerability. Increased physical activity has been demonstrated to not cause serious adverse effects or injuries over 1- to 2-year interventions.⁶³ Despite concerns that caloric restriction could lead to an increase in eating disorder symptoms, this hypothesis was not supported by a randomized controlled trial that demonstrated this intervention had benign or beneficial psychological and behavioral effects,⁶⁴ although screening for disordered eating or eating disorders using the SCOFF or EDE-Q 21 item is recommended early on in therapy to best guide appropriate care.¹¹ Furthermore, a consensus panel of experts agreed that the benefits of dieting for weight management outweigh potential negative side effects such as an increased risk of gallstone formation, loss of lean muscle mass, or electrolyte imbalance^{65,66}; however, further empirical evidence is needed to confirm such statements. Additional benefits of lifestyle changes for PCOS management that are not specific to this condition include a reduced risk of cardiovascular disease and type 2 diabetes mellitus.⁴⁸ Lifestyle interventions have been demonstrated to decrease all-cause mortality in a population with impaired glucose tolerance,⁶⁷ which is highly prevalent in individuals with PCOS.⁶⁸ Improvements in cardiorespiratory fitness, measured using VO₂ max as a proxy, have been shown to reduce cardiovascular risk,⁶⁹ and are achievable through exercise in a PCOS population.^{12,14,48}

Dietary Specifications in PCOS

An accredited practicing dietitian can contribute significantly to the management of all women with PCOS and should be offered if resources are available, independent of PCOS phenotype or presenting weight. Dietary management should focus on the immediate presenting needs and prevention of conditions associated with PCOS.^{4,5} In doing so, dietary interventions should incorporate person-centered care to minimize attrition and promote long-term motivation and behavior change.⁷⁰ However, the evidence regarding specific dietary interventions is limited to studies with a small number of participants and moderate-to-high risk of bias; therefore, these specific recommendations serve as a guide but should be adapted to individual preference (**Table 3**).

Overall, individuals with PCOS exhibit poorer intake of grains, fruits, vegetables, proteins, nuts, seeds, and dairy when compared to those without PCOS.⁷¹ Plant-based diets are rich in dietary fiber and abundant in phytochemicals that promote glycemic control, reduce hyperglycemia, and enhance acute insulin response and sensitivity.^{72,73} Plant-based eating patterns such as the MedDiet are primarily based on sufficient intake of wholefoods, particularly green leafy vegetables, fruits, whole grains, legumes, lentils, and seafood, with moderate amounts of poultry and dairy, and limited red meat consumption (**Table 3**).

The MedDiet emphasizes 60 mL/day of extra virgin olive oil, incorporates full fat or low-fat dairy, and limits alcohol to no more than 2 glasses per day of wine.⁵⁶ Interestingly, individuals with PCOS report lower consumption of extra virgin olive oil, legumes, fish, and nuts when compared to those without PCOS.⁵⁶ Greater emphasis on these food groups may elicit improvements in various cardiometabolic risk factors among individuals with PCOS. For people with minimal improvements in insulin sensitivity after following traditional MedDiet principles over 12 weeks, a low carbohydrate (<100 g/day) MedDiet may be beneficial to help reduce anthropometric measures, LH to FSH ratios, insulin resistance, and lipid profiles.⁷⁴ Clinicians may find it useful to use the PREDIMED 14-item questionnaire as a tool to monitor adherence to the MedDiet and highlight dietary recommendations.⁷⁵

Table 2 Recommended nutrition behaviors for the general population, applicable to PCOS

1. Eat small more frequent meals (3 main meals, 1–2 snacks per day)
2. Couple protein with carbohydrate sources in each meal and snack
3. Consume the majority of energy during the day and less at night time, particularly after 8 pm
4. Aim for a 12–16-h fasting window between finishing dinner and having breakfast
5. Incorporate vegetables in each main meal
6. Incorporate green leafy vegetables in main meals, when possible
7. Aim for at least 3 different vegetable colors in each meal
8. Enjoy all vegetables, with greater emphasis on those with lower glycemic index (e.g., artichokes, Brussels sprouts, asparagus, bean sprouts, celery, cucumber, eggplant, mushrooms, onions, leafy greens, spinach, tomato, turnips, zucchini, cauliflower, cabbage, broccoli, capsicums, and tomato).
9. Enjoy all fruit, with particular emphasis on lower glycemic index varieties (e.g., berries, strawberries, raspberries, blackberries, citrus fruits—tangerines, oranges, lemons, grapefruit, cherries, pears, plums, peaches).
10. Enjoy a variety of nuts and seeds—almonds, walnuts, pumpkin seeds, sunflower seeds, sesame seeds, poppy seeds
11. Recommended to limit alcohol and avoidance is best if taking metformin¹⁴²

Abbreviation: PCOS, polycystic ovary syndrome.

Table 3 General dietary recommendations based on the Mediterranean Diet

Recommendation	Serve	Additional information
EVOO	(60 mL or ≥ 4 T/d)	Add when cooking, to salad dressings and cooked vegetables
Nuts	3–5 serves/wk	Particularly include walnuts and almonds. 1 serve = 30 g
Fresh fruit	2–4 serves/d	
Vegetables	5 serves/d	Consume with every meal—particular focus on green leafy vegetables and tomatoes
Fish or seafood	2–3 serves/wk	Fatty fish best, e.g., salmon, sardines, mackerel, tuna
Legumes	≥ 3 serves/wk	E.g., soups, casseroles, vegetarian burgers, falafels, curries
Whole grains	6–8/d	
Dairy	2–4/d	Reduced fat
Tomato-based meals	≥ 3 serves/wk	Sauce made from tomatoes, onions, garlic, and herbs simmered in EVOO
White meat	2 serves/wk	e.g., chicken, turkey, pork, or rabbit without skin
Limit		
Red and processed meats	<1 serving/d	Lean and small portions
Carbonated beverages and sugary drinks	<1/d	
Commercial bakery products, sweets, pastries, biscuits, processed savory snacks	<2/wk	
Fat spreads and cream	<1 serving/d	

Abbreviation: EVOO, extra virgin olive oil.

Source: Adapted from Estruch et al.¹⁴³

An important consideration for dietary therapies is the overall intake and type of protein, with emphasis on both plant (e.g., tofu, tempeh, beans and legumes, and nuts) and animal-based (e.g., lean red meats, chickens, pork, turkey, fish, and dairy) sources, contributing 20 to 30% of total daily energy intake.⁷⁶ Individuals wishing to increase lean muscle mass may combine resistance training with higher protein intake at 2.2 g per kg of body weight per day.⁷⁷ Attention should also be placed on adequate omega-3 fatty acid intake, aiming for 2 g/day of supplemented or at least 400 mg/day of omega-3 through food for a minimum of 6 months, in order to meet daily requirements.⁷¹ Other nutrients of focus are calcium,⁷⁸ selenium,⁷⁹ chromium,⁸⁰ zinc,⁸¹ carotenoids, vitamin D,⁸² vitamin E,⁸³ and magnesium,⁸⁴ due to their positive effects on PCOS management. This is imperative in individuals with PCOS and metabolic syndrome who consume lower amounts of these nutrients when compared to leaner people with PCOS.⁸⁵ While all dietary recommendations should meet macronutrient reference values (protein 20–30%, carbohydrates 45–65%, fat 20%, saturated fat <20% total daily energy intake), an individualized person-centered approach will likely allow for greater long-term sustainability and health,⁸⁶ while correcting nutrient deficiencies, in particular those often deficient in individuals with PCOS.

Gastrointestinal dysbiosis is hypothesized to play a significant role in the pathogenesis of PCOS due to less microbial diversity, changed microbiota composition, and damaged mucosal barrier when compared to individuals

without PCOS.⁸⁷ Interestingly, changes in structure and composition of gut microflora occur irrespective of insulin resistance in people with PCOS,⁸⁸ contributing to the manifestations of hyperandrogenism, insulin resistance, chronic inflammation, and abnormal levels of brain-gut peptides.^{89–91} As dysbiosis is associated with irritable bowel syndrome (IBS),⁹² and IBS is reported to impact the quality of life in 21 to 27% of those diagnosed with PCOS,⁹³ focusing on interventions to treat dysbiosis through prebiotics, probiotics, and synbiotics is an important part of PCOS nutritional care. Probiotics are thought to stabilize the hormonal imbalance through the gut-brain axis, leading to a reduction in the LH/FSH ratio in PCOS populations.⁹⁴ Beneficial probiotics over 8 to 12 weeks include *Lactobacillus rhamnosus GGs*, *Bacillus coagulans*, *Bacillus indicus*, *Lactobacillus acidophilus*, *Lactobacillus casei*, *Bifidobacterium bifidum*, *Lactobacillus rhamnosus*, *Lactobacillus bulgaricus*, *Bifidobacterium breve*, and *Streptococcus thermophilus*, commonly coupled with inulin as a probiotic.^{60–62,95} To partner with probiotics, nutrition recommendations include a high-fiber diet (incorporating 28–30 g of soluble and insoluble fiber per day), reduced saturated fat intake, meeting hydration needs, and limiting gastrointestinal irritants such as spicy, deep-fried foods, carbonated beverages, caffeine, and alcohol.⁹⁶ If these dietary recommendations lead to unsatisfactory results, following the three phases of the low fermentable oligosaccharides, disaccharides, and monosaccharides and polyols (FODMAP) diet can be beneficial in reducing IBS symptoms.⁹⁷

Weight Loss, a Byproduct but Not Goal of Lifestyle Intervention

As higher weight, which is highly prevalent in PCOS, exacerbates PCOS symptoms, it is natural to focus on weight loss as a therapeutic goal. However, the benefits of lifestyle changes in managing PCOS have been shown to be independent of weight loss.^{12,44–46} Given that sustained weight loss is seldom achieved, shifting the focus from weight loss, particularly when trying to commence healthy lifestyle behaviors, may be beneficial. Concentrating instead on the outcomes recognized to improve with exercise, such as cardiorespiratory fitness and physical capacity, may allow these individuals to appreciate the effects of lifestyle intervention notwithstanding the absence of weight loss.^{12,14} Beyond physical changes, individuals with PCOS who undertake healthy behaviors will likely see improvements in psychological and patient-reported outcomes such as quality of life.⁹⁸

"Diet failure" is often accompanied by weight cycling or "yo-yo dieting" in which periods of weight loss and regain occur.⁹⁹ Weight cycling leads to excess fat and decreased muscle mass. During the period of intentional weight loss, muscle mass is lost along with fat, and in the subsequent period of weight gain, the muscle mass is not recovered while fat mass increases.^{100,101} This pattern increases all-cause mortality by 41% and cardiovascular mortality risk by 36%, due to reduced resting metabolic rate¹⁰² and lean muscle mass, and changes in the use of brown adipose tissue.¹⁰³ Each weight cycle results in 20 to 25% of loss in brown fat and lean muscle mass,¹⁰⁴ contributing to insulin resistance,¹⁰⁵ increased abdominal fat,¹⁰⁶ elevated triglycerides,¹⁰⁷ chronic inflammation,¹⁰⁸ and overall sarcopenic obesity over multiple weight cycles.¹⁰⁹ Adaptive thermogenesis makes maintaining newly suppressed weight highly difficult, needing to employ rigid dietary habits so as to not exceed lower daily energy requirements (e.g., $\leq 1,500$ cal/day) compared to 2,000 cal/day in those without weight cycling behaviors.¹⁰⁹

Body recompensation, a concomitant increase in skeletal muscle mass and decrease in fat mass, is a strategy that can address this phenomenon in weight cycling and is a goal in clinical and nonclinical settings.^{110,111} Maintenance of skeletal muscle is an important consideration in PCOS patients, as it is associated with improvements in insulin resistance.¹¹² Muscle is one of the main targets of insulin, and the metabolic effects of insulin and insulin resistance partially depend on the quality and quantity of muscle mass.¹¹³ Resistance training and dietary strategies, such as whey protein supplementation, can preserve muscle mass during a weight loss program,^{114,115} but also increase the relative proportion of protein intake to fat and carbohydrates. Rather than aiming for overall weight loss, lifestyle intervention in individuals with PCOS may focus on body recompensation, which can occur without a change in BMI.¹¹⁴

Continuously restricting dietary intake and linking thinness as a value of self-worth leads to greater psychological distress,¹¹⁶ increases weight over time, reduces physical activity, and increases binge eating¹¹⁷ in those who weight

cycle. There is an overall increased risk of eating disorders when compared to people who remain weight stable.¹¹⁸ Individuals with PCOS are at increased risk of cardiovascular disease,¹¹⁹ disordered eating, eating disorders,^{120,121} low self-esteem, and overall psychological distress.¹²² Therefore, coupled with the weight stigma commonly experienced from patients when seeking help to manage PCOS,¹²³ weight management should be one of, but not the central treatment goal in cases where it has the capacity to worsen PCOS psychopathology. In such instances, focusing on other outcomes such as insulin sensitivity, cardiorespiratory fitness, and behavioral goals such as increased physical activity may lead to greater long-term effects.

Barriers to Lifestyle Intervention

Lifestyle changes are most effective if they are realistic and adapted to meet the health goals of the individual. Unfortunately, many people with PCOS experience barriers to sustained lifestyle change due to feeling discouraged by a lack of results, lack of time, feeling embarrassed, and financial costs,¹²⁴ resulting in an average attrition rate of 47.1%.¹²⁵ These findings coincide with other metabolic conditions affecting women such as gestational diabetes mellitus,¹²⁶ for which PCOS is a significant risk factor.¹²⁷ Therefore, part of realistic lifestyle intervention is identifying and minimizing the barriers to change. An important barrier to lifestyle intervention includes patients' perception that they are not achieving their health goals through diet and exercise changes, and this remains a common theme when considering dietary intervention.¹²⁴ A study found that more than 82% of participants had modified their diet for health reasons; however, a third of participants did not achieve their health goals or any positive effect from dietary changes.¹²⁸ A lack of adequate information may be a contributor. Individuals with PCOS report dissatisfaction with the information provided at the time of diagnosis, including details on lifestyle interventions.¹²⁹

Weight stigmatization is an often overlooked contributor to negative health outcomes and behaviors.¹³⁰ The phenomenon of weight stigma and the associated negative stereotyping of obese individuals has been documented by multiple studies.^{131,132} The resulting stress leads to depleted self-regulation and low self-esteem.¹³³ Weight stigma extends to healthcare settings, with a patient's weight affecting how they are viewed and treated by physicians.¹³⁴ The negative attitudes toward higher weight displayed by healthcare providers can act as a barrier to the management of medical conditions.^{135,136} Even the language utilized can be detrimental; using person-first language, an evidence-based terminology that puts the person in front of the condition can help address the stigma.¹³⁷ While it is well established that higher weight leads to adverse health outcomes⁶⁵ and exacerbates PCOS symptoms,²⁹ and therefore weight loss plays a role in the management of this condition, it can be counterproductive and stigmatizing to focus on weight reduction as the main pillar of PCOS management. Instead, adopting a balanced and individualized approach

that focuses on the specific goals of treatment relevant to the individual, uses person-first language, and shifts the focus of management from weight loss to behavioral change and body recomposition may be a more appropriate therapeutic strategy.¹³⁸

The management of PCOS should be practical through positive psychology, motivational interviewing, open-ended questions, active listening, tools for behavior change, and positive communication, with the responsibility of self-care and behavior change falling on the individual.¹³⁹ Providing a non-judgmental, shame-free space, and being aware of weight stigmatizing beliefs and attitudes which may unconsciously drive lifestyle suggestions is the duty of health practitioners. Individual preferences, including not wishing to discuss weight as part of therapy, should be respected.¹³⁹ Identifying weight stigmatizing beliefs in the individual and working through these is also important. The use of weight-neutral approaches such as basic nutritional therapy information, mindful eating, body image work, hunger-fullness work, building self-esteem, and understanding diet cycles have the same weight loss outcomes as prescribed dietary therapies over 12 months¹⁴⁰ while motivating sustainable healthy behaviors.

Conclusion

Lifestyle interventions in PCOS lead to improvements in anthropometric, metabolic, reproductive, and psychological outcomes,^{12,14,31} and should incorporate psychology, nutrition, and movement, using person-centered approaches to facilitate self-determined health goals and empower long-term change.¹⁴¹ A personalized approach, focusing on the individual's specific goals rather than a one-size-fits-most approach, is essential in the management of this condition. Another key element in the management of PCOS through lifestyle changes is shifting the focus from weight loss to behavioral change and body recomposition. Setting realistic goals and minimizing barriers to lifestyle intervention will increase the long-term sustainability of this management strategy.

Dietary intake, body composition and energy expenditure in women with polycystic ovary syndrome (PCOS) compared with healthy controls: an observational study

Yvonne Jeanes¹, Suzanne Barr¹, Sue Reeves¹, Sharon Burt¹, Manuela Abbate¹ and Kathryn Hart²
¹Roehampton University, London, UK and ²University of Surrey, Guildford, UK

PCOS affects $\leq 10\%$ of women of reproductive age in the UK. Obesity is a common feature of the syndrome, with approximately 33% of UK women with PCOS (wPCOS) being obese⁽¹⁾ compared with 20% of women in the general population⁽²⁾. The present study aims to compare the diet and energy expenditure of wPCOS with matched controls to further elucidate the complex relationship between weight and PCOS presentation.

A 7 d food diary and a medical questionnaire were completed by thirty-seven wPCOS and thirty-one age- and weight-matched controls. A pedometer was also provided to record physical activity levels on the same 7 d. Anthropometric data (BMI, waist:hip ratio (WHR) and percentage body fat (%BF), using bioelectrical impedance) were measured. Energy expenditure was estimated in a subset (sixteen wPCOS, seventeen controls); values derived from BMR, which was measured by indirect calorimetry, were used to calculate metabolic equivalent intensity levels for activities⁽³⁾ from the 7 d activity diary.

The mean age of the sample as a whole was 31 (sd 6) years, with 97% of the sample being white British women. Mean BMI (kg/m^2) were 24.4 (sd 4.1) and 24.2 (sd 4.5) for wPCOS and control women respectively (NS). Mean WHR and %BF for wPCOS were 0.77 (sd 0.07) and 30 (sd 7) respectively, compared with 0.7 (sd 0.06) and 29 (sd 7) respectively for controls (NS). A similar percentage of women reported their weight as being stable (wPCOS 62, controls 72) and a similar percentage reported their weight to be increasing (wPCOS 19, controls 13). Mean energy intake for wPCOS was 7980 (sd 1516) kJ (1906 (sd 362) kcal)/d, not significantly different from that reported by controls (7624 (sd 175) kJ (1821 (sd 418) kcal)/d). However, percentage energy (%E) from fat was significantly higher for wPCOS (40 (sd 6)) compared with controls (35 (sd 5); $P=0.001$). %E from carbohydrate for wPCOS was significantly lower (41 (sd 8)) compared with controls (46 (sd 5); $P=0.003$) with no differences in %E from protein. The mean number of steps per d was 9308 (sd 2672) for the whole sample, with no significant difference between wPCOS and controls (9240 (sd 2699) and 9392 (sd 2682) respectively). Mean energy expenditure for wPCOS (n 16) was 9772 (sd 2010) kJ (2334 (sd 480) kcal)/d, which was not significantly different from that reported by controls (n 17; 9010 (sd 1369) kJ (2152 (sd 327) kcal)/d).

Results indicate qualitative differences in the dietary intakes of wPCOS compared with age- and weight-matched controls. However, no significant differences in activity levels or body composition have been identified. Analysis of biochemical data, including lipid profiles and insulin resistance would help to further elucidate the relationship between behaviour, weight and risk factor profile in wPCOS. The present study is the first to report the habitual dietary intake of UK wPCOS compared with matched controls, and results are similar to US findings⁽⁴⁾. Identification of suboptimal dietary patterns in wPCOS in the UK will allow dietary information for this population to be more effectively tailored to help maximise the success of lifestyle interventions.

ABSTRACT

Polycystic Ovary Syndrome (PCOS), is a hormonal disorder that occurs among women in their reproductive age. It has effective conflicts throughout this gynecological disorder, as it affects one in ten women at a nearly age. There are certain symptoms such as irregular menstrual cycles, missed periods, heavy bleeding during the menstruation period, excess of androgen hormones, obesity, acne or oily skin, hair growth on the face, and a typical weight gain. The exact cause of PCOS is not yet properly defined, but it could involve genetic causes and a metabolic balance in the diet. Due to certain effectiveness like the risk of heart attack, and type two diabetes, it is necessary to get detected and diagnosed as early as possible and start the possible treatments which include a healthy diet and exercises, with medications like birth control pills that control the level of hormones. Certain Machine Learning algorithms are used to detect this disorder. The data set consists of 541 patients, and out of 44 features, 10 potential features were identified using the filter method. This paper includes a detection model of PCOS using various machine learning algorithms like Random Forest, Logistic Regression, Support Vector Classifier, and Decision Tree. Among all these algorithms, Random Forest has 83.48% accuracy for the model.

Keywords: Polycystic Ovary Syndrome, Machine Learning, Random Forest, Logistic Regression, Support Vector Classifier, Decision Tree.

INTRODUCTION

Technology is boosting its measure every single time which makes every transformation very flexible whether it is in the gadgets or the health care industry and services. Machine Learning plays a paramount role in all health-related domains as it is a constituent subset of artificial intelligence. There are distinct application areas of it such as image recognition, health monitoring, robotic perception, anomaly detection, and many more. It predominantly focuses on the development of algorithms that can be easily accessible from the data sets that are provided for detecting and predicting the required information. Thus, Machine Learning algorithms are utilized efficiently for the detection of PCOS. PCOS is a common hormonal disorder observed in women of childbearing age. Few symptoms indicate the

Diya Gandhi et al.,

hormonal balance, and it results in obesity associated with an enlarged polycystic ovary. In the productive age of 15-40, women experience their regular trend of their menstruation with hormonal effects, which shows that PCOS can affect individuals at any age. There are certain health risks due to this disorder including cardiovascular diseases which generally increase blood pressure and cholesterol levels, and uterine cancer occurs because the least ovulation leads to the build up of the uterine lining, mental health issues affect physiological conditions such as depression and anxiety, and type two diabetes happens due to insulin resistance and high blood sugar levels increase the risks of circumstances. The significant element in this heterogeneous condition is hormones. Luteinizing Hormone (LH), Follicle-Stimulating Hormone (FSH), and Anti-Mullerian Hormone (AMH) affect follicles and the development of the eggs, creating issues in ovulation, and FSH levels might be normal or lower than the usual values. Estrogens and Progesterone are essential for balancing the level of hormones to get the regular menstrual cycle. Among every suffering patient, 70% are undiagnosed. Hence, the prediction and detection of PCOS is necessary at the preliminary phase as it sustains the life of an individual by reducing lifelong health risks and creating a healthy life style.

The certain work focused in this paper is:

- I. Selection of the influential components affecting the patients of PCOS with the help of feature selection.
- II. Implementation of various machine learning algorithms on the selected features of the dataset. Comparing the accuracy of the different algorithms to fit the best model

LITERATURE REVIEW

PCOS detection has become a hot topic for researchers in the last decade. Few individuals have implemented the various methodologies in this field to achieve the desired outcome for the health benefit to all women.

This section consists of the distinct literature works done previously based on various implemented methods such as follicles detection, feature extraction, and classification, Cross Validation, Support Vector Machine (SVM), Logistic Regression, k nearest neighbors (kNN), and many more [4].

METHODOLOGY

Data Collection

Data collection is a crucial step. For this, various platforms are available example for Kaggle, UCI Repository etc. In this paper, we have used a dataset from Kaggle [1]. This dataset is composed of 44 different features with more than 500 records. Such features include pimples, hair growth, cycles, vitamin d3, etc.

Data Preprocessing

Data Preprocessing is a step that takes raw data and transforms it into a format that can be understood and analyzed. Unprocessed data must contain some Missing values, Outliers, Unstructured manner, and Categorical data. Missing values can be corrected in many ways but the most common methods are Delete Rows with Missing Values and replace the missing value with some arbitrary value using `fillna()`. Missing values can also be imputed using 'interpolation'. Here we have also dropped unnecessary features. Furthermore, the dataset should only contain a value that is float or integer so that algorithms can process the data. The next step is Exploratory data analysis. This process involves summarizing, visualizing, and getting deeply acquainted with the important traits of a dataset. It examines a correlation matrix of all the features, and how all the features correlate with the PCOS, having a look at features bearing significant correlation.[4].

Feature Selection

The feature selection method intends to select the most useful feature for a model to predict the output. Feature selection is performed to improve predictivity, reduce the dimensionality of feature space, and get rid of noisy data.

Some favored techniques for feature selection are Filter Methods, Wrapper Methods, and Embedded methods. In this paper, we have used the filter method to rank each feature based on some univariate metric and then select the highest-ranking features and we have also referred to previous research to select the highest-ranking features [5].

Fitting into models

After the Data preprocessing, it is now ready to be handled by the models. Selected sets of features are used to study the algorithm. Among countless ML algorithms available, we have applied Logistic Regression (LR), Decision Tree Classifier, Random Forest Classifier, Gradient Boosting Classifier, and Support Vector Machine.

Logistic Regression (LR)

Logistic Regression, a supervised learning algorithm, uncovers its preliminary application in classification tasks by assessing the probability of a sample belonging to a distinct class. It is specifically fitted for binary classification, where the output variable is categorical. This algorithm operates the logistic function, also known as the sigmoid function, to convert the result of a linear equation into a value within the range of 0 to 1. This altered value represents the likelihood or probability of a data point being associated with a certain class. [11]. The accuracy of this algorithm was 82.56% here

Decision Tree Classifier

The Decision Tree classifier is a supervised algorithm principally operated for classification tasks. This technique operates by iteratively splitting the dataset into subsets according to the attribute values, resulting in a tree-like configuration. In this structure, individual inner node exemplifies a conclusion based on a distinctive characteristic, and each leaf node corresponds to a class label. Here, the accuracy of this algorithm was 77.98%. [12]

Gradient Boosting Classifier

Gradient Boosting is a significant boosting approach that assembles numerous weak learners into vital learners. This methodology involves training individually unique samples to minimize the loss function, such as mean squared error or cross-entropy, based on the performance of the previous model employing gradient descent. In each iteration, the algorithm computes the gradient of the loss function regarding the predictions assembled by the current ensemble. Thereafter, a unique weak representative is trained to minimize this gradient. The predictions yielded by the new model are incorporated into the ensemble, and this iterative approach persists until a predefined stopping criterion is satisfied. The accuracy here was 82.56% [12].

Random Forest Classifier

The Random Forest Algorithm is a supervised machine learning technique employed for addressing both classification and regression challenges in the realm of machine learning. It can be considered as an ensemble of decision trees. Instead of depending on a single decision tree, the random forest contains multiple decision trees, each prepared on distinct subsets of the delivered dataset. To enhance predictive accuracy, the algorithm computes the intermediate prediction from these trees. Instead of just depending on one tree's outcome, the absolute prediction is determined by a majority vote among the predictions from the ensemble of trees. The accuracy for this algorithm was 83.48%. [13]

Support Vector Machine

The Support Vector Machine (SVM) is a supervised learning algorithm appropriate for both classification and regression tasks, although it is primarily employed in classification problems in the field of machine learning. The primary objective of SVM is to establish an optimal conclusion limitation, usually directed to as a hyperplane, within an n-dimensional distance to effectively distinguish between different classes. This hyperplane relieves the proper categorization of further data attributes in the future. SVM identifies the critical data points that play a major role in determining this hyperplane; these pivotal representatives are known as support vectors, giving rise to the name "Support Vector Machine". The accuracy was 70% here. [14]

**Evaluation and Comparison of Models**

The comparison of these models is done based on accuracy. Various classification algorithms are used to find the most acceptable models. As shown in the table and plot the best accuracy is given by Random Forest Classifier, Gradient Boosting classifier, and Logistic Regression

RESULT

The dataset contained 541 samples with 44 features. Out of these 44 parameters, only ten parameters are considered. Parameters that are more important for the diagnosis of PCOS are shown in Table III, after analyzing the performance of all five models, we can conclude Random Forest is most Suitable.

CONCLUSION

This paper exhibits the different Machine Learning algorithms and a model to detect the early phase of PCOS, as it is essential for women's health. This hormonal disorder impacts the regular condition of women and disturbs the psychological, physical, and metabolic components. Day-to-day exercise and a regular healthy diet are initialized to decrease the effect and maintain a nourishing lifestyle. The model in this paper ventures the comfortable system to detect the disorder at an early stage, with a definitive set of parameters. Among all the various algorithms used, the Random Forest Classifier possesses the foremost result in its performance with 83.48% by considering the relevant 10 features. This model is flexible such that it can be utilized by doctors for the early detection of PCOS. Hence, we have built the model with different machine-learning techniques to detect PCOS at an early stage

ACKNOWLEDGEMENT

We would like to express our sincere gratitude to all those who supported and assisted us with their determination and invaluable contribution that led to the completion of our paper. We are grateful to the medical professionals who shared their insights and expertise by giving us their valuable time. We are also thankful to our college as they supported us generously with their essential resources.

Table 1. Research Methodology

AUTHORS	OBJECTIVES	RESEARCH METHODOLOGY	RESULTS
Rihana et.al. [2013] [2]	classificationn in ovary and Cysts detection, ultrasound images with geometricalfeatures of the cyst.	Image pre-processing,Feature extraction, SVM classifier, andValidation were used byROC.	Accuracy of 90% was achieved and cysts were detected inovary ultrasound images.
Purnama et al. [2015][3]	Detecting follicles via ultrasound (USG) pictures through a process involving binary follicle images, feature extraction, and segmentationn.	Multiple classification methods were developed suchas SVM – RBF kernel, Neural Network – LVQ, and KNN – Euclidean distance.	At K=5,KNN attained an accuracy of 78%, and on C=40, 82% accuracy was achieved in the SVM-RBF kernel.
Denny et al. [2019][4]	Diagnosis of PCOS based on dataset available on Kaggle.	Attributes of PCOS are transformed with PCA by various machine learning algorithms such as Decision Trees, Random Forest, SVM, KNN, etc.	Random Forest was the best model for PCOS detection with an accuracyof 89%.
Subrato et al. [2020][5]	Diagnosis of PCOS using Kaggle dataset.	Algorithm used for classification are gradient boosting, Random Forest , Logistic regression, RFLR and used holdout and cross validation methods	RFLR gave highest accuracy of 91.01% with 90% recall value
Madhumita ha et al. [2021][6]	Used image segmentation to get details of the ovary for example follicle size, type of cysts.	SVM, KNN and Logistic Regression were used as per pre- processing and morphological operations.	With the combination of all three algorithm, the hybrid model gave 0.98 accuracy.
Pijush et al. [2021] [7]	Detection and prevention of PCOS.	The algorithm used were SMOTE and five other algorithms Logistic Regression, Random Forest, Support vector machine and K- NN, and Random Forest together for early detection of PCOS.	The best model achieved, Recall: 98%, Precision: 98% and AUROC: 95.6%.

Shamik Tiwari et al. [2022] [8]	To diagnose PCOS using Machine Learning	The algorithms used for classification are SVM, DT, RF, LR, GB, AB, XB, AND CB for correlation coefficients of various levels.	Random Forest (RF) gave highest accuracy of 93.25%
Samia Ahmed et al. [2023] [9]	A review on the PCOS using the Machine Learning	A study on various dataset used for PCOS diagnosis was conducted. In quantitative and Qualitative approaches, the performance of algorithms are compared.	The shortcomings like insufficient dataset, lack of clustering approach, not were detected in this paper.

Table 2. Accuracy of all Models

Summary **Background.** Insulin resistance is one of the major metabolic disorders. The composition of one's diet has a crucial effect on the risk of developing this disorder and is a key component of treatment. Following a vegetarian diet seems to be promising for health benefits.

Objectives. The aim of the study is to assess the eating habits of women suffering from insulin resistance following vegetarian and non-vegetarian diets.

Material and methods. The survey was conducted among 248 women between the age of 18 to 64 in Poland from January to March 2022. The research tool was a website survey questionnaire. The analysis was performed using the Statistica 10 program. The data obtained was subjected to statistical analysis using the chi-square test. Results were considered significant at $p \leq 0.05$.

Results. Women on a vegetarian diet had the correct body weight more often (47.4%) compared to those following a traditional diet (40.5%) or not following any diet (38.5%). 69.3% of vegetarians assessed their nutritional knowledge as better than good. Women on a plant-based diet included legumes in their diet and consumed vegetables much more often than others. Attitudes towards plant-based meat substitutes and plant-based dairy substitutes were significantly more positive among vegetarians than others.

Conclusions. Women with insulin resistance on a vegetarian diet often have better nutritional choices compared to women on a traditional diet or those not following any diet. These promising findings may be helpful in preventing and treating this disorder. However, the amount of research and results is insufficient and requires further analyses on a larger group of subjects.

Key words: insulin resistance, feeding behavior, diet, vegetarians.

Background

Insulin resistance is one of the major metabolic disorders on which a lot of research is being carried out. Detection of this disorder has increased significantly in recent years. The prevalence among people shown in studies depends on population, but it is reported to be 10% to 30% [1]. Insulin resistance is highly correlated with obesity, but it has been proven that people with a healthy body weight can also struggle with it. If they are left untreated, it can also have serious health consequences, despite being non-obese [2].

Insulin resistance is defined as the lack of ability of insulin-target tissues to dispose glucose from blood and inhibition of endogenous glucose production and lipolysis. At the same time, inability of stimulating glycogen synthesis at high plasma insulin concentrations occurs. An imbalance of energy intake and expenditure is the main reason for common insulin resistance. Genetic predispositions are also important issues [3].

The frequency of this condition is associated with age, body weight, gender, physical activity, as well as genetic and lifestyle issues. Moreover, scientific research has shown that insulin resistance can be related to stress and overstimulation of the sympathetic nervous system. This condition is also correlated with the occurrence of inflammation in the body [1].

The composition of one's diet has a major effect on the risk of developing this condition and is a key component of treatment for insulin resistance. This is why the assessment of the

nutritional habits of patients is very important [1]. Diet models most suitable for patients with insulin resistance have also been investigated. The Third National Health and Nutrition Examination Survey (NHANES III) found that people who follow a diet very similar to the Mediterranean diet had lower BMI and waist circumference. These indicators correlated with lower glycated haemoglobin levels, fasting insulin levels and Homeostatic Model Assessment for Insulin Resistance (HOMA-IR) index values [4].

Referring to the individual components of the diet, lower insulin sensitivity was associated with high consumption of animal products and low intake of vegetable food. It has been shown that this is correlated with type 2 diabetes and cardiovascular disease [5]. Eating habits, physical activity and lifestyle are extremely important but also modifiable factors on which the risk of insulin resistance depends [1]. Since 1935, when Hinsworth and Marshall [6] investigated and noted that a diet high in animal products and low consumption of plant-based foods increased the risk of type 2 diabetes, it has been proven that we should focus on prevention through proper and healthy eating habits.

A lot of research has been done, and now we have evidence that a nutrition model based on high consumption of animal and low-vegetable proteins promotes insulin resistance in patients with diabetes and in healthy people [7–9]. This is caused by glucagon secretion activated by amino acids, like arginine and alanine from animal protein. In the liver, glucagon is opposite to insulin and interferes with its action. High plasma glu-

cagon is maintained for at least four hours after a meal which is high in animal protein. This mechanism is very well observed in diabetic patients. Hyperglucagonemia that lasts a long time may induce insulin resistance [5].

A meta-analysis that included 19 trials showed that a diet rich in fruits, vegetables, whole grains, nuts, legumes, fat-free/low-fat dairy and a diet low in saturated fat, cholesterol, red and processed meats, refined grains and sweets had a good effect in improving insulin sensitivity. It is also important that a diet should be based on products with a low glycaemic index (GI) as low GI diets have been reported to improve insulin sensitivity and lower blood glucose. Foods rich in dietary fibre and micro-nutrients are essential in diet for insulin resistance. It has also been found that a calorie-restricted diet may have positive effect for glycaemic control by improving insulin sensitivity and β -cell function. Moreover, treatment and following a diet duration also had an important influence on the positive effects for glycaemic control by improving insulin sensitivity and β -cell function [10].

Objectives

The aim of the study is to assess the eating habits of people suffering from insulin resistance following vegetarian and non-vegetarian diets.

Material and methods

The survey was carried out in Poland from January to March 2022. The questionnaire was completed by 356 individuals. Incomplete data was rejected, and 248 participants aged 18–64 were enrolled in the study.

A survey was prepared by the authors. The questions concerned one's behaviours and eating habits, the frequency of meals, the subjective frequency of eating snacks, the consumption of vegetable, meat and dairy substitutes, the frequency of meat consumption and stimulants used, the type and amount of physical activity. Besides these, the KomPAN® questionnaire was used to assess the frequency of food consumption [11]. Moreover, there were questions concerning anthropometric parameters (body weight and height, waist circumference), as well as questions related to socio-demographic characteristics. There were 97 questions in the survey, 11 of which concerned anthropometric and socio-demographic data, and the rest concerned the frequency of food consumption and eating behaviours. The percentage of analysed questions with a $p < 0.05$ level was 45.3.

The exclusion criteria were being under 18 years of age, body mass index (BMI) below or equal to 18, anorexia, bulimia, malnutrition, as well as severe diseases (alcoholism, severe and extensive surgery, kidney failure), cancer in the last 5 years and the use of enteral and parenteral nutrition. Inclusion criteria were age and BMI over 18 and being diagnosed with insulin resistance, which the respondents declared in the survey. The study participants were people that voluntarily consented to take part in the study, which was announced on social media.

Statistical analysis was carried out with the use of the Statistica 10 program. The division of people into three groups was introduced due to type of diet (traditional, vegetarian and non-diet) and was verified using the chi-square independence test. In all analyses, a significance level of $\alpha = 0.05$ was assumed.

Results

248 women aged 18–64 suffering from insulin resistance participated in the study. More than a half of them were on a traditional diet, while 31.5% were on a vegetarian diet, and 15.7% declared to be non-dieters. BMI (body mass index) range was 18.0–46.4 kg/m². A large majority of participants (68.5%) had high education. The exact population data is presented in Table 1.

Table 1. General description of the studied population

Number of participants	n = 248
Age (year) (age range)	18–64
BMI (kg/m ²) (BMI range)	18.0–46.4
Smoking (%)	21.8
Age groups (%)	
18–20 years	4.3
21–40 years	85.0
41–60 years	10.7
Physical activity (%)	
low level	44.8
middle level	43.5
high level	11.7
Commune size (%)	
< 10,000 inhabitants	14.9
10,000–20,000 inhabitants	6.0
20,001–100,000 inhabitants	13.7
> 100,000 inhabitants	65.3
Level of education (%)	
under middle	1.6
middle	28.2
high	68.5
vocational	1.6
Type of diet (%)	
traditional	52.8
vegetarian	31.5
non-diet	15.7

Nutritional habits

Women on a vegetarian diet were much more likely to not consume milk and milk drinks (53.8%) than those on a traditional diet (19.1%) and those who do not follow any diet (10.3%). 52.7% of the respondents on a traditional diet chose low-fat dairy products compared to 26.9% of vegetarian women and 51.3% of non-dieters ($p < 0.01$). In contrast, 77.0% of the respondents on a vegetarian diet consumed dairy alternatives (e.g. drinks, yoghurts, vegetable spreads) once a week or more often ($p < 0.01$). The data is presented in Tables 2 and 3.

Regarding the frequency of eating alternatives to meat products, such as vegetable sausages, burgers, meatballs, nuggets, etc., 68.0% of the surveyed women on a vegetarian diet consumed those products more often than once a week. Compared to them, this was 16.0% of the respondents on a traditional diet and 23.1% of the women who do not follow any diet ($p < 0.01$). The data is presented in Table 4.

Table 2. Type of milk

Type of diet	Traditional (n = 131)	Vegetarian (n = 78)	Non-diet (n = 39)	p
I do not consume milk or milk drinks	25 (19.1%)	42 (53.8%)	4 (10.3%)	$p < 0.01$
Fat-free milk	3 (2.3%)	2 (2.6%)	2 (5.1%)	$p < 0.01$
Low-fat milk	69 (52.7%)	21 (26.9%)	20 (51.3%)	$p < 0.01$
Full-fat milk	34 (26.0%)	13 (16.7%)	13 (33.3%)	$p < 0.01$

Table 3. Frequency of consumption of dairy alternatives (e.g. plant-based soy and coconut yogurts, plant-based drinks, vegetable spreads)

Type of diet	Traditional (n = 131)	Vegetarian (n = 78)	Non-diet (n = 39)	p
Never	35 (26.7%)	2 (2.6%)	18 (46.2%)	p < 0.01
1–3 times a month	37 (28.2%)	16 (20.5%)	7 (17.9%)	p < 0.01
Once a week	19 (14.5%)	6 (7.7%)	4 (10.3%)	p < 0.01
A few times a week	31 (23.7%)	24 (30.8%)	7 (17.9%)	p < 0.01
Once a day	6 (4.6%)	13 (16.7%)	2 (5.1%)	p < 0.01
A few times a day	3 (2.3%)	17 (21.8%)	1 (2.6%)	p < 0.01

Table 4. Frequency of consumption of meat alternatives (e.g. vegetable cutlets, sausages, burgers, meatballs, schnitzels, nuggets)

Type of diet	Traditional (n = 131)	Vegetarian (n = 78)	Non-diet (n = 39)	p
Never	61 (46.6%)	7 (9.0%)	22 (56.4%)	p < 0.01
1–3 times a month	49 (37.4%)	18 (23.1%)	8 (20.5%)	p < 0.01
Once a week	11 (8.4%)	20 (25.6%)	6 (15.4%)	p < 0.01
A few times a week	10 (7.6%)	30 (38.5%)	3 (7.7%)	p < 0.01
Once a day	0 (0%)	1 (2.6%)	0 (0%)	p < 0.01
A few times a day	0 (0%)	1 (1.3%)	0 (0%)	p < 0.01

Table 5. Frequency of consumption of legumes, e.g. beans, peas, soybeans, lentils

Type of diet	Traditional (n = 131)	Vegetarian (n = 78)	Non-diet (n = 39)	p
Never	18 (13.7%)	1 (1.3%)	2 (5.1%)	p < 0.01
1–3 times a month	46 (35.1%)	6 (7.7%)	11 (28.2%)	p < 0.01
Once a week	25 (19.1%)	23 (29.5%)	14 (35.9%)	p < 0.01
A few times a week	31 (23.7%)	30 (38.5%)	10 (25.6%)	p < 0.01
Once a day	8 (6.1%)	14 (17.9%)	2 (5.1%)	p < 0.01
A few times a day	3 (2.3%)	4 (5.1%)	0 (0%)	p < 0.01

Table 6. Self-assessment of nutritional knowledge

Type of diet	Traditional (n = 131)	Vegetarian (n = 78)	Non-diet (n = 39)	p
Very Good	15 (11.5%)	19 (24.4%)	1 (2.6%)	p < 0.01
Good	42 (32.1%)	35 (44.9%)	12 (30.8%)	p < 0.01
Bad	50 (38.2%)	18 (23.1%)	16 (41.0%)	p < 0.01
Very bad	24 (18.3%)	6 (7.7%)	10 (25.6%)	p < 0.01

Another point is that more of the surveyed women on a vegetarian diet (25.6%) stated that they never eat fried foods (meat or flour) compared to those on a traditional diet (10.7%) and non-diet (12.8%) ($p < 0.01$).

A large majority of participants (89.7%) on a vegetarian diet declared that they include legumes in their diet at least once a week. In the case of people following a traditional diet, this was 51.9%, while those not following any diet – 46.2%. Among the respondents on a vegetarian diet, there was not a single person who declared to never consume legumes ($p < 0.01$). The data is presented in Table 5.

Regarding the frequency of eating vegetables, most people on a plant-based diet consumed vegetables several times a day (75.6%) compared to those on a traditional diet, with less than half of the respondents – 49.6%, and people not following any diet – 51.3% ($p < 0.02$).

Attitude to plant-based products

We examined the association between the type of diet and attitudes towards plant-based meat substitutes and plant-based dairy substitutes. A large majority of participants on a vegetar-

ian diet (82.1%) declared that plant-based meat substitutes are for them a wholesome alternative to meat products. However, the same was stated only by 36.6% of respondents on a traditional diet and 28.2% of women not following any diet ($p < 0.01$).

As for the same claim regarding plant-based dairy alternatives, the results were similar. 76.9% of vegetarians declared that plant-based substitutes for dairy products were a full-fledged alternative. Only 42.0% of non-vegetarians and 38.5% of non-dieters agreed with this statement.

Self-assessment of nutritional knowledge and nutrition, well-being, physical activity, sleep habits

Additionally, we examined the respondents' opinion on their nutritional knowledge. 69.3% of vegetarians defined it as good or very good, only 43.6% of women following a traditional diet had the same opinion about their own knowledge, and this was even less (33.4%) for respondents who did not follow any diet ($p < 0.01$). The data is presented in Table 6.

The results related to the amount of sleep, physical activity, well-being and self-assessment of nutrition were not statistically significant ($p > 0.05$).

Body Mass Index

Body mass index (BMI) was calculated based on the data concerning the height and weight of the surveyed women. Correct BMI was within the range of 18.5–24.99 kg/m². The results showed that 47.4% of the women on a vegetarian diet had the correct body weight compared to those following a traditional diet (40.5%) and those not following any diet (38.5%). BMI over 24.9 kg/m² (overweight or obesity) amounted to 55.0% of the respondents on a traditional model of nutrition, 44.9% of women eating plant-based foods and 61.5% of non-dieters ($p < 0.02$).

Discussion

As far as we know, there is no other study comparing the eating habits of women suffering from insulin resistance on a vegetarian or non-vegetarian diet. From the results that we were able to collect, we obtained data confirming our research hypothesis that the eating habits of women on a non-vegetarian diet differ from those on a plant-based diet, and this has further consequences.

The respondents on a plant-based diet displayed healthier eating habits by consuming more legumes and vegetables and more often chose low-fat milk or plant-based substitutes for meat and dairy products. Similar results were obtained in a study among Argentinean vegetarians and non-vegetarians. In this survey, the respondents on a plant-based diet were also more likely to eat legumes and vegetables more often, as well as fruit, whole grains, seeds and nuts. Researchers compared adherence to healthy vegan lifestyle habits according to the vegetarian diet pattern category and presented results that indicated that non-vegetarians scored significantly lower than the vegetarian groups [12]. On this basis, we can assume that vegetarians may have better eating habits.

In our research, we discovered that women following a plant-based diet had normal BMI more often than non-vegetarians. The same results were found in the Rotterdam Study [13], which also examined this relationship. In this study, they constructed an overall plant-based dietary index measured by the food frequency questionnaires (FFQs) divided into 23 food categories. A higher score on the plant-based dietary index was related to lower longitudinal HOMA-IR and BMI. Referring to our results and those of the the Rotterdam Study, it can be assumed that a plant-based model of eating probably has a positive effect on the occurrence and course of the disease.

Epidemiology, pathogenesis, genetics & management of polycystic ovary syndrome in India

Mohammad Ashraf Ganie, Vishnu Vasudevan, Imtiyaz Ahmad Wani, Mohammad Salem Baba, Tasleem Arif & Aafia Rashid

Department of Endocrinology & Metabolism, Sher-i-Kashmir Institute of Medical Sciences, Srinagar, Jammu and Kashmir, India

Received December 6, 2017

Polycystic ovary syndrome (PCOS) is a common endocrine disorder predominantly affecting women of reproductive age. Clinical manifestations are diverse including hyperandrogenism, anovulation, infertility and increased risk of metabolic diseases besides psychosocial dysfunction. This review provides information on the problem of PCOS in India, its pathophysiology, genetics and an overview of current management options to instigate further research in this field. Prevalence of PCOS in India ranges from 3.7 to 22.5 per cent depending on the population studied and the criteria used for diagnosis. Abnormalities in leptin-adiponectin (adipocyte biology), oxidative stress and autoimmunity are among the mechanisms studied regarding pathogenesis of PCOS. Many candidate gene studies have shown associations with PCOS in various studies. Studies have consistently demonstrated the relationship between the well-known manifestation of hyperandrogenism among Indian PCOS women and the metabolic morbidities including insulin resistance, glucose intolerance and cardiovascular risk. Management of individual components of PCOS can be achieved by medications or surgical methods, though further clarification regarding pathogenesis of PCOS is needed to sharpen our therapeutic armamentarium.

Key words Epidemiology - genetics - India - management - pathogenesis - pathophysiology - polycystic ovary syndrome - prevalence

Introduction

Polycystic ovary syndrome (PCOS) is considered to be a multifaceted disease with a spectrum of manifestations affecting not only women of childbearing age, but also adolescents and postmenopausal women¹. PCOS, by the nature of the disease, adversely influences the fertility and reproductive health of the affected women²; moreover, with its association with other lifestyle diseases, it is also

the cause of significant cardiovascular and metabolic morbidity³. The exact aetiology and pathogenesis of PCOS are still an area of active research, although multiple hypotheses have been postulated, ranging from genetic susceptibility to environmental exposure, both *in utero* and in the postnatal life⁴. Data on the genetics, metabolic parameters and clinical aspects of PCOS in Indian women are available. This article was aimed at reviewing the literature related to the

pathogenesis, epidemiology and genetics of PCOS in India, and biochemical and hormonal abnormalities in this disorder besides providing a brief overview of the management options.

Evolution of PCOS as a distinct syndrome - A historical overview

PCOS, discovered by Stein and Leventhal⁵, earned its name based on the ovarian morphology. The authors described seven women who shared the common features of menstrual disturbances, hirsutism and enlarged ovaries with many small follicles⁵. They also suspected that bilateral cystic ovaries were the result of abnormal hormonal stimulation, which was confirmed by the later investigators. Medical treatment became the preferred treatment over surgical resection of the ovaries when options such as clomiphene and follicle-stimulating hormone (FSH) became available⁶. There was a renewed interest in the surgical treatment of PCOS when laparoscopic treatment became popular. Newer technologies such as ultrasound to image ovaries were a breakthrough in the history of PCOS, and the ease of this technique made the diagnosis of PCOS simpler. However, this had the unexpected result that many women were diagnosed with mild or no other features of PCOS, but had polycystic ovaries⁷. This led to the term of polycystic ovarian morphology, the significance of which is still a subject of debate. It has been argued that the widespread acceptance of the Rotterdam criteria⁸, which included oligo-anovulatory women with polycystic ovarian morphology without clinical or biochemical evidence of hyperandrogenism, is premature and will lead to unnecessary diagnosis, laboratory evaluation and probably lifelong implications in these women⁹. Even after so many years of the recognition, the exact aetiology of this syndrome remains elusive and is now considered to be multifactorial, with a strong genetic component. Although insulin resistance (IR) is consistently found in women with PCOS, yet it is not included in any diagnostic criteria.

Clinical features, comorbidities and diagnostic criteria of PCOS

The clinical manifestations of PCOS include oligomenorrhoea, hirsutism, excessive acne and hair loss. In adolescence, it causes significant psychiatric disturbances such as anxiety and depression. PCOS is the leading cause of anovulatory infertility in women. The metabolic consequences include impaired glucose tolerance, type 2 diabetes, obesity and increased risk of cardiovascular diseases. Metabolic complications and increased cardiovascular morbidity were found to be more in the classic PCOS compared to other phenotypes, even after adjustment for obesity¹⁰. Clinicians now have these three sets of criteria (Table I) to choose from, though the Rotterdam criteria⁸ are found to be more preferred. The National Institutes of Health (NIH) Evidence-based Methodology Workshop in 2012 published the final report¹³ which stated that the following specific phenotypes (Table II) should be reported explicitly in all research studies.

Epidemiology of PCOS in India

Only a few researchers have studied the prevalence of PCOS in India and among those, most of the sampling was convenience based, which might not reflect the true status of PCOS prevalence in the community. A pilot cross-sectional study conducted in Tamil Nadu assessed young adolescent females and found a prevalence of 18 per cent for PCOS¹⁴. They also concluded that the proportion of PCOS was higher in urban women in comparison to the rural women. A similar study conducted in Mumbai, which was an urban community-based study, found that the prevalence of PCOS was 22.5 per cent by the Rotterdam criteria and 10.7 per cent by the Androgen Excess Society criteria¹⁵. A study conducted among medical students at a private medical college in south India using the modified Cronin questionnaire¹⁶, which included 10 items, found that PCOS was a common disorder among the participants and reported a high

Table I. Diagnostic criteria of polycystic ovary syndrome (1990-2009)

PCOS definition	Clinical hyperandrogenism or biochemical hyperandrogenism (elevated total/free testosterone)	Oligomenorrhoea or oligo-anovulation	Polycystic ovaries on ultrasound
NIH (1990) ¹¹	Yes	Yes	Not included
ESHRE/ASRM Rotterdam (2003) ⁸ 2 of 3 criteria	Yes/no	Yes/no	Yes/no
AE-PCOS Society (2006) ¹²	Yes	Yes/no	Yes/no

PCOS, polycystic ovary syndrome; AE, androgen excess; NIH, National Institutes of Health; ASRM, American Society for Reproductive Medicine; ESHRE, European Society of Human Reproduction and Embryology

incidence of mood disorders among them¹⁶. A study from Lucknow was published, in which college-going women with menstrual irregularity and hirsutism, in the age range of 18-25 yr, were studied, and it was reported that the calculated prevalence using the NIH criteria, among the participants, was only 3.7 per cent¹⁷. Another study from Andhra Pradesh studied young women from a residential college and found that 9.13 per cent of them satisfied the Rotterdam criteria for PCOS¹⁸. Vidya Bharathi *et al*¹⁹ showed that the prevalence of PCOS diagnosed by the Rotterdam criteria in community-dwelling women from rural and urban areas of Chennai was 6 per cent. International studies report the prevalence of PCOS to be in the range of 4-10 per cent of women of reproductive age²⁰. As the prevalence of PCOS has been found to be higher or lower depending on the criteria used in these studies, which might be the obvious reason for the discrepancy in the prevalence rates among the studies from India, it is difficult to draw a clear conclusion. Hence, from the limited data available, it can be said that the prevalence

of PCOS in India ranges from 3.7 to 22.5 per cent (Table III).

Pathophysiology and genetics of PCOS

PCOS is a disease with a complex multipronged pathogenesis which is still under investigation (Figure). The various pathogenetic mechanisms of PCOS include abnormal gonadotropin-releasing hormone (GnRH) regulation leading to increased luteinizing hormone (LH) and decreased FSH; decreased response of ovarian follicles to FSH; increased anti-Mullerian hormone (AMH); follicular arrest and increased secretion of testosterone, estradiol and dehydroepiandrosterone (DHEA). Obesity, especially abdominal fat deposition, is the major predisposing factor for the expression of IR and metabolic phenotype in PCOS²². Thus, IR at post-receptor level and adipocyte dysfunction are responsible for the metabolic consequences of

PCOS²¹⁻²⁵. Many other biochemical and hormonal aspects apart from the widely known pathophysiological mechanisms underlying PCOS have been studied by Indian researchers and are reviewed in detail below.

Studies on PCOS pathogenesis from India

Role of leptin and adiponectin in PCOS pathogenesis

Leptin is a major intermediary between nutritional status and reproductive health of women. High levels of leptin have been found to be associated with the markers of IR in PCOS patients^{24,26}. After adjusting for potential confounders such as obesity status, PCOS women had higher leptin levels as compared to controls and leptin also was positively correlated with the serum testosterone levels²⁷. Another study also demonstrated that high leptin in PCOS women was independent of the obesity status, but this study did not find a significant correlation between leptin levels and serum testosterone²⁷. From these case-control studies, it is difficult to ascertain the cause and effect relationship between leptin levels and hyperandrogenemia or PCOS phenotype, though it is imperative that the complex nature of the same needs further exploration. Singh *et al*²⁸ in a case-control study demonstrated lower serum adiponectin levels in women with PCOS as compared to controls. The adiponectin levels were lowest in obese women with PCOS and even non-obese PCOS women had low adiponectin, which improved with metformin treatment. Independent of obesity status, hypoadiponectinemia correlated with IR and hyperandrogenemia; this may be because lean PCOS women also may have intra-abdominal fat and thus unhealthy metabolic profile. Reiterating the role of adiponectin in PCOS pathogenesis, animal studies showed that adiponectin treatment reduced androgen synthesis in DHEA-treated PCOS mice in an *in vitro* study²⁹. In another case-control study, plasma leptin:adiponectin ratio (L:A ratio) seemed to be positively associated with markers of metabolic syndrome and IR, thus reconfirming the lower adiponectin levels to be a potential biomarker of metabolic risk and IR in PCOS women³⁰.

Evidence from proteomics and metabolomics studies

In large case-control study on the proteomics of follicular fluid from women with PCOS and controls undergoing *in vitro* fertilization (IVF) treatment found altered levels of proteins involved in extracellular matrix remodelling, complement coagulation cascade, fibrinolysis, vasculature development, angiogenesis, lipid transport and metabolism, and the authors

postulated that it might reflect the molecular defects in folliculogenesis³¹. A study of the serum metabolomics of Indian women with PCOS during day 3 to 5 of their menstrual cycle using proton nuclear magnetic resonance and pattern recognition approach showed dysregulation in the expression of various metabolites in the serum of PCOS women, which indicated involvement of multiple pathways in amino acid metabolism, carbohydrate/lipid metabolism, purine and pyrimidine metabolism and protein synthesis³².

Role of oxidative stress and autoimmunity in PCOS pathogenesis

The role of oxidative stress in the pathogenesis of various reproductive diseases and conditions including infertility, recurrent abortions and pre-eclampsia has been postulated, and PCOS is no exception. Plasma amino acid levels were found to be significantly deranged (lower levels of methionine, cystine, isoleucine, phenylalanine, valine, tyrosine, proline, glycine, lysine and histidine and higher arginine and alanine levels) in PCOS women as compared to controls³³, and the authors suggested this to be a marker of higher metabolic and oxidative stress in PCOS women. Reduced arginine bioavailability was found in PCOS women, which correlated with low nitric oxide levels, increased oxidative stress and thus lowered regulatory T cells (Treg cells) in patients with PCOS³⁴. Krishna *et al*³⁵ demonstrated for the first time that the immunosuppressive action of CD4+CD25+CD 127-Treg cells was reduced in PCOS, and this might influence the reproductive function of these women adversely. Sumithra *et al*³⁶ studied the markers of oxidative stress and high sensitivity C-reactive protein levels (marker of cardiovascular risk), in patients with PCOS compared to controls, and found that both are significantly elevated in the PCOS cases. Deepika *et al*³⁷ studied genomic instability and cytotoxicity due to oxidative stress, assessed by estimating the frequency of micronucleated cells in epithelial samples and serum malondialdehyde levels, respectively, and found a positive correlation in patients of PCOS as compared to controls, which suggested high oxidative stress in PCOS women. Other investigators have specifically demonstrated elevated oxidative stress markers in lean PCOS patients³⁸. In oral contraceptive pill (OCP)-treated women, plasma intercellular adhesion molecule-1 (ICAM-1) and tumour necrosis factor- α (TNF- α) levels were significantly higher, compared to drug-naïve PCOS women, which suggested a pro-

inflammatory state in the OCP-treated women, despite reduced androgen and regularized menstrual cycles³⁹.

PCOS has long been suspected to have a component of autoimmune origin. Arora *et al*⁴⁰ from New Delhi found higher prevalence of antithyroglobulin antibodies in PCOS women and suggested a possible role of autoimmunity in the pathogenesis of PCOS. A small case series of patients with both PCOS and Grave's disease also suggested a possible autoimmune aetiology of PCOS⁴¹.

Other mechanisms proposed to have a role in PCOS pathogenesis

Some studies have suggested a role of vitamin D deficiency in metabolic abnormalities seen in PCOS women, but many authors have opined that hypovitaminosis D is ubiquitous in India, and this does not seem to alter the metabolic phenotype in women with PCOS^{42,43}. Altered mineral status in the form of hypercalcaemia and very low manganese levels in addition to higher levels of zinc and copper was demonstrated in women with PCOS compared to controls⁴⁴, which led the authors to propose that altered trace mineral milieu might play a significant role in the pathogenesis of PCOS. The various metabolic, inflammatory and autoimmune components including the obesity-related cytokines and oxidative stress markers evaluated in relation to the pathogenesis of PCOS highlight the multifaceted nature of this disorder and the need for further research to better delineate the contribution of each of these markers and mediators in the final expression of the syndrome of PCOS.

Genetics in PCOS

The evidence that PCOS may be genetically determined initially came from twin studies, where the incidence of PCOS was twice as high in women with an affected twin as compared to the rest of population⁴⁵. Candidate gene approach worldwide has identified many susceptibility genes including cytochrome P1A1 (*CYP1A1*), *CYP11A*, *CYP17A1*, *CYP19*, 17 β -hydroxysteroid dehydrogenase (*HSD17B6*), androgen receptor (*AR*), sex hormone-binding globulin (*SHBG*), insulin receptor (*INSR*), insulin receptor substrate 1 (*IRSI*), peroxisome proliferator-activated receptor gamma (*PPAR- γ*), follicle stimulating hormone receptor (*FSHR*), luteinizing hormone/chorionic gonadotropin receptor (*LHCGR*), anti-Mullerian hormone receptor type 2 (*AMHR2*), interleukin (*IL*) IL-1A, IL-1B and IL-6⁴⁵, whereas genome-wide association studies have identified many susceptibility

loci including THADA, DENND1A, LHCGR, FSHR, C9orf3, YAP1, GATA4,-NEIL2 and ERBB4^{23,46}.

Studies in the genetics of PCOS from India

Diabetes and metabolic syndrome-related genes

In a small study from Hyderabad, 15 single-nucleotide polymorphisms (SNPs) from nine type 2 diabetes-related genes (such as *TCF7L2*, *IGF2BP2*, *SLC30A8*, *HHEX*, *CDKAL1*, *CDKN2A*, *IRSI*, *CAPN10* and *PPAR- γ*) were studied in PCOS women and controls; no significant association was found; the authors cited studies from other ethnic populations and suggested that the non-association might be universal⁴⁷. Gly972Arg SNP of IRS1 was found to have a positive association with PCOS in a south Indian study population, whereas *INS*, *IRS2*, *PPAR- γ* and *CAPN10* failed to show any association in the same study from Chennai⁴⁸. Insulin receptor gene polymorphism was studied later⁴⁹, for its association with IR in Indian women with PCOS; the study suggested that CC genotype (C1085T) might be developed as a marker for IR and metabolic complications in Indian women⁴⁸. Pro12Ala polymorphism of *PPAR- γ* showed significant association with reduced susceptibility for PCOS in a study published from Mumbai⁵⁰. The Calpain-10 (*CAPN10*) SNPs showed variable association with PCOS in the obese subgroup of patients⁵¹; the authors highlighted the importance of this gene in PCOS pathophysiology. The *IRSI* and *PPAR- γ* gene polymorphisms were found to have a probable protective role against the development of certain specific PCOS sub-phenotypes⁵². Angiotensin-converting enzyme (ACE) I/D polymorphism was found to be associated with an early age at onset of PCOS symptoms in a case-control study from Hyderabad⁵³. A preliminary study on vitamin D receptor polymorphisms in PCOS patients and controls found no significant association, though some of the SNPs suggested a possible functional significance with regard to PCOS-specific clinical/biochemical traits⁵⁴. In a study conducted by Yousuf *et al*⁵⁵ among Kashmiri women with PCOS and controls, it was found that the *ICAM 1* gene polymorphism was not significantly associated with PCOS women compared to controls.

Ovarian function-related gene polymorphisms

In a study to investigate the association of Connexin37/Gap junction alpha 4 gene C1019T SNP with the susceptibility to PCOS among south Indian women⁵⁶, cases of PCOS were found to be significantly more associated with C/C and C alleles of the C1019T

SNP, compared to the controls. Another study⁵⁷ conducted among two ethnically different PCOS case-control groups has shown that 5,10 methylene tetrahydrofolate reductase (*MTHFR*) gene 677 CT polymorphism does not affect PCOS susceptibility in Indian women. The *LHCGR* gene polymorphism rs-2293275 was found to be significantly associated with PCOS compared to controls in a study⁵⁸ from Hyderabad. Another study from Hyderabad⁵⁹ suggested that vascular endothelial growth factor +405G/C polymorphism might constitute an inheritable risk factor for PCOS in south Indian women. Insulin-like factor 3 gene polymorphisms were studied among women from Mumbai⁶⁰, and the authors showed a significant association between rs6523 polymorphism and increased risk of PCOS. Follistatin gene exons were amplified and studied⁶¹ for mutations in a large cohort of PCOS women and controls from south India; the authors found no significant role of follistatin gene variants in PCOS susceptibility. Androgen receptor CAG repeat length polymorphism was reported to have no significant association with PCOS in a case-control study⁶².

Oxidative stress and cytokine-related gene polymorphisms

Two polymorphisms (L55M and Q192R) of paraoxonase 1 (*PON1*) gene were studied for their association with PCOS susceptibility and related traits in Indian women from Mumbai⁶³, and the authors found that one of those SNPs (L55M) was associated with reduced PCOS susceptibility only in lean women and that it also impacted features such as hyperandrogenemia, lipid parameters and glucose metabolism in these women. This led the authors to suggest that the genetic pathophysiology of PCOS was different in lean and obese women. In another study from south India⁶⁴, *IL* 6174 G/C SNP was found to be significantly associated with PCOS risk. A case-control study from south India on the polymorphisms of *TNF-α* gene and found that the distribution of genotypes for rs1799964 was significantly different between the groups⁶⁵. *IL-β*, *IL-1Ra* and *FABP1* gene variants were found to be significantly associated with many metabolic features of PCOS⁶⁶. Adiponectin and resistin gene polymorphisms were studied in south Indian women⁶⁷; while it showed no association of the former with PCOS, the authors suggested that resistin gene variants might have a role in PCOS susceptibility. Another study from Hyderabad has shown that carriers of PPAR-γ coactivator 1α (PGC-1α) rs8192678 'Ser' allele have increased risk of developing PCOS⁶⁸.

Miscellaneous genes associated with PCOS

In a study from Hyderabad, *CYP11A1* microsatellite (ttta)n repeat polymorphism was found to be more common in PCOS patients as compared to controls⁶⁹, and the authors opined that because this cholesterol side-chain cleavage enzyme-encoding gene was instrumental in the synthesis of sex hormones, this could be a genetic marker of susceptibility to PCOS in the south Indian population studied. Lutinizing hormone β-subunit gene variants were studied among women⁷⁰ with PCOS from south India; although the ones found to have significant correlation were silent in nature, the authors suggested exploration of other significant polymorphisms in the hypothalamic-pituitary-gonadal axis⁷⁰. Plasminogen activator inhibitor 1 (PAI-1) 4G/5G polymorphism was found to be associated with risk for recurrent pregnancy loss and implantation failure²⁵. Sagvekar *et al*⁷¹ showed that altered global DNA hypomethylation in peripheral blood lymphocytes and granulosa cells was strongly associated with PCOS and recommended larger studies to shed light on such epigenetic modifications in the PCOS susceptibility.

Candidate gene polymorphism studies involving genes related to diabetes, metabolic syndrome, oxidative stress, cytokines, ovarian function *etc.*, have been conducted in the area of PCOS related genetic research in India. The limitations of candidate gene polymorphism studies in proving the association and the strength of the association need to be acknowledged. Genome-wide studies need to be planned in the future.

Clinical features and co-morbidities of PCOS

A clinical study⁷² reported that in PCOS subgroups, the phenotype with hyperandrogenism and regular menstrual cycles had higher IR and gonadotropic hormonal abnormalities compared to the subgroup which had patients with irregular menstruation. Another study demonstrated that hyperandrogenism, in the form of high testosterone values, correlated well with obesity and sleep-disordered breathing in PCOS women, and this might be one of the reasons for high cardiovascular morbidity in the PCOS patients⁷³. Hyperandrogenic phenotypes of PCOS were found to be more prone to metabolic complications as compared to the phenotypes with normal androgen levels⁷⁴.

PCOS occurs in both obese and non-obese women equally, although markers of IR are more common in obese women⁷⁵. Acanthosis nigricans (AN) was found to be present in more than half of the PCOS women examined in a study conducted at Manipal,

south India⁷⁶. The authors described an association of AN with a family history of diabetes in first-degree relatives in all of these patients. Cardiovascular autonomic function was tested in women with PCOS in a study from south India, which showed an imbalance in the sympathovagal output in patients as compared to controls, and the authors suggested that the altered autonomic function might predispose these patients to cardiovascular morbidity⁷⁷. The prevalence of abnormal glucose tolerance (AGT) detected by oral glucose tolerance test (OGTT) was found to be high (around 35%) in a large number of young Indian women with PCOS, and it was found that family history of diabetes was not a predictor of AGT in these women⁷⁸. Thus, studies from India have consistently demonstrated the relationship between the well-known manifestation of hyperandrogenism among Indian PCOS women and the metabolic morbidities including IR, glucose intolerance and cardiovascular risk in this population.

Management of PCOS

The management of PCOS is as complex as the condition itself. The management and treatment of PCOS include a healthy diet, regular physical activity, and medications, which address the associated manifestations and co-morbidities. PCOS management strategies mainly aim at resolving the four major components of PCOS including regularity of menstrual periods, control of hyperandrogenism (acne and hirsutism), management of infertility and IR along with its associated risk factors (type 2 diabetes mellitus, hyperlipidaemia, and obesity). Both non-pharmacological and pharmacological management strategies are important in the overall management of PCOS.

Non-pharmacological measures

Studies on non-pharmacological measures to treat PCOS are very limited in the Indian literature. In a study on reproductive-age women with PCOS, improvement in novel inflammatory cardiac risk markers such as hs-CRP was reported with lifestyle modification, although metformin was also given to the study participants⁷⁹.

Pharmacological treatment

In a randomized, single-blinded, dose-comparison study, Bhattacharya *et al*⁸⁰ reported that OCP containing 20 µg ethinyl estradiol (EE) with drospirenone had similar effects on free androgen index in PCOS women

as that containing 30 µg EE with drospirenone. The same authors had earlier studied⁸¹ a combination of EE with desogestrel and found significant improvement in hyperandrogenic parameters only during the first six months of treatment and further continuation was useless. A six-month, open-label, randomized trial by Ganie *et al*⁸², of low-dose spironolactone and metformin combination than either drug alone, showed the superiority of the former in terms of improved clinical parameters and compliance to treatment. A comparison of metformin and OCP (EE plus drospirenone) was done as a prospective observational study (n=46) over one year by Suvarna *et al*⁸³, and metformin alone was found to be equally effective in regularizing menstrual cycles and treating hyperandrogenism in Indian women with PCOS. Use of non-hormonal options *i.e.*, metformin and spironolactone, after a period of oral contraceptive use, was retrospectively studied by Kulshreshtha *et al*⁸⁴, in a small group of women with PCOS for regularization of their menstrual cycles. They concluded that 75 per cent of women achieved regular cycles with non-hormonal treatment within one year of stopping OCPs. Saini *et al*⁸⁵ have tried to develop metformin-loaded cationic niosomes amalgamated with thermosensitive gel for intravaginal use in PCOS patients.

Treatment of complications

Infertility

Meenakumari *et al*⁸⁶ studied the use of metformin in PCOS women with luteal-phase progesterone deficiency and reported improvement in the same after four weeks of treatment with metformin 500 mg thrice a day. A prospective randomized trial was conducted where letrozole and clomiphene citrate (CC) were compared in patients with PCOS and anovulatory infertility. After three cycles of treatment, both letrozole and clomiphene showed comparable ovulation rates, but endometrial response and pregnancy rates were better in the former group⁸⁷. In a randomized trial comparing metformin and CC, where the primary outcome was live birth rate (LBR), Kar and Sanchita⁸⁸ reported that the efficacy of metformin was similar to clomiphene in terms of LBR, and their combination gave the highest ovulation rate and LBR. Yanamandra and Gundabattula⁸⁹ conducted a retrospective study of women who failed ovulation induction for primary infertility and hence underwent diagnostic laparoscopy and hysteroscopy followed by ovarian drilling. They showed an enhanced conception rate (around 50%)

with laparoscopic ovarian drilling (LOD). In a small prospective cohort study, the author opined that LOD had no significant effect on AMH levels and thus ovarian reserve⁹⁰. However, as Mitra *et al*⁹¹ pointed out, use of this treatment in unselected cases of PCOS was not prudent owing to its potential risks such as iatrogenic adhesions and ovarian insufficiency. Moreover, many authorities have questioned⁹² the utility of LOD in infertility treatment citing lack of significant rates of clinical pregnancy in evidence-based reviews. Considering the adverse effects of LOD, medical treatment with rosiglitazone and CC was compared with LOD and CC in women with PCOS suffering from infertility in a prospective randomized trial⁹³, and the authors concluded that there was no significant difference in ovulation rate or pregnancy rate between the two groups. A retrospective analysis of four-year data at a tertiary care centre in north India was reported by Singh *et al*⁹⁴ where PCOS patients undergoing IVF cycle with long GnRH agonist protocol were compared with those on fixed GnRH antagonist protocol, and there was no significant difference in pregnancy rate or incidence of ovarian hyperstimulation syndrome between the two groups.

Obesity, diabetes and other co-morbidities

Kumar and Arora⁹⁵ reported the results of a randomized controlled trial (RCT) where they studied orlistat versus metformin for weight reduction and ovulation rates in obese PCOS women. Orlistat was equal to metformin in terms of achieving the outcomes of weight reduction and ovulation. They also noted that orlistat had a better side effect profile and was better tolerated than metformin in this trial population. In a retrospective study, the authors⁹⁶ reported that in women with PCOS with AGT measured by OGTT, six-month therapy with spironolactone and metformin had similar effects in reducing the glucose levels.

Use of unconventional and supplemental pharmacological treatment in PCOS and its complications

Supplementation of vitamin D on insulin sensitivity/resistance parameters in PCOS women was studied by Garg *et al*⁹⁷ in a double-blinded RCT, and they concluded that vitamin D at a dose of 4000 IU daily for six months had no significant effect on these parameters.

Conclusion

PCOS is a heterogeneous clinical syndrome with a multifaceted pathogenesis and is associated with

lifelong morbidity. The clinical manifestations of PCOS include oligomenorrhea, hirsutism, excessive acne and hair loss. The estimated prevalence in India ranged from 3.7 to 22.5 per cent. The prevalence of PCOS was found to be higher or lower depending on the criteria used, which might be the obvious reason for the discrepancy in the prevalence rates among the studies. Considering the vast diversity in the population of India, large-scale community-based studies using internationally accepted criteria, in various geographic regions, are necessary to shed light on the actual prevalence of this disorder. The various metabolic, inflammatory and autoimmune components including the obesity-related cytokines and oxidative stress markers in relation to the pathogenesis of PCOS highlight the multifaceted nature of the disorder and the need for further research into the subject to better delineate the contribution of each of these markers and mediators in the final expression of PCOS. Management and treatment of PCOS included healthy diet, regular physical activity, and medications, which address the associated manifestations and co-morbidities. More randomized trials are needed to find the best treatment options for Indian women suffering from this condition.

Background: Polycystic ovarian syndrome (PCOS) is a common endocrine disorder and leading cause of prolonged anovulation. PCOS has been linked to a variety of long-term health problems, including: heart disease; metabolic syndrome; and diabetes. It is interesting to know the risk factors for PCOS in local settings.

Objective: The aim of this research is to identify PCOS risk factors in our own settings (Asri Medical Center in Yogyakarta), so that we could identify the specific preparation to avoid having disorders personalized in local characteristics.

Methods: This is a descriptive-analytic cross-sectional study. The research was carried out at Asri Medical Center in Yogyakarta, Indonesia, with a total sample size of 92 people who met the inclusion and exclusion criteria. They were divided into two groups: non-PCOS and PCOS. Data were retrieved using the questionnaire. The variables evaluated were nutritional status, physical activity, carbohydrate diet, fiber diet, family history of diabetes, family history of PCOS, and age of menarche. The data was analyzed using the Chi-square test.

Results: Family history of PCOS, obesity, low physical activity and a low-fiber diet proved to differ significantly between the two groups ($p<0.05$).

Conclusion: Family history of PCOS, obesity, low physical activity, low fiber diet had a substantial impact on the occurrence of PCOS.

Latar Belakang: Polycystic ovary syndrome (PCOS) adalah gangguan endokrin umum dan merupakan penyebab penting anovulasi kronis pada wanita. PCOS terkait dengan banyak masalah kesehatan jangka panjang seperti penyakit kardiovaskular, penyakit sindrom metabolik, dan diabetes. Penting untuk menyelidiki faktor-faktor yang meningkatkan risiko PCOS.

Tujuan: Tujuan dari penelitian ini adalah untuk mengetahui faktor risiko PCOS sehingga wanita yang memiliki faktor risiko dapat mengantisipasi untuk menghindari PCOS.

Metode: Penelitian ini merupakan penelitian deskriptif analitik dengan desain penelitian cross sectional. Pengambilan sampel dilakukan di Asri Medical Center Yogyakarta, dengan jumlah sampel sebanyak 92 orang yang memenuhi kriteria inklusi dan eksklusi. Sampel dibagi menjadi 2 yaitu kelompok kontrol (non PCOS) dan kelompok PCOS. Kueisioner digunakan untuk pengambilan data. Variabel yang diamati adalah status nutrisi, aktivitas olahraga, diet karbohidrat, diet serat, riwayat keluarga DM, riwayat keluarga dengan PCOS

dan usia menarche. Analisis data menggunakan uji Chi square.

Hasil: Riwayat keluarga PCOS, obesity, aktivitas fisik rendah dan diet rendah serat terbukti berbeda secara signifikan antara kedua kelompok ($p<0,05$).

Kesimpulan: Ada hubungan yang bermakna antara riwayat keluarga PCOS, obesitas, kurang aktivitas fisik dan diet rendah serat dengan kejadian PCOS.

INTRODUCTION

PCOS is one of the most frequent type of endocrine disorder that affects women of childbearing age. Depending on the diagnostic criteria used in different parts of the world, the prevalence varies significantly. PCOS affects 5–10% of the world's reproductive-age population.^{1,3} Several studies have lately documented an increase in PCOS prevalence due to higher calorie intake, high carbohydrate intake, high fiber intake, and rarely exercise, as well as the tendency to gain weight, which promotes insulin resistance.⁴

The Rotterdam criteria are widely used to establish the diagnosis of PCOS. These criteria include 2 of the following 3 symptoms; anovulation, clinical and/or laboratory hyperandrogenism and ultrasound features typical of PCOS.¹ Approximately 50–70% of women with PCOS exhibit hyperandrogen-related clinical symptoms⁵, and 65–95% have increased insulin resistance.⁶ Genetic factors can influence the occurrence of PCOS but the association between its variables, on the other hand, is still uncertain. Consumption of junk food and a high-carbohydrate diet raises the risk of insulin resistance, which can lead to PCOS.⁷ Due to the hyperinsulinemia and insulin resistance caused by PCOS, one of the hazards is a lack of physical exercise.⁸ Obesity is the next most common risk factor.⁴ The sensitivity of pancreatic beta cells to elevated blood sugar is reduced as the result of obesity.⁹ The tissue's sensitivity to insulin will decrease as a result of this condition, and the pancreas' beta cells will instantly compensate by boosting insulin synthesis, resulting hyperinsulinemia.¹⁰ By complex processes, hyperinsulinemia increases androgen production.^{11,12} The age of menarche is

another factor that may influence the occurrence of PCOS. The early maturation of the adrenal cortex reticular zone promotes an increase in androgen production, resulting in a younger age of menarche. Increased androgen levels, also known as hyperandrogenism, are thought to have a role in the development of PCOS.¹³ Those factors that are described above could be different in our local setting in Yogyakarta. As the term of personalized medicine is increasingly prominent, it is necessary to find out the evidence of the specific characteristics in our own local settings.

METHODS

Design and subjects

This is a cross-sectional research with an analytic observational design. This study undertaken from May to August 2019 at the Asri Medical Center Hospital in Yogyakarta, Indonesia.

Data Collection

In this study, a purposive sample method was adopted. The inclusion criteria were all women who had menstruation issues and were willing to participate in the study. Whereas women with menstrual issues who also had liver disease, diabetes, kidney disease, or other causes of anovulatory infertility were excluded. The study included 46 women with PCOS diagnosed using the Rotterdam criteria, as well as 46 women with other menstrual problems. The data was gathered from the patient's medical records and also questionnaire. Diabetes mellitus (DM) in the family, PCOS in the family, age of menarche, nutritional status, physical activity, carbohydrate diet, and fiber diet are some of the questions asked. Nutritional status is measured by BMI (Obesity: >30; Overweight: 25-30, normal :<25). Physical activity is assessed by frequency of doing exercise in a week (high ≥ 3 times/week; low: < 3 times/week). Carbohydrate diet is assessed by the frequency of consuming high-carbohydrate foods beyond large meals (high: >3 times/week; low: <3 times/week), a high-fiber diet is assessed with frequency

consuming high-fiber foods (high: >3 times/week; low: <3 times/week).

The Health Research Ethics Committee of the Faculty of Medicine and Health Science, University of Muhammadiyah Yogyakarta, Indonesia has given its approval to this study (150/EP-FKIK-UMY/IV/2019).

Statistical analysis

Bivariate data analysis was done using the Chi-square test with a significance threshold of $p<0.05$ and Confidence Interval=95%.

RESULTS

Group characteristics

A total of 46 PCOS patients and 46 non-PCOS individuals participated in the study. The existence of a family history of PCOS, obesity, low physical activity, and a low-fiber diet were all linked with the incidence of PCOS. Based on the research that has been conducted, the following results were obtained using the Chi square test. Family history of PCOS, obesity, low physical activity and a low-fiber diet proved to differ significantly between the two groups ($p<0.05$, Table 1).

Table 1. Risk factor of PCOS

Variable	Group		p
	PCOS	non-PCOS	
Family history of Diabetes Mellitus			
Yes	9	13	0.328
No	37	33	
Family history of PCOS			
Yes	9	1	0.007*
No	37	45	
Age of menarche			
<12 years old (early)	12	12

Low	10	13	
Fiber diet			
High	1	11	0.000*
Low	45	36	

* $p<0.05$

DISCUSSION

There was a relationship between PCOS incidence and a family history of PCOS in this study, however it was not associated to a family history of diabetes mellitus. Genetic factors have a role in the pathophysiology of PCOS. Although this genetic explanation has not been verified, various theories suggest that PCOS is inherited by an autosomal dominant gene and several candidate genes that may impact PCOS occurrence.

The pathophysiology of PCOS is linked to an inherited genetic component; genetic factors influence the PCOS phenotype in at least 10% of cases. Several chromosomal locations and potential genes for PCOS have been found through genome-wide association studies (GWAS).¹⁴ According to a meta-analysis, polymorphisms in the steroidogenic acute regulatory gene (StAR), gonadotropin-releasing hormone receptor (GnRHR), follicle stimulating hormone receptor (FSHR), fat mass and associated obesity, insulin receptor (IR), IR substrate (IRS), vitamin D receptor (VDR) are all involved in the pathophysiology of PCOS.^{14,15} Despite the fact that most women with PCOS have insulin resistance, pancreatic B cell dysfunction, poor glucose tolerance, and/or type 2 diabetes, PCOS does not appear to be associated with genetic changes that increase the risk of type 2 diabetes. Family history of DM, on the other hand, is linked to the phenotype of PCOS. Sex Hormone Binding Globulin (SHBG) and Free Androgen Index (FAI) are both associated with a family history of DM. PCOS individuals with a family history of diabetes have higher rates of Homeostatic Model Assessment of Insulin Resistance (HOMA-IR) and FAI. A family history of diabetes is associated with elevated hemoglobin A1c (HbA1c) levels in PCOS women.¹⁶

Our findings indicate a link between obesity and the occurrence of PCOS. Patients with a family history of obesity had a greater percentage of body fat than those who did not. PCOS individuals who are obese are more prone to have irregular menstrual cycles and maturation

of ovarian follicles.¹⁷ Obesity appears to trigger insulin resistance that causing PCOS, and women with PCOS appear to be more prone to obesity.¹⁸ Obese PCOS women were shown to have higher systolic and diastolic blood pressure, as well as fasting blood sugar, insulin, HOMA-IR, total cholesterol, and triglycerides.⁶ In roughly 50-70 percent of PCOS women, and 95 percent of obese PCOS women, IR occurs. Obesity causes changes in adipokine production, such as a decrease in adiponectin and an increase in leptin, which leads to an increase in proinflammatory cytokines.¹⁹ Obesity and insulin resistance enhance the release of inflammatory cytokines such as high-sensitivity CRP (hs-CRP), IL-6, IL-18, and tumor necrosis factor alpha (TNF- α) in PCOS women, which is one of the low-grade chronic inflammatory illnesses.^{20,21} This increase in proinflammatory cytokines regulates IR by boosting IRS-1 serine phosphorylation and reducing Akt substrate of 160 kDa (AS160) phosphorylation, resulting in a decrease in the expression of the glucose transporter type 4 (GLUT-4) and decreasing glucose transport into cells.²² Obesity reduces the ability of the body's cells to fight insulin. The sensitivity of pancreatic beta cells to elevated blood sugar is reduced as a result of obesity. Because the tissue's sensitivity to insulin reduced, pancreatic beta cells will be instantly adjusted by boosting insulin synthesis, resulting in hyperinsulinemia. By a variety of processes, hyperinsulinemia increases androgen production.^{19,24}

On the other hand, PCOS also linked to a poor diet. The diet in question involves the proportion, quantity, variety, or a mix of different drinks and meals, as well as the frequency with which they are typically consumed. A healthy diet consists of foods that meet the body's energy requirements. However, there are a few PCOS women who consume more food than their bodies require. Dietary habits such as overeating in junk food and consuming macronutrients in excess of the body's requirements can increase the risk of polycystic ovaries. Content high carbohydrate, high calorie, and low fiber content

in junk and fast food raises the risk of insulin resistance, which can lead to PCOS.²³ This study found no link between excessive carbohydrate consumption in the diet and the occurrence of polycystic ovarian syndrome. Previous research has suggested that a high-carbohydrate diet can raise the risk of polycystic ovarian syndrome in women.⁷ This disparity might be attributed to discrepancies in measuring methodologies. In this study, measures were taken solely through the completion of questionnaires, with no in-depth dietary assessment.

The findings of this study revealed that there was no statistically significant difference in menarche age between the PCOS and non-PCOS groups. In comparison to normal girls, PCOS girls have a wide range of menarche ages. Menarche onset is influenced by a number of factors, including BMI and genetic variance. PCOS women have a delayed beginning of menarche due to delayed follicular development in prepubertal, hormonal imbalances of estradiol, progesterone, and androgens, and hormonal imbalances of estradiol, progesterone, and androgens. Girls who are later diagnosed with PCOS may have primary amenorrhea as a consequence. Menarche may occur early in PCOS girls who have a history of deliveries with dysmaturity and smaller for gestational age newborns. Menarche appears earlier in PCOS girls with a high BMI. Furthermore, genetic variations can influence the age of menarche in women with PCOS.^{24,25}

This research discovered a link between low physical activity and the occurrence of PCOS. Low physical activity might contribute to the development of PCOS, which is characterized by hyperinsulinemia and insulin resistance. Physical activity that is sufficient and consistent is directly tied to the metabolism of stored glucose in the muscles for use as energy, and if the glucose level is low, the muscle will compensate by pulling glucose from the bloodstream. This is what causes blood glucose levels to drop, allowing for better blood glucose control.⁸ Insulin secretion and sensitivity are affected by physical exercise in patients with polycystic ovarian syndrome. Excessive fat accumulation occurs in the absence

of physical activity, resulting in an increase in the amount of free fatty acids (FFA) and triglyceride levels.²¹ In PCOS women, this low-density lipoproteins (LDL) saturated fat inhibits insulin action, resulting in hyperinsulinemia. Insulin resistance will diminish and insulin sensitivity will rise when you get enough exercise or physical activity. Long-term calorie restriction (5-6 months) and increased physical activity can result in weight loss of 5-10% of the original weight. IR and hyperandrogenism, as well as menstrual function and fertility, can all be affected by this disorder. Additionally, it has the potential to promote long-term metabolic health.²³

CONFLICT OF INTEREST

Family history of PCOS, obesity, low physical exercise, a low-fiber diet were major PCOS risk factors.

Genetic, hormonal and metabolic aspects of PCOS: an update

V. De Leo*, M. C. Musacchio, V. Cappelli, M. G. Massaro, G. Morgante and F. Petraglia

Abstract

Polycystic ovary syndrome (PCOS) is a complex endocrine disorder affecting 5–10 % of women of reproductive age. It generally manifests with oligo/anovulatory cycles, hirsutism and polycystic ovaries, together with a considerable prevalence of insulin resistance. Although the aetiology of the syndrome is not completely understood yet, PCOS is considered a multifactorial disorder with various genetic, endocrine and environmental abnormalities. Moreover, PCOS patients have a higher risk of metabolic and cardiovascular diseases and their related morbidity, if compared to the general population.

Keywords: PCOS, Genetic, Insulin-resistance, Hyperandrogenism, Infertility, Metformin, Oral contraceptives, Myo-inositol

Background

Definition and diagnostic criteria

Polycystic ovary syndrome (PCOS) is the most common endocrine disorder in women and major cause of anovulatory infertility. PCOS patients can present a wide range of signs and symptoms, which make difficult the precise grading of the condition. Diagnosis of PCOS is currently based on the criteria of the ESHRE/ASRM Rotterdam consensus meeting in 2003 [1], which broadened the previous NIH classification of 1990 [2]. It based on at least two of the following features: oligo-anovulation, hyperandrogenism and polycystic ovaries by ultrasound [1]. In 2006, the Androgen Excess Society (AES) set up a committee of experts to review all the data published on PCOS for the purpose of simplifying diagnosis [3]. The AES criteria require clinical and/or biochemical hyperandrogenism simultaneously with oligo/anovulation and ultrasonographic evidence of polycystic ovaries.

Although the aetiology of PCOS is not completely understood yet, PCOS is considered a multifactorial disorder with various genetic, metabolic, endocrine and environmental abnormalities [4].

There is increasing evidence suggesting that PCOS affects the whole life of a woman, can begin *in utero* in

genetically predisposed subjects, it manifests clinically at puberty, continues during the reproductive years. It can also expose patients to increased risk of cardiovascular disease, hypertension, diabetes and other metabolic complications, especially after menopause [4]. During the fertile period it may cause anovulatory infertility and could be associated with increased prevalence of gestational complications, such as miscarriage, gestational diabetes and preeclampsia [5]. Early diagnosis is therefore crucial by enabling close follow-up and in an attempt to reduce the risk of such complications.

It is now widely recognised that insulin resistance, manifesting above all in obese or overweight women, but often also in lean PCOS women, is one of the key to this complex disorder. It determines hyperandrogenism by acting synergically with luteinising hormone (LH) on ovarian steroidogenic enzymes and on sex hormone-binding globulin (SHBG) production by the liver [5].

Diagnostic workup includes hormonal evaluation of androgen levels, clinical evaluation of hirsutism through Ferriman-Gallwey score and ultrasonographic examination of the number of antral follicles and ovarian volume. Insulin resistance should be evaluated by HOMA INDEX (product of fasting plasma insulin [μ U/L] and glucose [mmol/L] concentrations divided by 22.5). Future diagnostic approaches could be ultrasonographic 3D evaluation of follicles and is under discussion the role of anti-mullerian hormone (AMH) [6, 7].

Etiopathogenesis and pathophysiology: role of genetic, environmental and endocrine factors

Genetic and endocrine factors, together with environmental influences. In the research of etiopathogenesis of the syndrome and in the subsequent pathophysiological expression play a role genetic and endocrine as well as environmental factors. The most interesting hypothesis was proposed by Franks et al. [4], who defined PCOS as a genetically determined ovarian pathology characterised by over-production of androgens and manifesting heterogeneously according to the interaction of this genetic "predisposition" with other genetic and environmental factors. This hypothesis is persistent by the finding of polycystic ovaries in pre-pubertal girls [4, 8]. Studies in rhesus monkeys have demonstrated that exposure of foetuses to high levels of androgens during intrauterine life determines the onset of clinical manifestations of PCOS during adolescence. Studies in sheep have shown that an excessive androgen exposure during foetal life influences early ovarian follicular activity and it may explain the typical altered folliculogenesis shown in PCOS [4, 8].

The aforementioned observations may suggest that exposure of the foetal hypothalamus-pituitary-ovarian axis to androgen excess may trigger a series of events that could determine PCOS onset at puberty.

The source of intra-uterine androgens excess is unlikely to be maternal, since the foetus is protected by placental aromatase activity and by high maternal SHBG concentrations.

The expression of aromatase in the placenta of PCOS women may be diminished [9] and this could potentially be unable to prevent foetal testosterone (T) excess in PCOS pregnancies [10]. It has been seen that the prevalence of decreased aromatase required to carry out T excess in female fetuses was reported to be extremely rare [11]. On the other hand, recent studies on hypertensive preeclamptic pregnancies have demonstrated a significant reduction in placental ability to synthesize oestrogens, indicating a gestational impairment of T aromatization that is more common than was previously considered [12, 13].

The source of androgens excess is more likely to be the foetal ovary, which is normally quiescent, but it could produce an excess of androgens in response to maternal hCG in subjects genetically predisposed to PCOS.

In newborn daughters of PCOS women, elevated T levels have been observed in the umbilical venous blood [14, 15]. This finding was not confirmed in other studies that demonstrated instead a reduced umbilical cord blood androstenedione levels [9, 16]. Hickey et al., showed no increase in T levels in umbilical cord blood of adolescent girls diagnosed with PCOS [17]. Taken the ovary as a key foetal site for gestational T excess, during

critical mid-gestational age for target organ differentiation [9], studies at the time of birth, are likely to be too late to detect any remaining hormonal differences [18, 19]. The mid-gestational T excess in human female foetuses can be accompanied by gestational hyperglycaemia and foetal hyperinsulinemia. Interestingly, elevated mid-gestation maternal T levels predict high AMH levels in adolescent daughters [20]. Since elevated AMH represents a characteristic of adolescents and women with PCOS [21] and daughters of PCOS women [22, 23], such associations might suggest a cross-generational relationship between the degree of maternal hyperandrogenism and the development of PCOS in their daughters.

Complete manifestation of the syndrome occurs at adolescence, when the hypothalamus-pituitary-ovarian access is activated. At this time, metabolic changes leading to modifications in the distribution of body fat also occur. In particular, at puberty there is a physiological increase in insulin levels, determining on one hand a reduction in SHBG levels with amplification of the effects of circulating androgens, and on the other hand, direct stimulation of ovarian steroidogenesis [24]. In women with PCOS, the physiologic hyperinsulinemia of adolescence may be a triggering factor for the development of hyperandrogenism and anovulation. Girls predisposed to insulin-resistance and overweight are even more at risk of developing early adrenarche and subsequent PCOS at adolescence [24] (Fig. 1).

Daughters of women with PCOS evaluated during early childhood (age 4–8 years) and early puberty (age 9–13 years) have exaggerated adrenarche compared with daughters of non-PCOS women of similar pubertal stage and body mass index (BMI) [25]. This is consistent with a role of obesity-related insulin-resistance in causing hyperandrogenemia in these girls through an effect of insulin on adrenal and ovarian steroidogenesis [26], manifesting as early adrenarche [27] and subsequent PCOS [28]. Such hyperandrogenemia appears to modulate gonadotropin levels, as has been demonstrated in obese peri-pubertal girls who were found to have increased LH frequency but low LH amplitude, and diminished overnight LH pulse amplitude compared with normal-weight girls [29]. These changes may reflect initial effect of obesity on LH pulses [30]. Subsequently, hyperandrogenemia reduces the inhibition of GnRH pulse frequency by progesterone, causing rapid LH pulse secretion and further increase in ovarian androgen production [30–32].

Epigenetics and PCOS

Since the development of other diseases in adulthood, induced by nutritional or environmental factors in utero, usually involves an epigenetic mechanism, it seems likely that the same mechanism may also occur in PCOS.

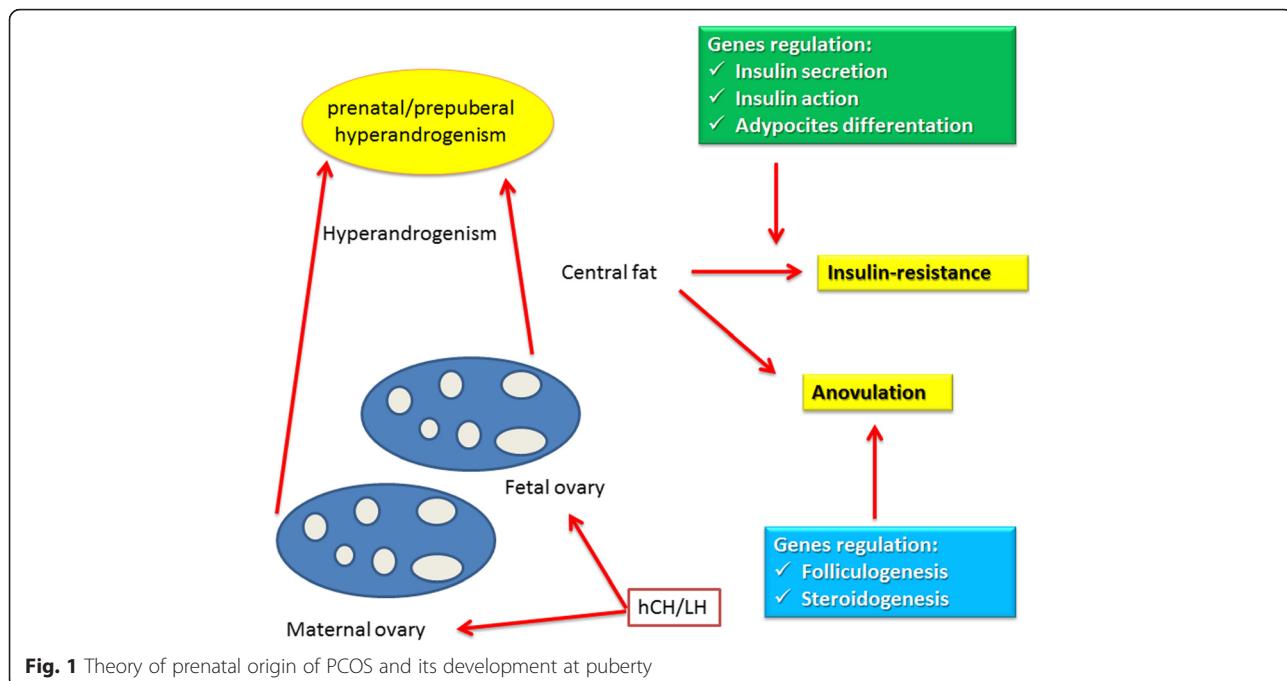

Fig. 1 Theory of prenatal origin of PCOS and its development at puberty

According to this hypothesis, exposure to hyperandrogenism *in utero* may lead to epigenetic reprogramming anomalies in foetal reproductive tissue, which is translated into the PCOS phenotype in adulthood. Moreover, if such epigenetic alterations persist in the germ cell line, transgenerational transmission of the PCOS phenotype is promoted. Clearly other genetic factors (i.e. linked to insulin resistance) and post-natal environmental factors (i.e. diet) may contribute to the development of PCOS phenotype, possibly in association with epigenetic anomalies.

In particular, epidemiologic and clinical studies conducted largely in adult human populations suggest a link between foetal growth restriction, and subsequent risk of type 2 Diabetes Mellitus (DM) and cardiovascular disease [33, 34]. The increased risk for these metabolic diseases has been linked to elevated insulin resistance in young individuals exposed to an adverse *in utero* environment and born small for gestational age (SGA) [35, 36]. These studies support an overall relationship between foetal growth restriction and increased adiposity and insulin resistance starting early in the childhood period. In addition to the *in utero* environmental factors, genetic polymorphisms may modulate insulin resistance parameters in SGA individuals. This may partially explain the variable degree of insulin resistance in subjects exposed to an adverse *in utero* environment [37]. At the other extreme, over-nutrition of these foetuses appears to have long-term effects on obesity, insulin resistance, and predisposition to disorders of glycemic regulation. Offspring of mothers with diabetes during pregnancy

have a higher frequency of childhood obesity and earlier onset of impaired glucose tolerance [38, 39] and type 2 DM [40]. Given the effect of insulin on modulating ovarian [41] and adrenal [42] steroidogenesis, a role of intrauterine adverse events which lead to insulin resistance and/or hyperinsulinemia may predispose adolescents to PCOS. Overall, these studies indicate that at least some metabolic components of the PCOS phenotype are programmed *in utero*, particularly the tendency for higher fat mass, visceral adiposity, and insulin resistance.

If further research verifies this hypothesis, new prospects for preventive treatment during the critical prenatal period will be mandatory.

Genetic factors

Increasing evidences over many years point to familial aggregation of women with PCOS, hyperandrogenism and metabolic alterations [43]. The model of inheritance of PCOS has not yet been defined. Some researchers have postulated autosomal dominant transmission linked to a single genetic defect, but most authors define PCOS as a polygenic pathology. It is also possible that a particular gene in a given family may have a predominant effect, influencing the phenotypic manifestations of the syndrome. The main candidate genes are those encoding for factors involved in the synthesis, transport, regulation and effects of androgens. Other candidate genes are those encoding for factors involved in insulin metabolism, such as insulin receptors, signalling cascade proteins responsible for binding of insulin to its receptor, IGF system, other growth factors and the gene encoding

for Calpain-10 enzyme, responsible for insulin secretion and action [43].

An association has also been found between “pro-inflammatory” genotypes and PCOS, linked to polymorphism of genes coding for TNF-alfa, IL-6 and IL-6 receptor [43]. Finally, recent evidence of altered early gonadotropin-independent folliculogenesis in women with PCOS suggests that genes involved in folliculogenesis may also be candidates in the etiopathogenesis of this syndrome [1].

However, only a few PCOS susceptibility genes have been repeatedly identified in studies of women with Chinese or European ancestry: allelic variants of fibrillin-3 (FBN3) [44–47], and variants of LH receptor (LHR) [44, 48, 49]. FBN3 encodes for an extracellular matrix protein that regulates transforming growth factor (TGF) signaling. Its PCOS associated allelic variant, A8, manifests a metabolically distinct phenotype, including insulin resistance [50]. FBN3 expression, is limited to early to mid-gestation in many organs and tissues, including the ovary [51, 52]. Such a gestational stage includes a period of foetal developmental at which T exposure induces altered DNA methylation of TGF-beta-regulating genes and subsequent PCOS-like traits [53]. Due to the degree and type of fibrillin expression contributes to differences in elasticity of cell extracellular matrix interactions and storage of TGF-beta, fibrillin may provide gestationally relevant [51] tissue-specific bases for cell mediated engagement of extracellular matrix-stored TGF-beta in proliferation, differentiation, and apoptosis [54, 55]. In the ovary, variants of LHR may diminish or enhance pituitary LH stimulation of ovarian theca and stroma cell T production, ovarian follicle development, LH surge-induced ovulation, and corpus luteum function [56], while in adipocytes, LHR variants may alter LH stimulation of adipogenesis [57]. Variants in these multi-organ system genes could contribute to genetically determination of PCOS phenotypes for reproductive and metabolic pathophysiology.

Environmental factors

Although the prevalence of PCOS is similar in all countries, ethnic factors influence the phenotypic manifestations of the syndrome. The prevalence of PCOS among Caucasian women, varies from 4.7 % in Alabama, to 6.5 % in Spain and 6.8 % in Greece [58]. In the United Kingdom, PCOS and type II diabetes are more frequent in women of Asian origin [58]. These observations suggest the existence of different environmental factors, such as diet, physical activity and life-style in general.

The increasing effects of metabolic disorders in economically developed countries has led authors to suggest that the pathogenic mechanisms of these disorders are associated with evolutionary advantages in terms of

survival [58]. On one hand, insulin resistance increases the availability of glucose for brain metabolism, while on the other, it increases blood pressure by mechanisms such as fluid retention and increase in the sympathetic tone. It also induces modifications in clotting factors (hypercoagulation) and a propensity for obesity characterised by a proinflammatory condition with increased secretion of cytokines and inflammatory factors. All the aforementioned alterations make the subject more resistant and favours survival when faced with stressors such as reduced availability of food, wounds and epidemics. The relative infertility of these women increases the interval between pregnancies and reduces the number of children, favouring survival of mothers and children. In the absence of stressors, as in the case of developed countries, these pathogenic mechanisms predispose to cardiovascular disease and atherosclerosis.

Endocrine factors

Ovarian folliculogenesis is regulated by a delicate equilibrium between extra- and intra-ovarian factors. Disturbance of this equilibrium may alter and compromise follicular development and the formation of mature oocytes, leading to infertility (Fig. 2).

Extraovarian factors

Extraovarian factors include a series of endocrine, paracrine and metabolic alterations, which by causing abnormalities in the follicular microenvironment, may alter folliculogenesis and oocyte development. These alterations include FSH deficit, hypersecretion of LH, hyperandrogenemia of ovarian or adrenal origin and hyperinsulinemia with insulin resistance [59]. Folliculogenesis and oogenesis also depend on intraovarian factors, especially follicular fluid factors (FFFs) [59] that are directly correlated with their levels in plasma. Recent studies suggest that FFFs implicated in folliculogenesis of polycystic ovaries belong to the family of growth factors including cytokines and inhibins [59].

Vitamin D is an essential regulator of bone and mineral homeostasis. Recent studies have demonstrated hypovitaminosis D is associated with an increased likelihood of developing metabolic disorders. [60]. Vit.D deficiency has also been demonstrated in patients with POCS [61]. Obese patients with PCOS have been shown to have lower serum levels of 25-OH-D than non obese women with PCOS and vitamin D deficiency has been suggested to have a role in the development of insulin resistance (IR) and impaired glucose tolerance in such patients [62].

Altered secretion of GnRH and gonadotropins

Although the etiopathogenesis of PCOS is still controversial, series of hypotheses have been proposed in the

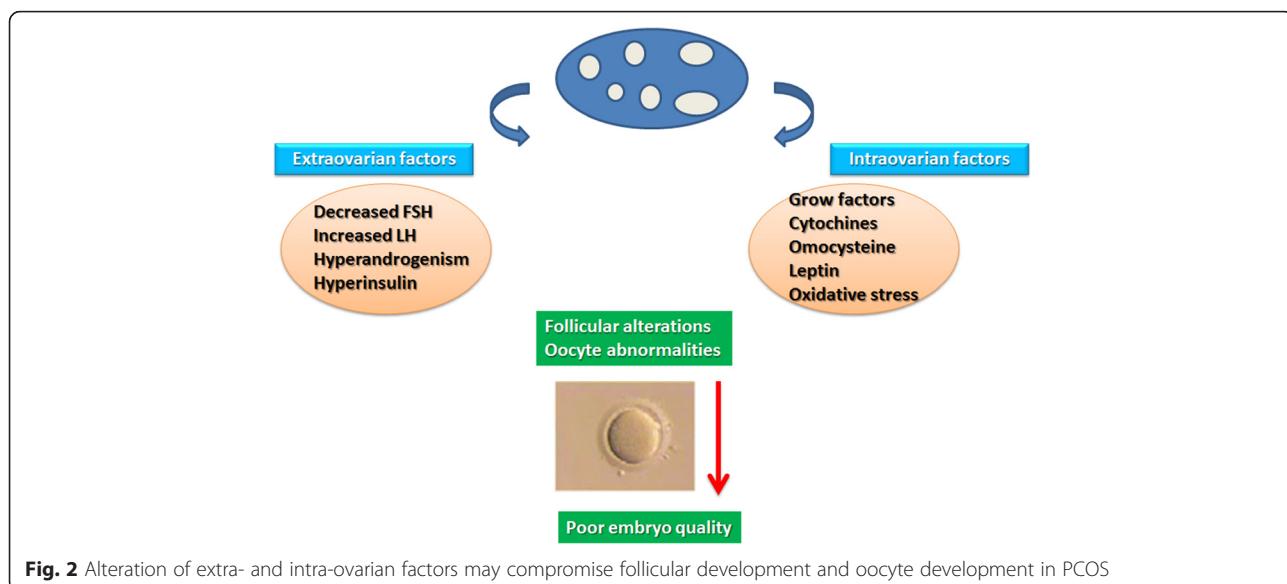

Fig. 2 Alteration of extra- and intra-ovarian factors may compromise follicular development and oocyte development in PCOS

recent decades. A high percentage (55–75 %) of women with PCOS have an elevated LH/FSH ratio presumably due to high levels of LH rather than reduced production of FSH. GnRH stimulation causes, indeed, excessive LH production [63] in those women. This condition may be determined by a higher frequency or amplitude of GnRH [60]. It is not yet clear whether alteration of the hypothalamo-pituitary axis in PCOS is primary or secondary to alterations in steroid hormones secretion. The role of FSH is to recruit ovarian follicles and stimulate their growth: 2–5 mm follicles are sensitive to FSH, whereas larger ones (6–8 mm) acquire aromatase activity and may increase oestradiol (E2) and inhibin B, reducing levels of FSH in late follicular stage. On the other hand, PCOS patients (having LH and FSH concentrations higher and lower than normal, respectively)

accumulate antral follicles (2–8 mm) that differentiate early and undergo premature growth arrest [63]. Hypersecretion of LH in these women may promote early luteinisation of granulosa cells and contribute to early growth arrest of antral follicles (Fig. 3). LH may also activate premature meiotic processes that damage oocyte quality and contribute to the formation of embryonic aneuploidies [64].

Altered dopaminergic and opioid tone has also been found in these patients. However, administration of opioid antagonists or dopaminergic agonists in PCOS patients have little influence on LH pulsatility [63].

Among the excitatory elements of the reproductive axis, kisspeptins have recently emerged as essential upstream regulators of GnRH neurons, with indispensable roles in key aspects of reproduction, such as brain sex

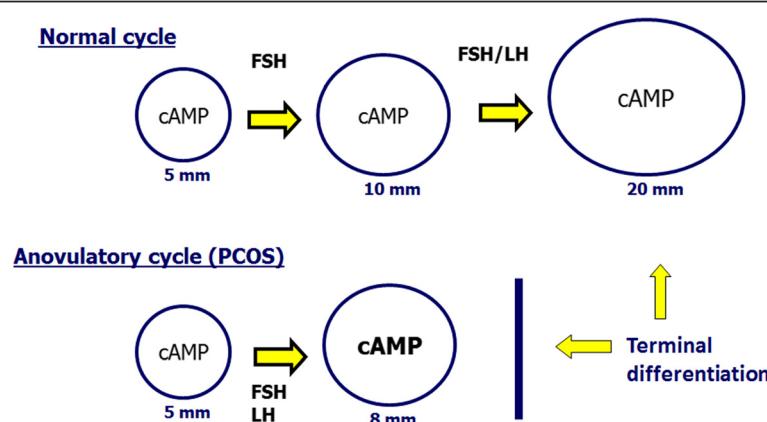

Fig. 3 In a normal cycle, only the dominant follicle responds to LH when it reaches 10 mm diameter. In PCOS the response to LH occurs inappropriately in smaller follicles and many antral follicles reach terminal differentiation before time, producing a greater quantity of steroids and inhibin B that exert negative feedback on FSH production

differentiation, puberty onset, gonadotropin secretion, ovulation, and the metabolic regulation of fertility [64–68]. Kisspeptins are a family of closely related peptides of different amino acid length (such as Kp-54 and Kp-10) that are encoded by the Kiss1 gene and operate through the G protein-coupled receptor Gpr54, also named kisspeptin receptor or Kiss1R [64, 65, 68]. Expression of the elements of the Kiss1 system in different ovarian compartments has been documented in human and rodent species [69, 70]. Ovarian expression of Kiss1 is under the positive control of gonadotropins [69]. On the other hand, local mediators also participate in the control of ovarian Kiss1 expression; inhibition of prostaglandin synthesis, which causes ovulatory dysfunction, evokes a marked suppression of ovarian Kiss1 mRNA levels during the periovulatory period. Moreover, inhibition of prostaglandin synthesis blocks the positive effect of gonadotropins on Kiss1 gene expression in the ovary [70].

Taken as a whole, these observations suggest a potential role of locally produced kisspeptins in the control of ovulation. Whether alterations of such local actions of kisspeptins might contribute to the ovulatory dysfunction seen in PCOS warrants specific investigation.

Ovarian and extraovarian hyperandrogenism

Hyperandrogenemia is the most typical hormonal alteration of PCOS. Biochemically, hyperandrogenism is usually assessed by assay of total testosterone (TT), free testosterone (fT), sex hormone binding globulin (SHBG), androstenedione (A), 17-hydroxy progesterone (17-OHP) and dehydroepiandrosterone sulphate (DHEAS) in serum and by calculation of the free androgen index ($FAI = (TT/SHBG)100$). Women with PCOS often have

higher than normal serum concentrations of all these androgens. Hyperandrogenism has a multifactorial origin attributed mostly to the ovaries with a substantial contribution from the adrenals and a minor contribution from fatty tissue.

Biosynthesis of androgens is mediated by microsomal P450c17 which catalyses 17–20 lyase activity. Alterations in P450c17 at transcriptional and post-transcriptional level have been implicated in the aetiology of PCOS [71]. These women show, indeed, relative inhibition of 17–20 lyase activity with respect to 17-hydroxylase, leading to an increased 17OHP/A ratio. Administration of GnRH or hCG in women with PCOS causes excessive production of 17OHP [68]. Low aromatase activity has also been demonstrated in women with PCOS. Aromatase is a granulosa cell enzyme that converts androgens into estrogens. It may be partly responsible for hyperandrogenism in this syndrome [70, 71] (Fig. 4).

Elevated levels of androgens may have a negative impact on follicular development, causing atresia, and on ovarian development, inhibiting meiotic maturation by decreasing oscillations of intracytoplasmic calcium levels [59].

Hyperinsulinemia and insulin resistance

Insulin resistance is defined as a pathological condition in which a cell, tissue or organism requires above-normal quantities of insulin to respond normally. It causes increased insulin secretion by pancreatic β cells and compensatory hyperinsulinemia, while blood glucose remains normal. When the response of pancreatic cells decreases, the patient develops glucose intolerance or type II diabetes [5].

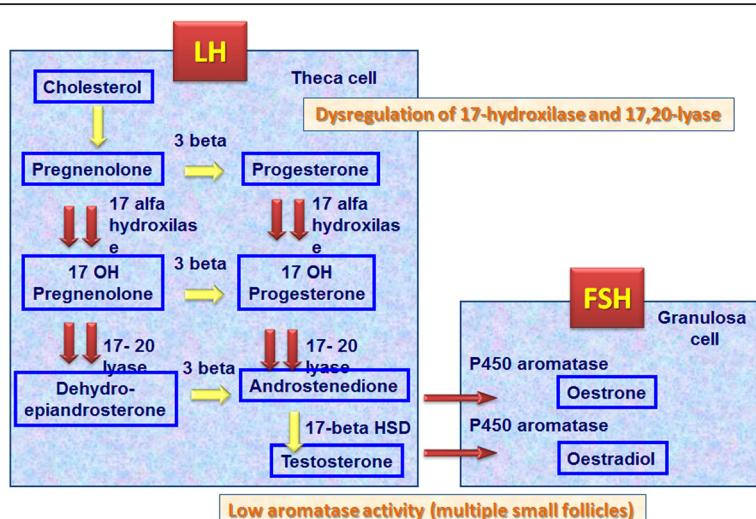

Fig. 4 Relative inhibition of 17–20 lyase activity with respect to 17-hydroxylase has been found in women with PCOS. This leads to an increase in the 17OHP/A ratio and reduction of aromatase activity, the enzyme of granulosa cells that converts androgens into estrogens

Since many women with PCOS seem to have insulin resistance, compensatory hyperinsulinemia is thought to contribute to hyperandrogenism [72, 73] by direct stimulation of ovarian production of androgens and by inhibition of liver synthesis of SHGB that increases testosterone availability. Insulin also increases ACTH-mediated adrenal androgen production and accentuates LH-stimulated ovarian steroidogenesis [73] (Fig. 5).

About 60–70 % of women with PCOS are obese or overweight, and obesity is associated with insulin resistance. However, many studies have shown that insulin resistance is also present in many lean women with PCOS [5, 73]. The mechanisms leading to insulin resistance consist of a defect in insulin binding to its receptor or to changes in insulin signal transmission [5, 74]. However, the ovaries of these women maintain approximately a normal response to insulin. A partial elucidation of this mechanism is explained by the action of insulin on the ovary through the IGF-1 receptor. This binding occurs when insulin reaches high concentrations, as compensatory hyperinsulinemia. Moreover, the action of insulin on the ovary uses the inositol glycan system as a signal mediator, a different mechanism from the system

activated by phosphorylation of the receptor at tyrosine level in other tissues [75]. An increase was observed in urinary clearance of inositol in some American and Greek women with PCOS. It reduces tissue availability of inositol. This mechanism could contribute to insulin resistance present in PCOS women [76]. Hyperinsulinemia directly stimulates ovarian steroidogenesis by acting on thecal and granulosa cells. *In vitro* studies have demonstrated that insulin stimulates thecal cell proliferation, increases secretion of androgens mediated by LH and increases cytochrome P450 expression of LH and IGF-1 receptor. Since the enzymes involved in ovarian steroidogenesis are similar to those of the adrenals, many studies have shown that insulin may act directly as stimulator adrenal steroidogenesis [5, 73]. The administration of metformin, an insulin-sensitising drug, significantly reduces production of 17OHP, T and A in response to ACTH in PCOS women [5].

In vitro data, obtained with cell culture models, indicate that co-incubation of insulin and FSH with bovine oocytes promotes up-regulation of LH receptors on granulosa cells of antral follicles. It contributes to arrest of follicular growth, inhibits of aromatase activity, and

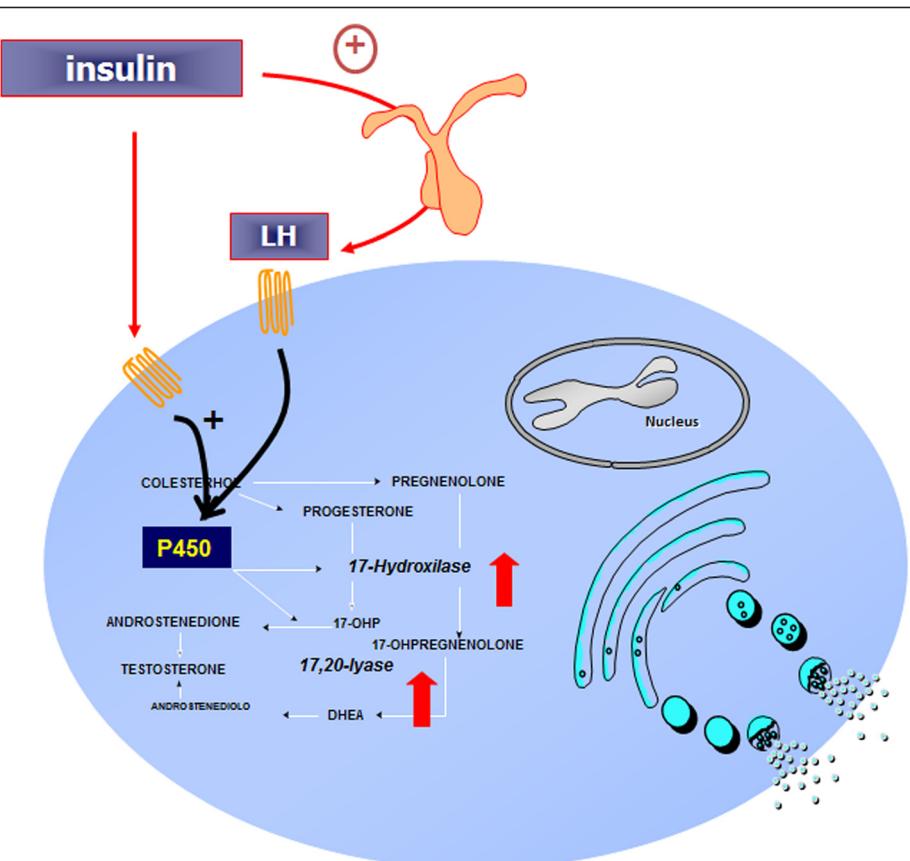

Fig. 5 Hyperinsulinemia stimulates directly cytochrome p450 enzymes in the ovary or indirectly through action of LH or IGF-1, causing hyperandrogenism

potentially triggers to ovarian hyperandrogenism. Looking at the molecular level, insulin binds to its receptor on granulosa and thecal cells and on oocytes where it may alter expression of certain genes involved in the meiotic process of the oocyte [59].

In vitro studies have demonstrated that insulin also has receptors at hypothalamus and pituitary levels, through which it stimulates the release of FSH and LH under basal conditions and after GnRH stimulation [5, 59].

Furthermore, insulin also influences hyperandrogenism by inhibiting liver synthesis of SHBG² and IGFBP-1, which binds IGF-1 [5, 59]. IGF-1 is a growth factor with endocrine action. It is mainly synthetized by the liver, but is also produced by other tissues, including the ovaries, where it has autocrine/paracrine functions. Many studies have shown a significant increase in the IGF-1/IGFBP-1 ratio in women with PCOS. An increased availability of IGF-1 in thecal cells can induce increased production of androgens. Moreover, IGF-1 stimulates oestrogen production by granulosa cells and synergically acts with FSH and LH in modulating expression of aromatase in granulosa cells. IGF-1, like insulin, also exerts an indirect control on ovarian steroidogenesis through the hypothalamus-pituitary axis. It induces, in fact, expression of GnRH and release of gonadotropins by the pituitary [5, 59]. Treatment with insulin-sensitising drugs increases IGFBP-1 levels, reduces the IGF-1/IGFBP-1 ratio and decreases IGF-1 availability in peripheral tissues [77].

Intra and extra-ovarian factors

Epidermal growth factors (EGF)

Epidermal growth factor (EGF) plays an important role in regulation of cell growth, as well as in proliferation and differentiation through interaction with its receptor EGFR (ErbB1, ErbB2-4) [59, 71]. In the human ovary, EGF is present in follicular fluid (FF), where it regulates follicle development and oocyte maturation. In women with PCOS, FF EGF levels are higher than in normal ovulating women. In PCOS condition, EGF may inhibit granulosa cell oestrogen synthesis, which is translated into arrest of follicle growth [59, 71].

Insulin-like growth factors (IGF)

These growth factors are multifunctional polypeptides with insulin-like activity that play important regulatory functions for follicle and oocyte development [59, 71, 78]. Circulating IGFs are produced by the liver: IGF-1 is secreted by thecal cells, whereas IGF-2 is synthesised by granulosa cells and IGFBP (insulin-like growth factor binding protein) has been found in FF and is expressed by granulosa and thecal cells [78]. FF IGF-1 levels in PCOS women are elevated than in normal women,

whereas IGFBP-1 are lower in PCOS patients, causing the arrest follicle growth [78].

Neurotrophin growth factor (NGF)

NGF is not only involved in development of the nervous system but also acts in the ovaries of humans and other mammals. It plays a fundamental role in folliculogenesis and oocyte maturation [59, 71, 78]. This factor promotes nuclear and cytoplasmic maturation of oocytes, and processes essential for the development of good quality oocytes and embryos. Elevated NGF concentrations in FF have been reported in women with PCOS [59, 71, 78].

Transforming growth factor-*b* (TGF-beta)

Members of the TGF-beta family play a role in follicle growth and oocyte development. They include anti-mullerian hormone, activin, follistatin, inhibins, bone morphogenetic protein (BMP)-9 and growth and differentiation factor (GDF)-9 [78, 79]. In different occasions, these growth factors may promote or block follicle growth and/or differentiation [74, 80].

Anti-Mullerian hormone (AMH)

AMH is a homodimeric glycoprotein that inhibits the development of Mullerian ducts in male embryos [59]. It is expressed by granulosa cells in the ovaries of women of reproductive age, where it controls the formation of primary follicles and follicle recruitment by FSH. Therefore playing an important role in folliculogenesis [74, 78, 79]. Women with PCOS have higher serum and FF concentrations of AMH compared to controls. This is closely correlated with greater development of antral follicles and arrest of follicular growth [79, 80]. High serum levels of AMH are directly correlated with an increase in testosterone and/or LH concentrations in women with PCOS, as well as with altered oocyte maturation and low embryo quality [64, 80]. Furthermore, elevated concentrations of AMH in FF of women with PCOS are correlated with a higher percentage of immature oocytes and lower fertilisation rates compared to women with endometriosis or pelvic adhesion syndrome [80].

Activin, follistatin and inhibin

Activin, follistatin (FS) and inhibin are polypeptides, which were originally isolated from ovarian FF. FS is a binding protein produced by ovarian granulosa cells; cellular growth and differentiation is regulated by autocrine/paracrine action. Over-expression of FS has been associated with arrest of follicle growth and reduced oocyte development. Activin is mostly secreted by smaller follicles. It promotes follicle development by increasing granulosa cell response to FSH stimulation; it decreases androgen synthesis and stimulating oocyte maturation. Besides inhibiting FSH production, inhibins

are produced by the dominant follicle and stimulate thecal cells to produce androgens as substrate for estrogen formation [59, 74, 78, 79]. An increased FS/activin ratio and elevated concentrations of inhibin B have been found in PCOS [59, 74, 78, 79].

Vascular endothelial growth factor (VEGF)

VEGF is a homodimeric glycoprotein expressed in granulosa and thecal cells [78] and also present in FF [59]. It plays an important role in angiogenesis, follicular vascularisation and intra-follicular oxygenation. It has therefore an impact of follicle maturation, oocyte quality, fertilisation and embryo development [59, 74, 78, 79]. The alterations in FF concentrations of VEGF in patients with PCOS is indicative of oocyte immaturity [78]. The elevated concentrations are useful as an indicator of oocyte maturity, successful fertilisation and embryo development in women with PCOS [78].

Interleukins (IL)

Interleukins are a group of cytokines produced by leukocytes. In particular, IL-1, IL-2, IL-6, IL-8, IL-11 and IL-12 play different roles in the regulation of folliculogenesis, ovulation and corpus luteum function. Concentrations of IL-12 in FF differ from immature follicles and those in pre-ovulatory phase [78], and reduced FF concentrations of IL-12 and elevated FF concentrations of IL-13 in patients with PCOS are correlated with reduced oocyte maturation, fertilisation and pregnancy [59, 74, 78, 79].

Tumour necrosis factor α (TNF- α)

TNF- α is involved in the regulation of ovarian function, exerting an influence on proliferation, differentiation, follicle maturation, steroidogenesis and apoptosis. TNF- α is expressed by the oocyte, thecal cells, granulosa cells and the corpus luteum in the ovary. Alterations in TNF- α levels in FF are correlated to poor oocyte quality. Increased FF concentrations of TNF- α in women with PCOS are also significantly inverse correlated to FF concentrations of E2, which are indicative of poor oocyte and embryo quality [78].

Fas and Fas ligand (FasL)

Fas and FasL are membrane proteins belonging to a TNF subfamily, and they respectively have anti- and pro-apoptotic functions. Concentrations of Fas in FF are positively correlated with oocyte maturity [78]. In women with PCOS treated with metformin, a reduction in FF concentrations of FasL has been reported, with a consequent increase in implant and pregnancy percentages [59, 74, 78, 79].

Biomolecules related to carbohydrate metabolism

Proteomic studies show modulation of several proteins related to the carbohydrate metabolism. The abundance of many proteins such as aconitate hydratase, fructose bisphosphate aldolase A, malate dehydrogenase, isoenzymes M1/M2 of pyruvate kinase, and transaldolase has been found to be increased in ovarian tissue and in ovarian granulosa cells from PCOS patients. Instead, UDP-glucose 6-dehydrogenase protein was reduced in PCOS women.

Moreover, triosephosphate isomerase was shown to have increased gene expression in ovarian tissue from PCOS patients.

Biomolecules related to lipid metabolism

Women with PCOS frequently present an atherogenic serum lipid profile consisting of increased triglycerides, cholesterol, low-density lipoprotein cholesterol concentrations and reduced apolipoprotein A-I levels. Insulin resistance, androgen excess and obesity may all contribute to the abnormalities of lipid metabolism observed in women with PCOS.

Apolipoprotein A-1 (ApoA-I), the major structural protein component of HDL-cholesterol particles, has several pleiotropic biological functions: promotion of macrophage cholesterol efflux, stimulation of reverse lipid transport, inhibition of LDL oxidation, removal of toxic phospholipids and also many other anti-inflammatory properties. Proteomic techniques found a decreased abundance of ApoA-I in visceral adipose tissue and in whole ovarian tissue from women with PCOS [80–82]. Moreover, reduced ApoA-I abundance in granulosa cells from these women may influence the expression of steroidogenic enzymes and the production of the steroid hormone progesterone [83].

Apolipoprotein C-I (ApoC-I) inhibits lipoprotein metabolism in the liver. Several authors showed, thus, increased serum ApoC-I levels in women with PCOS compared to normal controls, especially in those presenting with insulin resistance [84].

Adipocyte plasma membrane-associated protein (APMAP) may represent a novel member of paraoxonases [85], which are known to be involved in antioxidant processes. Lower level of APMAP has been found in visceral adipose tissue in patients with PCOS [81] might contribute to the impairment in antioxidant defense characteristic of PCOS [86].

Biomolecules related to protein metabolism

Proteomic techniques indicated that ovarian tissue (in patients with PCOS) presents high levels of proteins involved in the metabolism of amino acids, in post-translational protein modification and in protein degradation [82].

Methionine adenosyltransferase II (MAT2B), an enzyme involved in the removal of homocysteine, is decreased in the PCOS ovary [82]. Moreover, cathepsin D, an acid protease involved in intracellular protein breakdown implied in the pathogenesis of several diseases, such as, breast cancer [87, 88]; it is decreased in T lymphocytes from women with PCOS. The biological significance of this decrease is not clear [89].

Other factors

Heat shock proteins (HSPs)

Heat shock proteins (HSPs) are a highly conserved family of molecules involved in protein folding. Many components of survival and apoptotic pathways are regulated by molecular chaperones such as heat shock proteins [90]. The decrease at the protein level of Hsp10, Hsp27 and Hsp60 in ovarian tissue and granulosa cells from patients with PCOS [79, 80] might contribute to apoptosis within the ovarian follicle. In accordance, Hsp60 is down-regulated in adipose tissue in PCOS gene expression studies [91].

Transferrin

Transferrin is the major iron transporter in the circulation and it is increased in PCOS women. High levels of transferrin may not be related to inflammation but represent a compensatory mechanism against the limitation of iron availability for erythropoiesis characteristic of chronic disorders [92]. Similarly, the decrease in $\alpha 2$ macroglobulin observed in patients with PCOS might be related to the increased body iron stores, observed in these women [93, 94].

Homocysteine

Homocysteine (Hcy) is a homologue of the amino acid cysteine and may be converted into methionine or cysteine in the presence of B-complex vitamins. Many studies have shown that elevated Hcy levels in serum and FF are inversely proportional to oocyte and embryo quality [59, 74, 78, 79]. High FF and serum concentrations of Hcy may suppress E2 synthesis and therefore interfere with follicle growth and oocyte maturation in women with PCOS [59, 74, 78, 79].

Leptin

Leptin is a protein hormone that plays a key role in regulating energy supply and demand. High FF and serum concentrations of leptin are closely associated with a decrease in oocyte maturity and embryo quality in patients with PCOS. Certain studies have also demonstrated that high levels of leptin in women with PCOS play a role in PCOS pathogenesis, acting by inhibiting E2 production and interfering with follicle development and oocyte maturation. On the other hand, some

authors have demonstrated that leptin is reduced in FF of women with PCOS and is therefore not a useful marker for evaluating oocyte quality [59, 74, 78, 79]. In-depth research is therefore needed to elucidate the role of leptin in the pathophysiology of PCOS.

Oxidative stress (OS)

Oxygen free radicals or reactive oxygen species (ROS) are involved in many physiological functions where they act as mediators in a variety of signal transduction pathways [59]. An excess of these substances can cause cellular damage. In women with PCOS, elevated levels of ROS in FF and reduced antioxidant capacity are closely associated with reduced oocyte maturation and low embryo quality [59, 74, 78, 79]. These molecules may reduce oocyte quality by altering the equilibrium of FFFs in the follicular microenvironment.

The decrease in mitochondrial O₂ consumption and glutathione (GSH) levels, along with increased ROS production, explains the observed mitochondrial dysfunction in PCOS patients [95]. The mononuclear cells of women with PCOS are increased in this inflammatory state [96], which occurs more often in response to hyperglycemia and C-reactive protein (CRP). Physiological hyperglycemia generates increased levels of ROS from mononuclear cells, which then activate the release of TNF- α and increase inflammatory transcription factor NF-kappa B. As a result, the concentrations of TNF- α , a known mediator of insulin resistance, are further increased. The resulting OS creates an inflammatory environment that promotes insulin resistance and contributes to hyperandrogenism [97].

Clinical manifestations

The typical clinical indications of PCOS are: anovulatory cycles, ultrasonographic evidence of polycystic ovaries and hirsutism. Many women are also overweight or obese and have an increased risk of developing metabolic syndromes in later life. During pregnancy, there is a higher chance of miscarriage, gestational diabetes and hypertension.

Anovulatory cycles

Anovulatory cycles often manifest with oligoamenorrhea, secondary amenorrhea or abnormal uterine bleeding. The term oligomenorrhea refers to cycles of more than 35 days, while secondary amenorrhea is an absence of menstruation for more than three months. Polymenorrhea condition, meaning more frequent cycles, generally with an interval of less than 24 days, may occur in a minority of cases. Since regular cycles do not exclude chronic anovulation, it is necessary to measure serum concentrations of progesterone in luteal phase of the

cycle (days 20–24). If they are below 5 ng/mL, the cycle is probably anovulatory.

Menstrual irregularities often begin after menarche and decrease when the patient approaches menopause [98]. This correlated to a decline in androgen levels with advancing age in women with PCOS [98]. While evaluating the length of the menstrual cycle, it should be recalled that oligo-anovulation is quite common in adolescents, especially in the first year after menarche. Settling into regular cycles may be a slow process, which, in some cases, may take three years after the first period. This is why it is important to be cautious in diagnosing and treating PCOS in adolescents. The incidence of irregular cycles in adolescents with PCOS seems to vary significantly: about 43 % with oligomenorrhea, 21 % with primary or secondary amenorrhea, 21 % with regular menstrual cycles and 7 % with polymenorrhea [99]. 95 % of adult women with PCOS have amenorrhea [5, 99].

Ultrasonographic features of the ovaries

The Rotterdam guidelines of 2003 include ultrasonographic evidence of polycystic ovaries as a criterion for the diagnosis of PCOS. This finding is not exclusive because young healthy women may have ovaries with polycystic features. Polycystic ovaries may also be observed during pubertal development in patients with hypothalamic amenorrhea and hyperprolactinemia [100].

The diagnostic criteria of PCOS are based on the presence of 12 or more follicles of diameter 2–9 mm or an ovarian volume of more than 10 mL in follicular phase. Another feature is an increase in stromal tissue. These morphological changes in the ovary may be encountered in more than 80 % of women with a clinical diagnosis of PCOS [100].

Hirsutism

Hyperandrogenism may manifest with hirsutism, acne and alopecia. Hirsutism is the presence of terminal hair on the face and/or body in a masculine pattern. It is the most common symptom, found in about 60 % of women with PCOS and it widely varies according to the ethnicity. For this reason, the threshold of hirsutism should be set considering the patient ethnicity. The most widely used method to determine the degree of hirsutism is the Ferriman-Gallwey score [101] which gives a score of 0 in the absence of terminal hair in a given area of the body, and a score of 4 for extensive hair growth. Hair is scored in 9 different areas of the body, such as, chin, upper lip, periareolar and intermammary areas, upper and lower back, upper and lower abdomen, upper and lower limbs. The score from each area is summed to obtain a final score used for diagnosis. A score of 7 is indicative of hirsutism. It is defined as “slight” for scores of 7–9, “moderate” for 10–14 and “severe” for scores ≥ 15 [101].

Hirsutism may be simultaneously due to androgen production, increased circulating levels of free testosterone (Ft) in women with PCOS; together with an increased activity of androgens in the pilosebaceous units through action of 5- α reductase, an enzyme that transforms testosterone into the more active dihydrotestosterone.

Acne

Acne occurs in 12–14 % of women with PCOS and varies according to ethnicity: the highest reported incidence regards Indo-Asian women and lowest, Pacific islanders [102]. Acne consists of comedones, due to accumulation of sebum and epithelial cell debris, which is colonised by the bacterium *Propionibacterium acnes*. Inflammation of the comedones leads to the formation of papules, pustules and nodules. Androgens may exacerbate this process, increasing sebum production by pilosebaceous units. About 50 % of women with acne have no clinical or biochemical evidence of hyperandrogenism. Moreover, many hirsute women with PCOS do not have acne. These differences may be due to different peripheral sensitivity of androgen receptors [102].

Alopecia

Alopecia consists in progressive hair loss or thinning. The intensity varies from subject to subject. Androgenic alopecia is often accompanied by seborrhea and dandruff. Sensitivity of the pilosebaceous unit to androgens is highly variable and there is little correlation between clinical features and biochemical profiles of hyperandrogenism [102]. Hair loss in PCOS usually involves thinning at the vertex with maintenance of the frontal hairline.

PCOS in adolescence and at menopause

It has been known for several years that PCOS patients have higher risk for a certain range of diseases compared to the general population. This risk exposes them to high morbidity and it is associated with high social impact, both economic and in healthcare. These pathologies include type II diabetes, metabolic syndrome, cardiovascular disease, endometrial carcinoma and many gestational complications. The clinical indicators of hyperandrogenism are another important aspect for adolescents with PCOS, considering of self-perception in this delicate period of life, when physical appearance is fundamental for self-acceptance and relationships with others. Hirsutism, acne and obesity cause psychological distress that may develop into personality disorders and depression. Early diagnosis and treatment of PCOS in adolescence is therefore fundamental because it can slow down or prevent the appearance of these pathologies in adulthood. Diagnosis of PCOS in adolescence is more

problematical than in adulthood and, according to some authors, should be based on all three Rotterdam criteria [103]. Oligomenorrhea should have a history of at least two years since menarche and diagnosis of polycystic ovary by abdominal ultrasonography should only be based on increased ovarian diameter ($>10 \text{ cm}^3$). If diagnosis cannot be confirmed patients should be carefully monitored until adulthood, and if symptoms persist the diagnosis should be reassessed [103].

The clinical manifestations of PCOS in perimenopause period are not well known. There is histological evidence that women with PCOS have a larger cohort of primary follicles than healthy women of the same age, a greater number of antral follicles detectable by ultrasonography and higher serum concentrations of AMH [104]. These results suggest prolonged reproductive function and greater ovarian reserves. Women with PCOS also seem to achieve better menstrual regularity and probability of ovulation with age (despite lower pregnancy rates). A study of a prospective cohort of women during menopause shows that those with PCOS go into menopause an average of two years later than controls [104].

Long-term sequelae

Insulin resistance in young healthy women raises the problem of other risk factors such as impaired glucose tolerance (IGT), diabetes, hyperlipidemia, hypertension, abdominal obesity and risk of cardiovascular disease [5, 105]. Since PCOS patients tend to have abdominal fat deposition and insulin resistance, it has been suggested that they may also have other metabolic alterations typical of so-called metabolic syndrome. This syndrome is characterised by a series of symptoms, such as insulin resistance, obesity, hypertension and hyperlipidemia. Women with PCOS have elevated blood pressure, serum

triglycerides, LDL, total cholesterol and lower HDL cholesterol than age-matched controls [5, 105]. Furthermore, PCOS patients have a seven times higher risk of myocardial infarction than controls of the same age (Fig. 6).

Insulin resistance is recognised as a major risk factor for type II diabetes [5, 105]. Factors such as obesity and family history of type II diabetes can increase the risk of diabetes in PCOS. About 30 % of obese women with PCOS have IGT. A retrospective study by Dahlgren et al. showed that prevalence of non-insulin-dependent diabetes mellitus (NIDDM) was 15 % in PCOS patients and 2 % in controls. Dunaif et al. [5, 105] suggested that up to 20 % of PCOS patients have IGT or NIDDM in the third decade.

It cannot be argued that PCOS patients with excess of androgens and anovulation are more vulnerable to metabolic dysfunction than other women. Women with PCOS and anovulation, but with normal levels androgens, and those with hyperandrogenism but regular cycles, usually have normal insulin sensitivity and presumably do not have the same risk of IGT or type II diabetes as those with the "classical phenotype" of the syndrome [106].

Besides, women with PCOS are also at higher risk for endometrial hyperplasia and carcinoma. This risk is, in fact, influenced by various factors, such as obesity, hyperandrogenism and infertility. All these factors can be present in women with PCOS. A recent prospective study of 56 PCOS patients showed a high prevalence of endometrial hyperplasia [5, 105]. An interesting recent review and meta-analysis confirms that women of all ages with PCOS have an increased risk of endometrial cancer but the risk of ovarian and breast cancer was not significantly increased [107]. For this reason, preventive

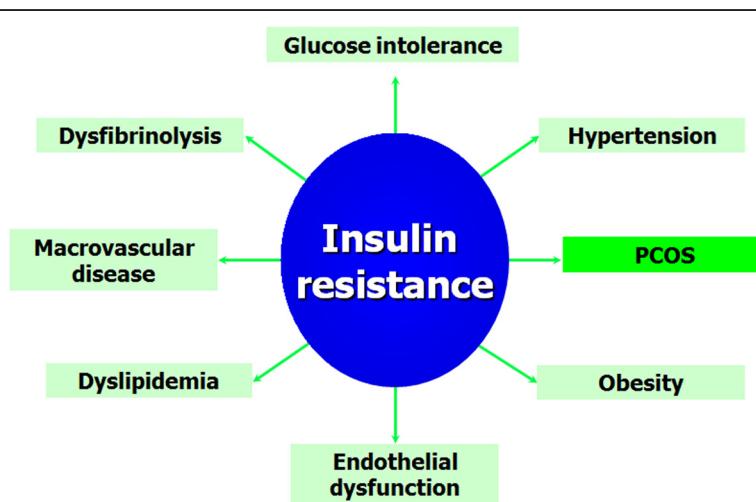

Fig. 6 Insulin resistance is the link between PCOS and metabolic syndrome

measures on PCOS patients for endometrial carcinoma are suggested. These include recognition and treatment of relative hyperestrogenism by periodic administration of progesterone and/or ultrasonography and endometrial biopsy in cases of long periods of amenorrhea. In any case, at least four episodes of suspension bleeding per year (every 3 months) are recommended.

PCOS and pregnancy: gestational complications

Women with PCOS show higher risk of gestational complications, such as miscarriage, gestational diabetes, hypertension and pre-eclampsia. These problems expose them to a higher risk of premature delivery and caesarean section [108]. Recent epigenetic theories suggest that during PCOS pregnancy the embryo is exposed to an excess androgens that disrupts functional reprogramming of foetal tissues [109, 110]. Maternal, placental or foetal hyperandrogenism can distress epigenetic reprogramming of tissues, especially of genes regulating reproduction and metabolism. Which can contribute to diseases such as type II diabetes, hypertension, autism^{31–32} and PCOS. Epigenetic alterations of the androgen receptor gene on chromosome X have, indeed, been observed in women with PCOS. However, a recent study failed to find any significant differences in overall methylation of peripheral leukocyte DNA between women with PCOS and matched controls [109, 110], so aforementioned theory has not yet been confirmed.

Women with PCOS have a 30–50 % of risk of miscarriage, which is three times higher than normal women [111]. The mechanisms probably involved in the pathogenesis of miscarriage in these women are:

1. overexpression of androgen and steroid receptors and simultaneous reduced expression of molecules

of implantation, such as α vs β 3 integrin and glycodelin [111];

2. hyperinsulinemia which inhibits endometrial and stromal differentiation *in vitro* (decidualisation) and locally down-regulates IGFBP-1 [111];
3. hypofibrinolysis mediated by high levels of plasminogen activator inhibitor (PAI) [111];
4. increased resistance of the uterine arteries blood flow leading to reduced sub-endometrial and endometrial vascularisation [111] (Fig. 7).

Moreover, women with PCOS have a higher incidence of gestational diabetes (20–30 %) and pre-eclampsia/pregnancy-induced hypertension (PE/PIH) (10–15 %) [108]. These alterations could be caused by obesity, alterations in glucose metabolism or in uterine vascularisation [112]. Obesity in pregnancy is, in fact, associated with various complications, such as miscarriage, pre-eclampsia, gestational diabetes, foetal macrosomia and caesarean section [112]. Fat tissue produces adipokines, including leptin, adiponectin, TNF- α , IL-6, resistin and visfatin, which could be involved in activation of insulin resistance in pregnancy. Adipokines can also produce an excessive local and systemic inflammatory reaction, which would play a key role in the pathophysiology of PE/PIH and the birth of SGA babies. It is also possible that placental macrophages contribute to inflammation within the placenta by secretion of pro-inflammatory cytokines such as IL-1, TNF- α and IL-6 in cytotrophoblast and syncytiotrophoblast cells [112].

Glucose intolerance and insulin resistance are elevated in women with PCOS even before pregnancy. Since pregnancy causes physiological insulin resistance through the action of placental hormones such as placental lactogen (hPL), placental growth hormone (hPGH) and

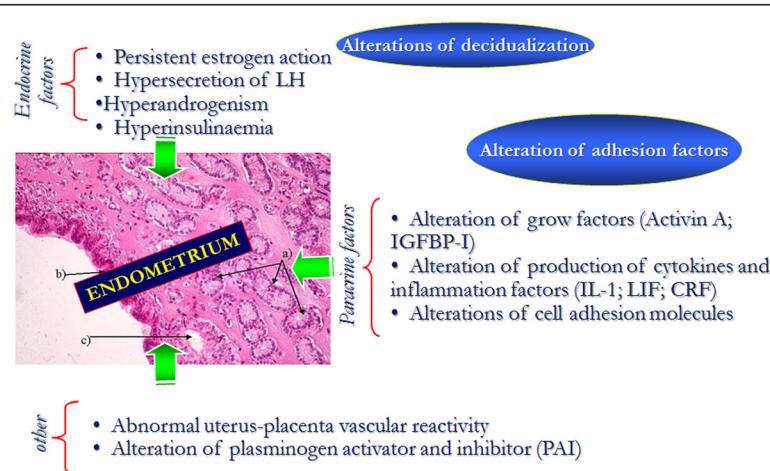

Fig. 7 Factors involved in the etiopathogenesis of miscarriage in women with PCOS

progesterone, women with PCOS have even an higher risk of developing gestational diabetes. However, studies on the prevalence of gestational diabetes in women with PCOS show conflicting results that reflect the heterogeneity of the syndrome and the diversity of methods used to diagnose gestational diabetes [108].

Furthermore, alterations of uterine vascularisation reported in these women can determine reduced trophoblastic invasion leading to increased incidence of hypertension and delivery of SGA babies [112].

Maternal and placental hyperandrogenism may contribute to an increased risk of PE/PIH. In normal condition, the androgens synthesised by the placenta are rapidly converted to oestrogens by placental aromatase. Insulin inhibits placental aromatase and stimulates 3 β HDS activity. Expression of androgen receptors is significantly increased in the placentas of women with PE/PIH and this may induce vasoconstriction and thrombosis [108, 112]. Finally, all these complications expose pregnant women with PCOS to a greater risk of premature delivery and caesarean section [108].

Outcome of newborns of mothers with PCOS

A meta-analysis aimed at evaluating neonatal complications in women with PCOS was recently conducted [108]. The newborns of PCOS patients had a significantly elevated risk of admission to the neonatal intensive care unit and a higher possibility of perinatal mortality [108]. Access to neonatal intensive care is partially linked to premature delivery, which causes hypoglycemia, jaundice and respiratory distress. Many women with PCOS also undergo ovulation induction and in vitro fertilisation and are therefore at chance for multiple pregnancies [113]. Multiple pregnancy is another major cause of increased perinatal morbidity. However, the studies aforementioned did not show any difference in multiple pregnancy between women with PCOS and healthy women [113].

Given the excessive rate of gestational diabetes in women with PCOS, an increased incidence of foetal macrosomia could be expected. However, newborns of women with PCOS show a significantly lower birth weight than controls, although the size of this difference (mean 40 g) is probably of limited clinical significance [108].

The foetus of PCOS mothers is exposed to greater glucose load, but placental distress can reduce the manifestation of macrosomia. The association of PCOS and PE/PIH suggests placental distress, especially in cases of pre-term delivery [108]. The above-mentioned meta-analysis had some limitations regarding heterogeneity of PCOS patients enrolled in the different studies. BMI, medically assisted procreation and smoking during pregnancy were not always considered, all of which are factors that may affect obstetric and neonatal outcome [108].

Conclusions

PCOS is not only a reproductive pathology but also a systemic condition and its etiopathogenesis is still not completely understood. Recently, the approach of clinical practice has been a progressive changed and improved towards prevention together with the standard treatments for diseases. Therapeutic tools are represented by hormonal contraceptives, antiandrogen drugs, metformin and inositol.

In this context, PCOS is an excellent example of pathology in which early diagnosis and treatment can prevent or delay its typical long-term sequelae.

In the past, therapy for PCOS has been centred on treatment of hirsutism and restoration of ovulation. However, it should be taken more into account the observation of hyperinsulinemia and insulin resistance, which are often implicated in the pathogenesis of the syndrome. Due to the fact that these alterations have major repercussions on health in the long period, the researchers should evaluate more appropriate strategies for control of the metabolic alterations of PCOS.

Abstract: Hirsutism is defined as the presence of terminal hair with male pattern distribution in women. While in the general population, hirsutism affects around 4–11% of women, it is the main manifestation of hyperandrogenism in women with polycystic ovary syndrome (PCOS), with a prevalence estimated at 65–75%. Hirsutism in PCOS is associated with both androgen excess and individual response of the pilosebaceous unit to androgens. The modified Ferriman–Gallwey (mFG) scoring system has been widely used in clinical practice to visually score excessive terminal hair, thus standardizing hirsutism evaluation and facilitating data comparison. Although a universal mFG score cutoff would be useful for comparisons, ethnic variations, as well as skin type and other factors, should be considered when evaluating hirsutism in distinct populations. In turn, androgen levels, measured by conventional techniques, have been shown to correlate poorly with the severity of hirsutism. Indeed, while most women with PCOS and hirsutism also have higher than reference values for serum androgen levels, some of them may not present with biochemical hyperandrogenism, representing a challenge to the diagnosis of PCOS. In this article, we critically review this not uncommon condition in women with PCOS presenting with hirsutism but normal androgen levels.

1. Introduction

Hirsutism is defined as an abnormal amount of terminal hair in a male pattern distribution in women and is the main manifestation of hyperandrogenism in women with polycystic ovary syndrome (PCOS). Acne and female pattern hair loss (FPHL) are also clinical manifestations of hyperandrogenism, although mild acne and FPHL are not recommended as diagnostic criteria in adolescents due to the paucity of data in this population, with progressive hirsutism remaining the primary marker of hyperandrogenism [1].

In response to increased androgen levels at puberty, vellus hair follicles in specific areas develop into terminal hair (larger, curlier, and darker, hence more visible), becoming sexual-hair follicles [2]. While pubic and axillary hair are quite sensitive to small amounts of androgens, other areas may need higher androgen concentration for follicle terminalization [3]. Free testosterone is the main active portion of plasma testosterone and is responsible for this action [4].

The broad and heterogeneous clinical expression of PCOS gave rise to the perception that no single criterion should be mandatory for the diagnosis of PCOS, which resulted in

the 2003 Rotterdam diagnostic criteria. According to that consensus, PCOS should be diagnosed when at least two of the following criteria are present: ovulatory dysfunction (oligo- or amenorrhea), hyperandrogenism (either biochemical or clinical), and polycystic ovarian morphology (follicle number per ovary of ≥ 20 and/or an ovarian volume ≥ 10 mL on either ovary, preferably with an endovaginal ultrasound) [1,5,6], excluding other related or mimicking disorders. The Rotterdam criteria for defining PCOS were endorsed by the US National Institutes of Health (NIH) in 2012 (<https://prevention.nih.gov/research-priorities/research-needs-and-gaps/pathways-prevention/evidence-based-methodology-workshop-polycystic-ovary-syndrome-pcos> (accessed on 21 June 2022)) and by the International Guideline on PCOS in 2018, based on the best available evidence [1] (Expert Panel from a NIH Evidence-Based Methodology Workshop on PCOS, December 2012). Indeed, while most women with PCOS and hirsutism also have higher than the reference values for serum androgen levels, some of them may not present with biochemical hyperandrogenism, representing a challenge for the diagnosis of PCOS. In this article, we critically review this not uncommon condition in women with PCOS presenting with hirsutism but normal androgen levels.

2. Hirsutism and Hair Follicle Cycling

Hirsutism is defined as the presence of terminal hair of the female body in male pattern. The male sexual pattern is observed in androgen-sensitive anatomic sites that include the face, chest, breast areola, linea alba, lower back, buttocks, inner thighs, and external genitalia [7,8]. While in the general population, hirsutism affects 4–11% of women, in PCOS, its prevalence is estimated at 65–75% [9] and severity varies according to the degree of androgen excess and individual variability in the sensitivity of the pilosebaceous unit to androgens [10,11].

Hair follicles are small organs formed by the interaction between epidermis and dermis and are important skin appendages. They exhibit a periodic growth cycle that occurs continuously throughout the human lifespan and have high regenerative capacity. These characteristics are due to the presence of many stem cell populations in the hair follicle, and the activity of these stem cells and growth of hair follicles are highly regulated by various signaling pathways [12]. Moreover, hair growth is affected by many factors, such as age, environment, and health status, which can influence the development of hair follicle tumors, alopecia areata, and other related diseases, such as hirsutism [13].

In humans, there are three types of hair: lanugo, vellus, and terminal hair. Lanugo is the very fine hair that covers the fetal body and disappears during the first weeks of life. Vellus hair is very short, fine, and usually non-pigmented, whereas terminal hair is longer, thick, and pigmented. In women, terminal hair is found mostly in such areas as the eyebrows, eyelashes, scalp, axilla, and pubis. Less commonly, women may also have terminal hair in areas of the so-called male sexual pattern. Hormonal influence may alter the pattern of hair distribution in women, leading to excessive hair growth [11,13].

The hair follicle cycle is divided into three stages named anagen, catagen, and telogen, which characterize the perpetual cycle of growth, involution, and rest, respectively. The anagen stage is the most active period of hair follicle growth, when the hair grows rapidly and forms a complete hair shaft. Epithelial cell differentiation and hair pigmentation occur during this stage. The duration of the anagen stage determines hair length and is associated with the continuous proliferation and differentiation of stromal cells at the base of hair follicles [11,13,14]. Moreover, there is substantial variation in anagen duration according to body region: up to 6 years in the scalp, 1 to 3 months in the arms, 4 to 6 months in the legs, and 1 to 2 months in the thighs. Approximately 85% to 90% of all scalp hair is in the anagen stage at any given moment. This figure changes according to the body region, age, and possibly gender. In the arms and legs, approximately 46% and 58% of all hair, respectively, is always in the anagen stage [11]. When hair follicles enter the catagen stage, hair usually stops growing and, at the end of this phase, the hair follicles have atrophied. Therefore, the catagen stage starts when the supply of matrix cells declines, leading to a

slowdown in the differentiation of the hair shaft and the inner root sheath (apoptosis-driven regression) [13,14]. During catagen, hair follicle degeneration is highly regulated, and a large number of keratinocytes from the hair follicle begin to undergo programmed death. At this stage, melanin production in hair follicles stops and melanin-containing cells in some hair follicles also begin to undergo apoptosis [13]. After regression, the hair follicle enters the telogen stage, recognized as a resting phase. This stage is characterized by low biological activity of the follicle and a drop in hair shaft. Telogen duration changes according to body region: 2 to 4 months in the scalp, 2 and a half months in the chest, 2 to 4 months in the arms, and 3 to 6 months in the legs [11,13,14]. The follicle remains in the telogen stage until it is reactivated. At this point, the expression and activity of the relevant regulatory factors in the hair follicle controlling its cyclical growth will be significantly enhanced to prepare for the beginning of the next anagen [11,13,14].

3. Actions and Metabolism of Androgens in the Hair Follicle

The importance of androgens for hair growth in humans was first established by Hamilton and colleagues in the 1950s [15], with observations that castration before puberty prevented the development of beard and axillary hair, whereas castration after puberty led to the atrophy of beard and axillary hair. In addition, patients with androgen insensitivity do not have pubic or axillary hair. Since then, androgens have been shown to increase hair follicle size in different body regions, hair diameter, and the proportion of time hair remains in the anagen stage [16]. The conversion of vellus to terminal hairs is mainly stimulated by androgens, through the prolongation of the anagen stage. Successive hair cycles and longer anagen duration promote an increase in follicle size. These larger follicles produce longer, thicker hair in androgen-dependent body areas. For this reason, androgen excess-related conditions, such as PCOS, are often associated with hirsutism [11,17].

It is important to note that the occurrence and severity of hirsutism are also associated with the sensitivity of hair follicles to androgens. In fact, not only do hair follicles respond to androgens, broadly expressing androgen receptors, but they also contain androgen-metabolizing enzymes that play a critical role in regulating the level of androgens in the hair follicle [11,17,18]. Main enzymes include cytochrome P450 aromatase, which converts testosterone and androstenedione to estrogens (17β -estradiol and estrone, respectively), type 2 17β -hydroxysteroid dehydrogenase (17β -HSD), which inactivates testosterone to androstenedione, and 5α -reductase, which converts testosterone to dihydrotestosterone (DHT). Therefore, altered expression of these enzymes may be associated with a greater or lesser androgenic activity in the hair follicle.

Previous studies have shown that the expression of the type 2 17β -HSD gene is lower in scalp hair follicles of women with hirsutism than of women without it but similar to that of men [19], and higher in the subumbilical region and arm skin [20]. These results suggest that type 2 17β -HSD may play a role in the development of hirsutism, as the enzyme is responsible for inactivating more potent sex steroids (such as testosterone) by oxidation reactions [19]. Other gene expression analyses using 5α -reductase confirmed the presence of isotype 1 on the vertex of the scalp in women, but there was no significant difference in the expression patterns of women with or without hirsutism [21]. No correlation was found between 5α -reductase type 1 and 2 gene expression in dermal papillae from the lower abdominal region and severity of hirsutism [22]. In turn, variants in the gene encoding 5α -reductase type 1 were associated with hirsutism in women with PCOS [23]. In previous studies, we found no associations between 17β -HSD or aromatase gene variants and the severity of hirsutism in women with PCOS [24,25] (Figure 1).

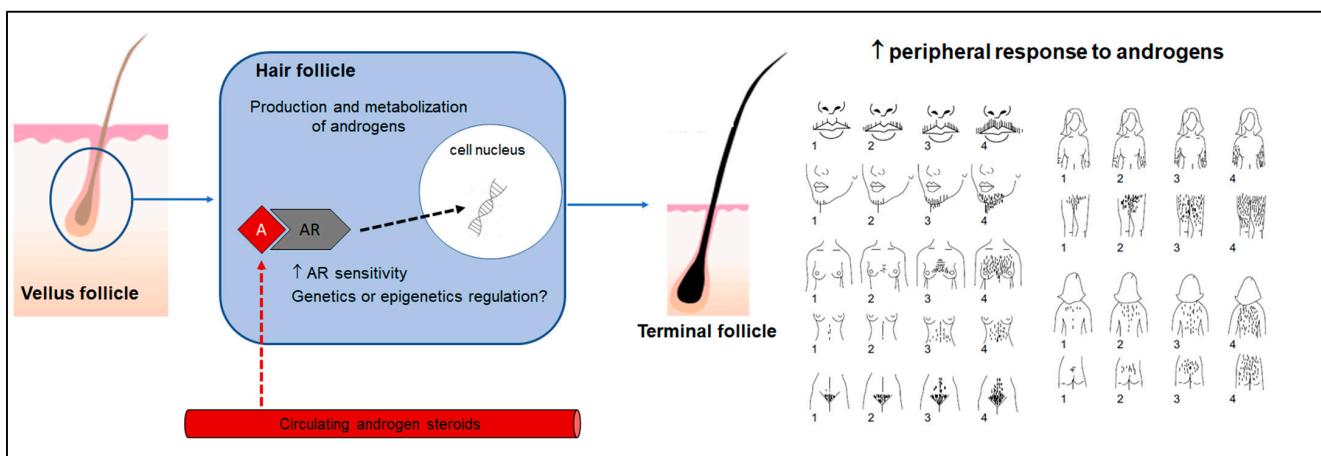

Figure 1. Role of androgens in the hair follicle and its peripheral response. A: androgens; AR: androgen receptor; ↑ peripheral response to androgens is expressed graphically by the modified Ferriman–Gallwey scale.

4. Molecular and Genetic Regulation of Hair Follicle

Different molecular signaling pathways are involved in the control of hair follicle growth and cycling [13]. MicroRNAs and gene variants in the androgen receptor gene appear to be promising for understanding the pathophysiology of hirsutism. MicroRNAs can contribute to the regulation of hair follicle morphogenesis and regeneration [13,14]. Shorter CAG repeat polymorphisms of the androgen receptor gene may be associated with increased activity of the receptor, leading to PCOS and hirsutism [26]. However, while some studies have shown a negative association between CAG repeat lengths and the prevalence of hyperandrogenic states, such as PCOS [27–31], or more severe clinical hyperandrogenism, such as hirsutism in women with PCOS [32], meta-analyses of studies correlating CAG repeat lengths with PCOS [33,34] and data in hirsute women with and without hyperandrogenemia [35,36] do not confirm this association. Therefore, many questions remain unanswered regarding the precise mechanisms underlying androgen/androgen receptor signaling pathways.

5. Scoring Hirsutism in the Context of PCOS

Although hirsutism reflects androgen action in the hair follicle, local factors, sensitivity to androgen, duration of exposure and local conversion of testosterone to a more potent androgen, DHT, by 5 α -reductase may be more important than plasma androgen levels [37,38]. Among local factors, an important contributor to hair follicle development and growth is the activity of L-ornithine decarboxylase, an enzyme that catalyzes the synthesis of polyamines implicated in cell migration, proliferation and differentiation of hair follicles, androgen receptor concentration, and 17 β -HSD and 5 α -reductase activities [3]. Most women with androgen levels more than twice the upper limit of the reference range have some degree of hirsutism, but it has been demonstrated that androgen levels, measured by conventional techniques, correlate poorly with the severity of hirsutism [39]. Likewise, women may present with excessive body hair growth but normal plasma androgen levels. Because of these observations, the most used criteria for the diagnosis of PCOS consider the hyperandrogenism criterion as clinical and/or biochemical [1]. Clinical hyperandrogenism is still very important while defining hyperandrogenism for the PCOS diagnosis, especially in women with normal androgens.

The Ferriman–Gallwey (FG) scoring system has been widely used in clinical practice to visually score excessive terminal hair [40], thus standardizing hirsutism evaluation and facilitating data comparison. The modified FG (mFG) score evaluates hair growth in nine body areas. Hair growth is rated from 0 (no terminal hair) to 4 (male pattern hair) in each area, with scores of 1, 2, and 3 indicating intermediate levels of body hair growth,

for a maximum score of 36 (Figure 1). The original method had a cutoff of 5 to define hirsutism [41], which was increased to 8 in the mFG score, based on the original data published by Ferriman and Gallwey considering the 95th percentile [42]. In shaved areas, self-scoring can be clinically useful especially for follow-up, as it correlates only modestly with scoring by a trained observer [43].

Although a universal mFG score cutoff would be useful for comparisons, ethnic variations, as well as skin type and other factors, should be considered when evaluating hirsutism in distinct populations [44]. Importantly, the data reported by Ferriman and Gallwey were derived from women attending a northern London general medical outpatient clinic, a selected homogeneous population. Besides that, other factors, such as obesity and insulin resistance, are known to play a role in the phenotypic expression of PCOS, and its predisposition also varies in different ethnic backgrounds [45]. Indeed, the international evidence-based guideline for the assessment and management of PCOS, published in 2018, proposes to consider ethnic origin when evaluating mFG scores in different populations [1]. The Endocrine Society also suggests different cutoffs for the mFG score depending on ethnicity, as follows: United States and United Kingdom black or white women, ≥ 8 ; Mediterranean, Hispanic, and Middle Eastern women, ≥ 9 to ≥ 10 ; South American women, ≥ 6 ; and Asian women, a range of ≥ 2 for Han Chinese women to ≥ 7 for Southern Chinese women [46]. Subsequently, data from a systematic review comparing hirsutism in women with PCOS from populations of different ethnicities showed that, compared with white women, East Asian women were less hirsute, whereas Hispanic women, South Asian women and Middle Eastern women were more hirsute [47]. In another systematic review and meta-regression analysis, FG scores were presented according to their distribution in different countries [48]. However, few data are available on hirsutism in women with PCOS from Latin America. In this respect, Figure 2 shows a comprehensive distribution of mFG scores based on studies from different countries [49–87], which include available data from the database of a systematic review on Latin American women with PCOS that we have recently published [88]. Importantly, most studies come from referral populations, which may have influenced the difference in FG scoring between regions, according to ethnicities.

In addition to ethnicity, skin type might be of some relevance to the hirsutism evaluation. The Fitzpatrick scale classifies skin type according to susceptibility to sunburn and melanin production in response to sunlight: type I (always burns, never tans), type II (usually burns, tans minimally), type III (sometimes burns mildly, tans uniformly), type IV (burns minimally, always tans well), type V (very rarely burns, tans very easily), and type VI (never burns, never tans) [89]. A study evaluating hirsutism according to the Fitzpatrick classification in 341 women (276 patients meeting the Rotterdam criteria for PCOS) found a significant difference in total mFG score and prevalence of hirsutism between different Fitzpatrick groups. Patients in group 3 (skin types V and VI) had the highest mFG scores and prevalence of hirsutism, followed by group 2 (skin types III and IV) and group 1 (skin types I and II). For the most part, the variation in hirsutism among skin types was due to differences in truncal mFG scores [90].

Age should also be considered when evaluating hirsutism, since it is well known that both clinical and biochemical characteristics change with age in women with PCOS [91–94]. Androgen secretion from ovaries and adrenal glands may diminish as a function of aging, and hirsutism scores accompany this trend [94]. In fact, hyperandrogenism may partially resolve before menopause in women with PCOS [93]. Serum concentrations of sex hormones increase from the pre- to postmenarchal periods as well [95], and mild hair growth is frequently seen in the late stages of puberty and early adolescence and may persist for several years; therefore, the diagnosis of PCOS is often not made until adulthood, when endocrine and metabolic dysfunctions have been firmly established [1,93]. Hence, ethnic origin, skin type, age and associated comorbidities (e.g., obesity and insulin resistance) must be combined when evaluating hirsutism in women with PCOS. Further studies with

different populations may deeper clarify this issue and find practical ways to clinically evaluate hirsutism in distinct populations.

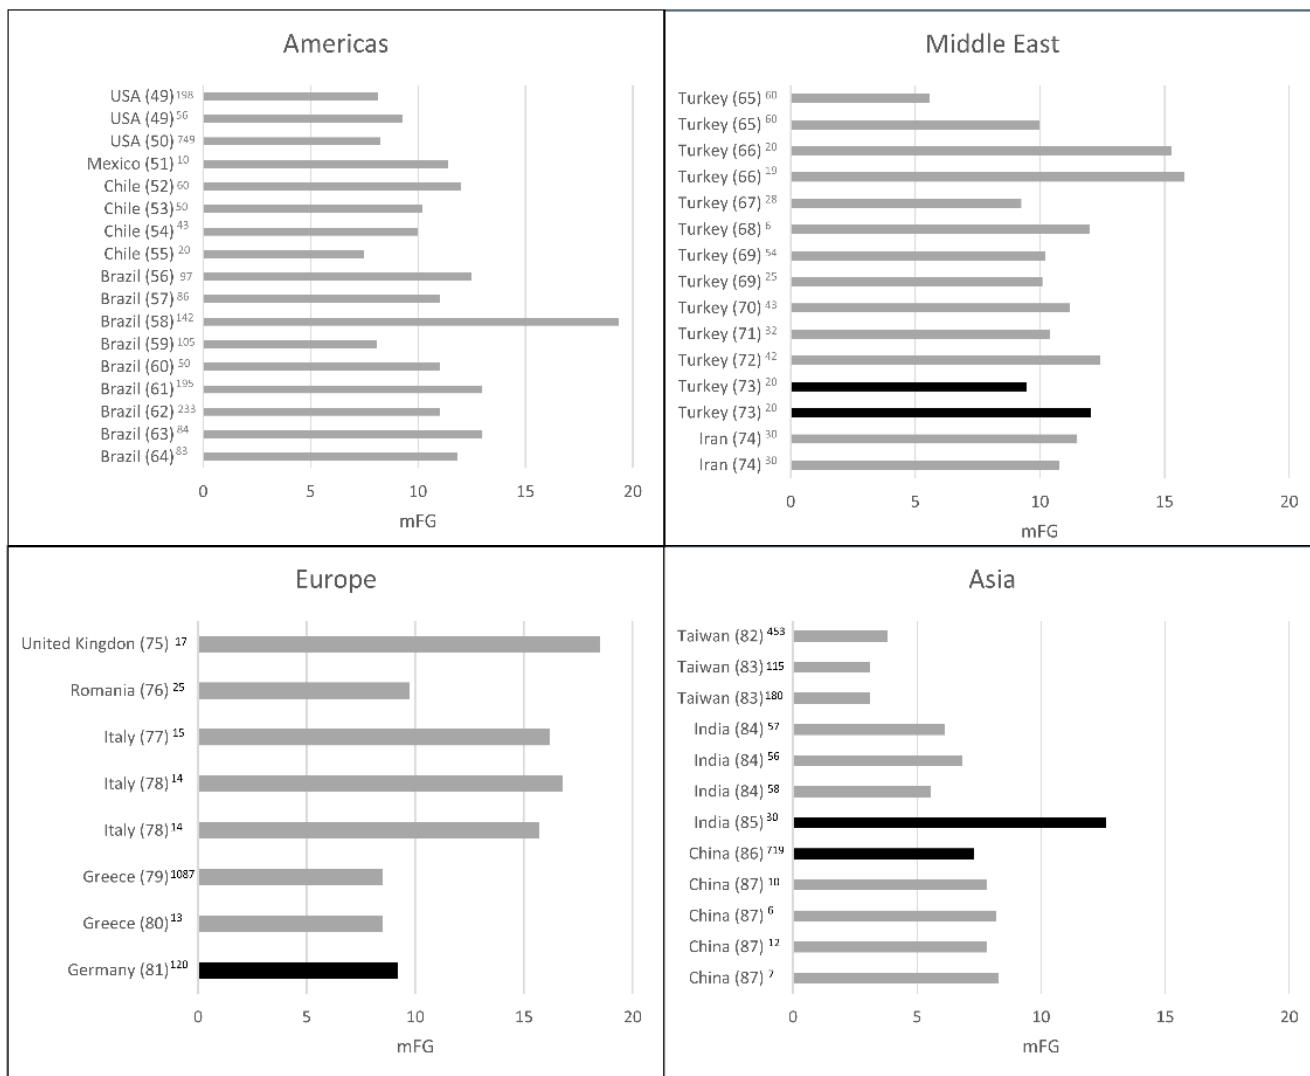

Figure 2. Hirsutism scores in women with polycystic ovary syndrome (PCOS) according to geographic distribution. PCOS was diagnosed by the Rotterdam, US National Institutes of Health (NIH), or Androgen Excess Society (AES) criteria. Black lines indicate unselected studies. Superscript numbers indicate sample size. mFG: modified Ferriman–Gallwey score.

6. Diagnosing PCOS: Clinical versus Biochemical Androgen Excess

Measurements of biochemical parameters of hyperandrogenism are very useful, particularly in patients without obvious signs of clinical hyperandrogenism, such as hirsutism, acne vulgaris, and FPHL [96]. Hirsutism has a multifactorial pathogenesis that is mainly affected by androgen levels, with the sensitivity of hair follicles to androgens also playing a role in this process. In fact, the correlation of biochemical hyperandrogenism with hirsutism severity was found not to be as significant as expected, suggesting that there may be other factors contributing to the mechanism described above. In vitro studies have shown that both insulin and insulin-like growth factor-1 may also have a dose-dependent effect on hair follicle growth [97,98]. In fact, sex hormone-binding globulin, a modulator of testosterone bioavailability, is suppressed by hyperinsulinemia resulting from insulin resistance. Therefore, not only biochemical hyperandrogenism, but also insulin resistance may contribute to the development of hirsutism [99]. Data from a large sample of Korean volunteers showed that the homeostasis model assessment of insulin resistance (HOMA-IR) was positively

associated with the FG score, even after adjustment for biochemical hyperandrogenism parameters [100]. Importantly, although within the reference range, patients with idiopathic hirsutism may have higher serum androgen levels and lower estradiol/testosterone ratio than healthy individuals, leading to relative hyperandrogenemia at the tissue level [101]. In addition, the response of the pilosebaceous unit to androgen varies considerably according to the skin area and between individuals, so not all patients with hirsutism have demonstrable hyperandrogenemia [102–106].

The biochemical assessment of sex steroids has important technical limitations. Androgen measurements in blood capture a moment in time, subject to the known pulsatility of these hormones [96]. Even in the setting of androgen excess, women usually show a slight increase in sex steroids, but the enzyme-linked immunosorbent or chemiluminescent assays used currently have low sensitivity and specificity in women. Indeed, the testosterone measurement may not be accurate at low levels (as expected in women), but liquid chromatography tandem-mass spectrometry, the most accurate method, is expensive and still not widely available [1,5]. Furthermore, serum androgen levels vary according to age, menstrual cycle day, and sampling time, but there is still no standardization based on these parameters [105]. Cross-reactivity between different steroids is another relevant issue related to the variability observed in androgen measurements in women [106]. In the clinical setting, only one-third of samples of patients with PCOS show abnormal testosterone, reaching 70% of samples for elevated serum concentration levels of free testosterone, the single most sensitive test for hyperandrogenemia [107]. Regarding other androgens, only 10% and 9% of patients with PCOS have isolated elevation of dehydroepiandrosterone sulfate (DHEAS) and androstenedione levels, respectively [108,109].

The concept of hyperandrogenism should be based primarily on clinical findings. Androgen measurements are not a substitute for clinical judgement, and it is particularly in patients without obvious signs of hyperandrogenism that biochemical evaluation is indispensable. Nonetheless, an abnormal scale of hirsutism associated with ovulatory dysfunction or ovarian morphological findings is sufficient for the diagnosis of PCOS, after the exclusion of related disorders as previously mentioned (96). The term idiopathic hirsutism should be applied only to hirsute women with normal ovulatory function and detectable normal androgen levels (testosterone, androstenedione, and DHEAS). In these cases, the cause of hair growth may be associated with abnormalities in peripheral androgen activity or increased sensitivity of the hair follicle [110].

7. Conclusions and Future Directions for Research

Several factors can potentially hinder the proper biochemical assessment of hyperandrogenism. Prominent among these are the questions of which androgens should be measured, which assay methods should be used, and how the reference ranges should be defined. Also of timely interest are the significant overlap of values obtained in women with PCOS and controls and the availability of and access to high-quality assays. Regarding clinical assessment, most patients with PCOS present with clinical features of hyperandrogenism, which are relatively inexpensive to assess and require only skilled vigilant clinicians. Both medical and cosmetic treatments of hirsutism have an impact on assessment.

Abstract

Purpose: This study aimed to evaluate the impact of a lifestyle modification program on menstrual irregularity among overweight or obese Women with polycystic ovarian syndrome. **Methods:** A quasi experimental research design was used to conduct this study on 82 women with polycystic ovarian syndrome at the Gynecology and Obesity clinics of Mansoura University Hospital, Egypt. Two groups were included; the study group received a lifestyle modification program for 48 weeks, while the control group was not subjected to this program. Three tools were used for data collection. The first was a structured questionnaire to assess the woman's general characteristics, anthropometric measurements, and menstrual pattern, the second was the Ferriman-Gallwey scale to assess the hirsutism score, while the third was 24-hours dietary recall to monitor food and drink intake. **Results:** After one year of lifestyle modification, the number of menstrual cycles significantly increased from 2.7 ± 1.6 to 6.9 ± 1.5 ($t=12.26$, $p<0.001$) in the study group compared to insignificant minor changes among the control group ($t= 0.69$, $p= 0.488$). Additionally, 58.5% were menstruating regularly compared to none in the control group ($\chi^2=33.93$, $p<0.001$). **Conclusion:** Participating in a lifestyle modification program was effective in reducing menstrual cycle's irregularity among overweight and obese women with PCOS. Thus, nurses need to be aware of and actively promote the benefits of lifestyle modification and supportive follow up for overweight/obese POCS women.

Keywords: Lifestyle modification, polycystic ovarian syndrome, menstrual cycle, overweight, obesity.

INTRODUCTION

Polycystic ovarian syndrome (PCOS) is one of the most common endocrine disorders; it affects 5-10% of women at reproductive age worldwide [1]. In Egypt, PCOS shows up to 26% of familial PCOS and 5.4% of women do not have a familial history [2]. Its hallmarks are biochemical and/or clinical hyperandrogenism in addition to chronic anovulation with subsequent menstrual disturbances such as oligo/amenorrhea [3].

Obesity, especially the truncal type, affects 17.2 % of Egyptian PCOS women [2]. It adversely influences the degree of associated insulin resistance, which in turn affects the androgen level; therefore, resulting in menstrual irregularity and hirsutism [4]. A previous study concluded that severe caloric restriction for weight reduction is associated with restoration of menstrual cycles [5]. However, long-term severe caloric restriction resulting in rapid weight loss, can lead to poor patient compliance; accordingly, the body gains its baseline weight within one year [6].

The increasing rates of obesity, among Egyptian population, are largely attributed to their lifestyles; including unhealthy dietary habits, like consuming the widely distributed junk, fast food coupled with increasing sedentary lifestyles, as it was reported that 63% of the Egyptian population at the age of twenty or more have sedentary lifestyles [7].

Recently, large studies investigated the impact of the lifestyle modification in PCOS women and suggested that modest weight loss, even as little as 5% from baseline body weight can positively affect hyperinsulinemia. As a result, it causes a decrease of androgens and normalization of menstrual cycles. Evidence supports the role of the healthcare providers in encouraging women with menstrual irregularities to change their lifestyle [8, 9].

Significance of the problem

PCOS has always been considered as a systemic problem that carries many risks at the time of presentation and later in a woman's life. For example, infrequent menstrual flow carries 3-fold increased risks of endometrial hyperplasia and endometrial carcinoma [10]. This stimulates the current study to evaluate the impact of a lifestyle modification program on menstrual irregularity among overweight or obese Women with polycystic ovarian syndrome, where Egyptian studies which investigated this topic are so limited.

1. Purpose of the study

The purpose of this study was to evaluate the impact of a lifestyle modification program on menstrual irregularity among overweight or obese Women with polycystic ovarian syndrome.

2. Hypothesis of the study

Overweight or obese women with PCOS who participate in a lifestyle modification program will experience less menstrual irregularity than those who do not participate.

METHODS

1. Study design and setting

This was designed as a quasi-experimental study. It was conducted at the obesity outpatient clinic of Rheumatology department in collaboration with the gynecology outpatient clinic of Obstetrics and Gynecology department at Mansoura University Hospitals, Egypt.

2. Sampling

A convenience sample of single women who had attended the study settings from January to August 2012, were eligible to participate in this study if they are: 1) diagnosed with PCOS based on the presence of menstrual cycle disturbances after ≥ 2 years of menarche; either in the form of oligomenorrhea (i.e. fewer than six menstrual cycles during the previous year), or amenorrhea (i.e. no menstruation for ≥ 6 months), and features of androgen excess such as hirsutism and acne (hirsutism based on the Ferriman-Gallwey score ≥ 8 after two weeks of omitting management of excessive hair) [11], 2) overweight or obese women (i.e. with a BMI of 25.0-29.9 or ≥ 30.0 respectively) [12], and 3) free from any serious medical disease requiring medical supervision and not on medical treatment known to cause menstrual disturbances.

Recruitment and group assignment

This study was comprised of a total sample of 82 clients based on visiting the study setting during the assigned study period. Each eligible client was consecutively allocated either to study or control group according to her attendance; giving two equal groups by the end of the study period. Accordingly, the study group comprised a total number of 41 clients and similarly the control group. During the study period,

five women dropped from the study group because they did not comply with the minimum number of follow-up interviews ($n=10$), and three were lost from the control group; two of them did not comply with the minimum number of follow-up interviews, while one was lost due to marriage, and all were replaced with the next potential candidates. The flowchart of the studied sample is presented in Figure 1.

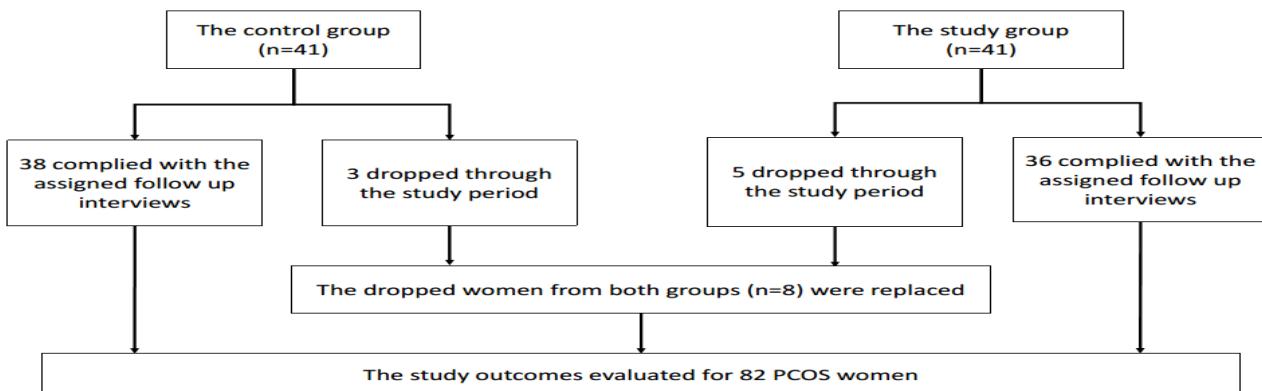

Figure (1): Flowchart of the sample

3. Measurement

Participants' general characteristics and study outcomes

A structured Questionnaire was developed by the researchers to assess the general characteristics of the participants and the study outcomes. It consists of three sections. The first section consisted of eight items on age, residence, education, and lifestyle habits (e.g., number of meals per day, components of meals, duration and form of exercise, duration of watching television per day). The second section included the menstrual history such as age of menarche, cycle length, duration of menstrual blood flow, and number and rhythm of menstrual cycles through the previous year. All the items of this section were self-reported by the clients. Moreover, the third section included anthropometrics measurements; specifically body weight, waist circumference, and BMI, those were measured by the nurse researcher.

Body weight was obtained using the same weighting scale and recorded to the nearest 0.1kg, height was measured with a fixed stadiometer and recorded to the nearest 0.5cm; while participants in bare feet, and waist circumference was measured during expiration according to the National Health and Nutrition Examination Survey anthropometric manual [13] and recorded in centimeters to the nearest 0.1cm.

Hirsutism

The Ferriman-Gallwey scale [11] is a valid universal scoring system that was used to evaluate the degree of hair growth in nine key anatomic areas (i.e. lips, chin, hands and legs, breasts, abdomen, pubic area, lower and upper back). The degree of hirsutism of each area was scored using a 4-grade scale ranged from 0 to 4, where 0 represents no hair growth and 4 means a maximum hair growth. For each respondent the scores of the nine areas were summed up to obtain the Ferriman-Gallwey Hirsutism total score. From a maximum possible score of 36, a score of ≥ 8 indicates androgen excess [11]. To maintain reliability of the collected data, hirsutism score was assessed only by the nurse investigator. This assessment was performed in a separate room and the client's privacy was strictly maintained.

Food and drink intake

A 24-hour dietary recall was used to describe the food and drink intake. It is a standardized design consisting of 3 items on a single sheet (i.e., time, quantity, and type of intake) [14]. It is a valid clinical tool filled in by every participant daily for the week preceding the clinic visit to be checked by the investigators on the interview day. Examples of type of food and drink include: At 7 am, 1/4 slice of brown bread, 5 spoons of light cheese, and a cup of tea with one spoon of sugar were consumed. At 2 pm, a chicken chest, 5 spoons green salad, two spoons of rice, and a glass of orange juice. At 7 pm, one cup of yoghurt and two apples.

4. The lifestyle modification program

The lifestyle modification program was designed as a comprehensive approach based on counseling the subjects about energy-restricted diet, eating behaviors, and physical activity. Energy-restricted diet depends on reducing the total caloric needs/day by 500 calories. The total caloric needs per day were calculated for every participant by means of the Harris-Benedict equation based on her activity level [15]. For the study group subjects, the daily caloric needs ranged from 1200-1800 calories that was divided on small frequent meals with 10-15 % from proteins, 30-35 % from fat and 55% from carbohydrates of low glycemic index [16].

Along with the energy-restricted diet, healthy balanced diet was recommended by asking the participants to consume 4-5 servings of fresh vegetables and fruits, whole grains, food rich with fibers content, daily drink a minimum of 1.5 liter of water and take a daily multivitamin supplement as ordered by the dietitian. Conversely, they were instructed to decrease food rich with saturated fats (e.g., meats, fried food), and fast food and caffeine were discouraged as a part of the healthy diet plan.

Additionally, participants were instructed on modifying their eating behaviors (e.g. avoid eating during the times of watching television or immediately before bedtime, avoid drinking through/immediately after meals; rather drink before meals time). Moreover, at least 150 minutes of moderate-intensity activity or 75 minutes of vigorous-intensity activity per week were recommended [17, 18]. The lifestyle modification program contents were prepared by the research team and revised by an interdisciplinary team of dietitian, exercise physiologist and a specialist of maternity and gynecology nursing before providing it to the participants.

5. Research process

The process of this research was carried out via three phases; initial assessment, implementation of the program, follows up visits, and outcomes evaluation.

1) Initial assessment

At the baseline and before the group assignment, gynecologic history was obtained to ensure women eligibility for participation; thereafter the aim and approach of this research were explained to the clients in order to get their informed consent. Full general and clinical assessment for anthropometrics was performed by the nurse investigator, the hirsutism score was assessed, menstrual history which describes the menstrual cycle characteristics during the year preceding enrollment was obtained and recorded as baseline data.

2) Implementation of the program

I. Study group

A lifestyle modifications program was provided to the study group through two educational sessions in small groups ($n=3-5$) on two consecutive days at the Obesity Clinic with duration of approximately 45-60 minutes for each session. PCOS

definition, symptoms, and complications, in addition to the importance of weight reduction were discussed during the 1st session, while the 2nd session concerned with the permitted, forbidden food, eating behaviors, and different forms of physical activity. Both sessions were presented in a power point presentation by the nurse researcher. The study group was provided with an instructional brochure to be used as a guide for the permitted and forbidden foods and behaviors. They were asked to accurately record their dietary intake daily for the week preceding the assigned clinic visit; using a 24-hour dietary recall.

II. Control group

On the other hand, the control group was not subjected to the lifestyle modification program.

3) Follow up schedule and Outcomes evaluation

Initially for the 1st two months of enrollment, participants were followed through biweekly face-to-face interview that the nurse investigator went along with a registered dietitian at the Obesity clinic to monitor the participant's compliance with the lifestyle modification program. Then, they moved on monthly face-to-face interviews, giving a total number of fifteen face-to-face individual interviews by end of the study, including the initial interview. A telephone conversation with a pre assigned researcher was made to the client who found a difficulty in attending one or two biweekly/monthly interview. Attending the two educational sessions and a minimum number of ten follows up face-to-face/telephone interviews was considered as sufficient participation to stay in the study.

Each interview took about 10-15 minutes. During this interview the investigators had to monitor the participant's compliance with the program by way of reviewing the 24-hours dietary recalls for the one week preceding the assigned interview. As well as, inquiring the clients verbally about the type and duration of performed exercise and their eating behavior during the same period. All the outcome measures including, anthropometric measures, menstrual history, and the hirsutism score were recorded at the initial assessment and were recorded again after one year of enrollment.

6. Ethical Considerations

This study was approved by the Ethics Committee in Faculty of Nursing and Faculty of Medicine, Mansoura University, Egypt. Informed consent was obtained from each participant after clarifying the study aim and approach. Participants were assured about the confidentiality of their data as well they were informed that they have the right to withdraw at any time. Additionally, at the end of the study, clients who had been allocated to the control group were invited to be involved in the same lifestyle modification program, but separate from the intervention group, so that they were not disadvantaged.

7. Data analysis

All statistical analyses were performed using SPSS for windows version 17.0 (SPSS, Chicago, IL). Continuous data were obtained at baseline and after 12 months follow-up period were expressed as mean \pm SD and compared pre- and post-test scores in each group using paired t test. Categorical data were expressed in numbers and percent and compared using the χ^2 test. The 95 % confidence intervals (CI) for the difference in means were calculated. Statistical significance was set at $p<0.05$.

RESULTS

1. General and Clinical Characteristics of the Groups

Table 1 reveals that the general characteristics of the two groups were similar at the baseline ($p >0.05$). BMI for the study and control groups were almost identical (33.1 \pm 1.6 and 33.4 \pm 1.9 respectively; $t= 0.77$, $p= 0.442$). Most of the study and control groups (90.2% and 92.7% respectively) were obese, while the minorities (9.8% and 7.3% respectively) were overweight. Mean number of menstrual cycles was almost similar for the study and control groups (2.7 \pm 1.6 and 2.5 \pm 1.3 respectively; $\chi^2= 0.62$, $p=0.536$). Around two thirds of the study and control groups (68.3% and 65.9% respectively) were amenorrhea. Differences observed between the two groups for waist circumference and hirsutism score were not statistically significant ($t= 0.27$, $p= 0.785$; and $t= 1.03$, $p= 0.305$ respectively).

2. Effects of Lifestyle Modification on Weight, BMI, Waist Circumference, and Hirsutism score

Table 2 shows that after one year of lifestyle modification, mean weight for the study group significantly decreased by 7.4 kg reflecting a reduction of 8.7% from the baseline value ($t=5.27$ & $p<0.001$), compared to insignificant reduction in the control group by 2.5 kg reflecting a weight loss of 2.9% at end of the study ($t= 1.55$, $p= 0.125$). Similarly, among the study group BMI decreased by 2.89 ($t=7.45$, $p<0.001$), and waist circumference decreased by 8.3 cm at the end of the study ($t= 3.48$, $p=0.001$). On contrary, the changes reported in the control group were insignificant. Moreover, the hirsutism score was similar in the two groups at baseline, after one year of lifestyle modification the hirsutism score was significantly reduced in the study group by 4.2 ($t=3.65$, $p<0.001$) compared to insignificant decrease by 0.6 in the control group ($t= 0.51$, $p= 0.609$).

3. Effects of Lifestyle Modification on Menstrual Patterns

Figure 2 illustrates that the number of the menstrual cycles among the two groups did not differ significantly at baseline. It was significantly increased by 4.2 points from 2.7 ± 1.6 at baseline to 6.9 ± 1.5 after one year of lifestyle modification program in the study group ($t=12.26$, $p<0.001$), compared to insignificant change in the control group ($t=0.69$, $p= 0.488$).

Table 3 shows that no subjects in both groups had regular menses at baseline. After one year of lifestyle modification, 24 women (58.5%) in the study group were menstruating regularly compared to none in the control group. Among the study group, women who were amenorrhea and oligomenorrhea (31.7% and 68.3% respectively) were approximately halved at one year (12.2% and 29.3% respectively) with statistically significant differences ($\chi^2= 4.56$, $p= 0.033$ for amenorrhea; $\chi^2= 12.49$, $p< 0.001$ for oligomenorrhea), in contrast to the control group, which showed insignificant minor changes.

Table1. General and clinical characteristics of the study and control groups at baseline N=82

Variables	Study group	Control group	χ^2 or t test	P

DISCUSSION

The present study aimed to evaluate the impact of a lifestyle modification program on menstrual irregularity among overweight or obese Women with polycystic ovarian syndrome. This aim was achieved through the present study finding which revealed a significant decrease in menstrual cycle irregularities among the study group after one year of lifestyle modification. Accordingly, the study hypothesis was confirmed, "overweight or obese women with PCOS who participate in a lifestyle modification program experience less menstrual irregularity than those who do not participate."

This study finding is consistent with previous studies that investigated the impact of lifestyle modification on managing PCOS symptoms among adult women. Such studies concluded that lifestyle modification results in weight loss with subsequent improvement of menstrual cycle irregularities and androgen excess [19-22].

The present study showed that among the study group with 8.7% weight reduction from the baseline value, frequency of amenorrhea and oligomenorrhea was significantly decreased and led more than half of the participants to have regular menstruation after one year of lifestyle modification compared to none at baseline. Similar to the present study, a previous study had analyzed the impact of a comprehensive lifestyle modification program on menstrual irregularities among 59 obese German girls with PCOS. After one year of lifestyle modification the authors

dichotomized the studied group into successful weight loss group (n=26) and unsuccessful weight loss group (n=33) and reported a significant decrease in the prevalence of amenorrhea and oligomenorrhea from baseline (by 42% and 19%, respectively) among the successful weight loss group compared to insignificant decrease (by 6% and 3% respectively) among the unsuccessful weight loss group [23].

Also, Hoeger et al. [24] conducted a clinical trial in New York; over one year, to study the effect of intensive lifestyle intervention and/or metformin on menstrual events among 38 overweight or obese women with PCOS. They found a significant restoration of ovulation and menstrual events only when the lifestyle modifications were implemented along with the medical treatment.

Such agreement between the present study findings and the findings of the previously described two studies [23, 24] may be explained by the fact that insulin resistance is more likely to be associated with hyperinsulinemia, and it is evidenced that hyperinsulinemia acts as a leading cause of elevated androgen levels among PCOS women [25]. Based on that notion the researchers of the present study attributed the improvement of menstrual irregularities to the decrease in insulin resistance in the study group; that was evidenced by a significant reduction in the waist circumference at end of the study [26], causing a reduction in hyperinsulinemia, accordingly improving menstrual irregularity.

Also, the present study investigated the changes in the number of menstrual cycles over the study period and revealed a significant increase in the study group compared to insignificant changes in the control group. Interestingly the present study results agreed with the findings of Ornstein et al. [27]. They had conducted a pilot study in New York on 24 young adult/adolescent women with PCOS, aiming to investigate the effect of weight loss on menstrual function by assigning the participants randomly into low fat or low caloric diet. The authors had found a significant increase in the average menstrual cycles over the study period from 0.6 ± 0.6 pre-treatment to 1.6 ± 1.3 post-treatment ($p=0.003$), with a weight loss of 6.5% ($p < 0.001$) in both dietary regimens groups. Moreover, by dichotomizing the participants into successful weight

loss or unsuccessful weight loss groups, the authors [27] observed that women who successfully lost their weight were 3.4 times more likely to have improvement in their menstrual function compared to those who did not loss their weight ($P = 0.001$). Our study recommended ‘energy-restricted diet’ for the study group and there were no specific recommendations for the control, which makes direct comparison with Ornstein’s study difficult, but we also found that menstrual patterns improved with weight loss. The reported significant increase in the number of the menstrual cycles may be related to the decrease in the stimulation of ovarian androgen production as a result of the associated reduction in hyperinsulinemia [19].

Using the Ferriman-Gallwey score, hirsutism showed a significant decrease in the study group compared to insignificant changes among the control group. Such finding is congruent with the finding of a prospective intervention study [28] conducted in Ain Shams maternity hospital, Egypt. It investigated the effectiveness of lifestyle modification; specifically, dietary counseling and exercise on PCOS symptoms in 64 women in their reproductive age. The investigators had concluded that women with PCOS who attained weight reduction as a result of lifestyle modification had showed a significant improvement in total hirsutism score. Such agreement between our finding and the Egyptian study finding [28] may be related to the improvement of the androgen excess level as a result of lifestyle modification that results in a decrease in hirsutism score.

Conversely, the present study disagrees with Hoeger et al. [24], mentioned above, which did not find significant changes of hirsutism scores by lifestyle intervention and/or metformin use. Such disagreement may be explained by two rationales; firstly, it may be related to how Hoeger and his colleagues had evaluated the hirsutism score. As in the current study the researchers considered that most women with PCOS are using cosmetic methods to manage their hirsutism, thus the women enrolled in this study were instructed to omit the hair management for the two weeks preceding hirsutism evaluation, while in the Hoeger's study [24] the interval between the excessive hair management and assessing hirsutism score is not clear, whether it was the same, shorter, or longer time interval and whether clients continued to manage the

hirsutism or not. Secondly, it may be due to the younger age group of enrolled clients in the current study. All the participants were young (in mid-twenties, compared to the Hoeger's sample [24] who had a mean age of 29.4 ± 5.7 years), post-pubertal, single, and had variable degrees of hirsutism, reflecting the exposure to the excess androgen in a relative shorter period of life.

Two limitations were raised in this study. First, the investigators relied only on the waist circumference as an indicator of insulin resistance, rather relying on more specific measures such as fasting glucose, HDL cholesterol, triglycerides and blood pressure would have been advantageous to confirm the study findings. Second, the dietary intake was evaluated according to the 24-hours dietary recalls for the last week preceding the assigned interview; indicating lack of data about the other days of the preceding month; however it was not applicable to ask the woman to daily record her intake.

Considering PCOS as heterogeneous in nature with a wide range of symptoms; health care providers working in gynecology clinics need an in-depth understanding of its pathophysiology, diagnostic measures, and symptom management. This study and others stress nurses' and gynecologists' role to ensure patients receive adequate oral and written information on lifestyle modification to be of guidance for them.

CONCLUSION & RECOMMENDATIONS

Based on the study findings the researchers conclude that lifestyle modification results in a significant reduction of menstrual irregularity with 8.7% weight reduction from the baseline value. Such findings stimulate the following recommendations:

1. Nurses need to be aware of and actively promote the benefits of lifestyle modification and supportive follow up for overweight/obese PCOS women.
2. Future research with larger sample size at different institutions is recommended.

Summary Statement

What is already known about this topic?

Lifestyle modification for PCOS women has been found to be successful in weight loss and normalization of menstrual cycles. However, there is lack of studies that employed a control group to ensure the effect of lifestyle modification where these subjects might have lost weight without any intervention.

What does this paper add?

Using a quasi-experimental design, a multidisciplinary team approach offered support/counseling in a lifestyle modification intervention to overweight/obese PCOS women for 48 weeks and was effective in reducing irregularity of menstrual cycles.

Implications for practice, education and/or policy

It is important for nurses to be aware that young Egyptian women with PCOS may be reluctant to seek help, and to actively promote the benefits of lifestyle modification and supportive follow up for overweight/obese PCOS women.

► I. Introduction

A. Background and historical perspective

POLYCYSTIC ovary syndrome (PCOS) is an exceptionally common disorder of premenopausal women characterized by hyperandrogenism and chronic anovulation ([1](#), [2](#)). Its etiology remains unknown. Although there have been no specific population-based studies, a 5–10% prevalence of this disorder in women of reproductive age is probably a reasonable conservative estimate. This is based as an upper limit on studies of the prevalence of polycystic ovaries, which found that ~20% of self-selected normal women had polycystic ovary morphology on ovarian ultrasound ([3](#)). Many of these women had subtle endocrine abnormalities ([3](#)). The lower estimate is based on the reported 3% prevalence rate of secondary amenorrhea for 3 or more months ([4](#)) and the fact that up to ~75% of women with secondary amenorrhea will fulfill diagnostic criteria for PCOS ([5](#)). PCOS women can also have less profound disturbances in menstrual function ([1](#), [3](#), [6](#)).

Since the report by Burghen *et al.* ([7](#)) in 1980 that PCOS was associated with hyperinsulinemia, it has become clear that the syndrome has major metabolic as well as reproductive morbidities. The recognition of this association has also instigated extensive investigation of the relationship between insulin and gonadal function ([1](#), [8](#), [9](#), [10](#), [11](#)). This review will summarize our current understanding of insulin action in PCOS, address areas of controversy, and propose several hypotheses for this association. Abnormalities of steroidogenesis and gonadotropin release will not be discussed in detail; these changes have been reviewed recently by Ehrmann and colleagues ([12](#)) and by Crowley ([13](#)), respectively.

The association between a disorder of carbohydrate metabolism and hyperandrogenism was first described in 1921 by Achard and Thiers ([14](#)) and was called "the diabetes of bearded women (diabète des femmes à barbe)." The skin lesion, acanthosis nigricans, was reported to occur frequently in women with hyperandrogenism and diabetes mellitus by Kierland *et al.* ([15](#)) in 1947. Brown and Winkelmann ([16](#)) noted in 1968 that it was insulin-resistant diabetes mellitus, and a genetic basis was suggested by reports of

affected sisters (17), including a pair of identical twins who also had acromegaloid features (18). Several additional syndromes with distinctive phenotypic features, acanthosis nigricans, hyperandrogenism, and insulin-resistant diabetes mellitus have been identified (Table 1+). These include the lipoatrophic (total and partial) diabetes syndromes, leprechaunism (intrauterine growth retardation, gonadal enlargement, elfin facies, and failure to thrive), and Rabson-Mendenhall syndrome (unusual facies, pineal hypertrophy, dental precocity, thickened nails, and ovarian enlargement) (8, 19, 20).

Table 1. Syndromes of hyperandrogenism and hyperinsulinemia

Attention was focused on the association of hyperandrogenism, insulin resistance, and acanthosis nigricans in 1976 when Kahn and colleagues (21) described a distinct disorder affecting adolescent girls, which they designated the type A syndrome. These girls were virilized (*i.e.*, increased muscle bulk, clitoromegaly, temporal balding, deepening of the voice) and had extreme insulin resistance with diabetes mellitus as well as striking acanthosis nigricans. This group identified a second distinct extreme insulin resistance syndrome in postmenopausal women with acanthosis nigricans and features of autoimmune disease, which they termed the type B syndrome and determined that it was caused by endogenous antiinsulin receptor antibodies (22, 23). Subsequent studies have identified insulin receptor mutations as the cause of leprechaunism, Rabson-Mendenhall Syndrome, and some cases of type A syndrome (19, 23).

In 1980 Burghen and colleagues (7) reported that women with the common hyperandrogenic disorder, PCOS, had basal and glucose-stimulated hyperinsulinemia compared with weight-matched control women, suggesting the presence of insulin resistance. They noted significant positive linear correlations between insulin and androgen levels and suggested that this might have etiological significance. In the mid-1980s several groups noted that acanthosis nigricans occurred frequently in obese hyperandrogenic women (24, 25, 26, 27) (Fig. 1+). These women had hyperinsulinemia basally and during an oral glucose tolerance test, compared with appropriately age- and weight-matched control women. The presence of hyperinsulinemia in PCOS women, independent of obesity, was confirmed by a number of groups worldwide (28, 29, 30).

Figure 1. A woman with PCOS who has acanthosis nigricans, a cutaneous marker of insulin resistance (panel A). She also has severe hirsutism on her face and chest (panels B and C). [Reproduced from A. Dunaif *et al.*: *Obstet Gynecol* 66:545–552, 1985 (25) with permission from The American College of Obstetricians and Gynecologists.]

Our study (25) suggested that these women had typical PCOS, except for increased ovarian stromal hyperthecosis, which is diagnosed by finding islands of luteinized theca cells within the ovarian stroma (25). When this is very extensive, it is called hyperthecosis and is associated with more profound hyperandrogenism (31). Hughesdon (32) reported, however, that upon careful examination of ovaries from PCOS women, small islands of hyperthecosis were usually present. This morphological change was more extensive in insulin-resistant PCOS women, suggesting that hyperinsulinemia had an impact on ovarian morphology as well as on function (25) (Fig. 2•). This hypothesis has been further supported by the finding, in a subsequent study (33), of a positive correlation between hyperinsulinemia and ovarian stromal hyperthecosis.

Figure 2. Section of a polycystic ovary with multiple subcapsular follicular cysts and stromal hypertrophy (*left panel*). At higher power (x100) islands of luteinized theca cells are visible in the stroma (*right panel*). This morphological change is called stromal hyperthecosis and appears to be directly correlated with circulating insulin levels. [Figure is used with permission from A. Dunaif.]

B. Definition of PCOS

The current recommended diagnostic criteria for PCOS are hyperandrogenism and ovulatory dysfunction with the exclusion of specific disorders, such as nonclassic adrenal 21-hydroxylase deficiency, hyperprolactinemia, or androgen-secreting neoplasms (1) (Table 2). The polycystic ovary morphology is consistent with, but not essential for, the diagnosis of the *syndrome* (1, 3). Polycystic ovaries are defined on ultrasound by the presence of eight or more subcapsular follicular cysts ≤ 10 mm and increased ovarian stroma (2, 3). These changes, however, can be present in women who are entirely endocrinologically normal (2, 3). Thus, the ovarian morphological change must be distinguished from the endocrine *syndrome* of hyperandrogenism and anovulation.

Table 2. Diagnostic criteria for PCOS—% participants agreeing at 1990 NICHD PCOS Conference (1)

Gonadotropin-secretory changes, with a characteristic increase in LH relative to FSH release, have long been appreciated in PCOS (34, 35). Frequent (e.g., every 10 min), prolonged (12–24 h) serial blood sampling studies have revealed that there is a significant increase in the frequency and the amplitude of LH release with normal FSH release in PCOS (36, 37). The increased LH pulse frequency reflects an increase in GnRH release and suggests the presence of a hypothalamic defect in PCOS (13, 37). Other causes of hyperandrogenism, however, can result in similar gonadotropin-secretory changes, such as androgen-secreting neoplasms (38) or adrenal hyperandrogenism resulting from nonclassic 21-hydroxylase deficiency (39). Ovulatory women with the polycystic ovary morphology can have increased LH/FSH ratios (2). Because of the pulsatile nature of gonadotropin release, a single blood sample can fail to detect an increased LH/FSH ratio (40). This, as well as its lack of specificity, has led to the recommendation that LH/FSH ratios not be included in the diagnostic criteria for PCOS (1).

Other nomenclature has been proposed for the *syndrome*, e.g., chronic hyperandrogenic anovulation (CHA) (1). Many hyperandrogenic anovulatory women have significantly increased ovarian steroidogenic responses to stimulation with GnRH analogs that Rosenfield and colleagues (41) have termed functional ovarian hyperandrogenism (FOH). They have proposed this as an alternative name for PCOS (12). The majority of

women who have hyperandrogenemia and chronic anovulation will have polycystic ovary (PCO) on ultrasound and will have responses to GnRH analogs consistent with FOH (1, 2, 12) (Fig. 3*). Thus, the terms PCOS, FOH, and CHA define similar groups of women (Fig. 3*).

[View larger version \(70K\):](#)

[\[in this window\]](#)

[\[in a new window\]](#)

Figure 3. The majority of women with CHA will also have polycystic ovary morphology (PCO) and responses to GnRH analogs consistent with FOH. [Figure is used with permission from A. Dunaif.]

PCOS often has a menarchal age of onset characterized by a failure to establish a regular pattern of menses (42). Hirsutism may develop peripubertally or during adolescence (42) or it may be absent until the third decade of life (43). Seborrhea, acne, and alopecia are other common clinical signs of hyperandrogenism (44, 45). Some women never develop signs of androgen excess because of genetic differences in target tissue number and/or sensitivity to androgens (46). The clinical consequence of chronic anovulation is some form of menstrual irregularity ranging from oligomenorrhea (menses every 6 weeks to 6 months), amenorrhea, or dysfunctional uterine bleeding (2, 5, 6). Infertility may be the presenting symptom of the anovulation. Depending on the population studied, 16–80% of PCOS women are obese (47, 48, 49). Mild to moderate acanthosis nigricans is commonly present in obese PCOS women (25, 26, 27, 49, 50). A rapid progression of androgenic symptoms and/or true virilization (increased muscle bulk, clitoromegaly, temporal balding, and/or deepening of the voice) are rare in PCOS (2, 6, 42). PCOS women can occasionally have acromegaloïd features (44).

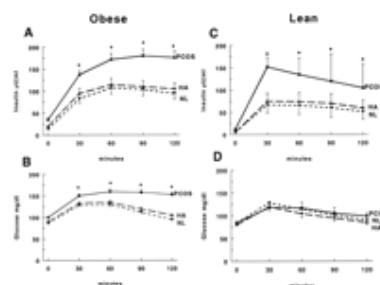

It is important to recognize that there is an inherent bias of ascertainment in studies of PCOS that constrains the assessment of the frequency of associated clinical and biochemical findings. Obviously, all women will have polycystic ovaries when this feature is an essential diagnostic criterion. Studies that use an increased LH/FSH ratio as a selection criterion will be biased toward finding increased pulsatile LH release when gonadotropin secretion is examined. The appropriate study would be a population-based one in which clinical and biochemical features were systematically examined in a defined population of women. Until such a study is performed, the prevalence of PCOS and frequency of associated findings will remain subject to debate.

► II. Insulin Action in PCOS

A. Glucose tolerance

Insulin resistance is an important defect in the pathogenesis of noninsulin-dependent diabetes mellitus (NIDDM) (51). Despite the fact that hyperinsulinemia, reflecting some degree of peripheral insulin resistance, was well recognized in PCOS by the mid-1980s (Fig. 4•), glucose tolerance was not systematically investigated until our study in 1987 (49). We found that obese PCOS women had significantly increased glucose levels during an oral glucose tolerance test compared with age- and weight-matched ovulatory hyperandrogenic (*i.e.*, elevated plasma androgen levels) and control women (Fig. 4•). Twenty percent of the obese PCOS women had impaired glucose tolerance or frank NIDDM by National Diabetes Data Group Criteria (49, 52) (Fig. 4•). The women studied ranged in age from 18–36 yr with a mean age of 27 yr for the obese PCOS women. There were no significant differences, however, in glucose levels during the oral glucose tolerance test in the nonobese PCOS women compared with age- and weight-matched control women (Fig. 4•).

[View larger version \(21K\):](#)

[\[in this window\]](#)

[\[in a new window\]](#)

Figure 4. Insulin (panels A and C) and glucose (panels B and D) responses basally and after a 40 g/m² oral glucose load in obese and lean PCOS women, ovulatory hyperandrogenic women (HA) women, and age- and weight-matched ovulatory control women. Insulin responses are significantly increased only in PCOS women, suggesting that hyperinsulinemia is a unique feature of PCOS and not hyperandrogenic states in general (panels A and B). Glucose responses are

significantly increased only in obese PCOS women (C), and ~20% of obese PCOS women have impaired glucose tolerance or NIDDM using National Diabetes Data Group Criteria (52). [Derived from Ref. 49.]

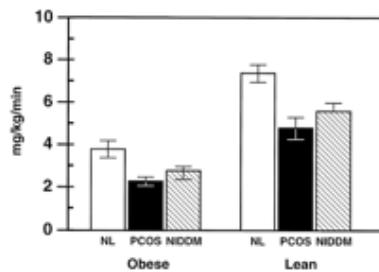

A subsequent study in postmenopausal women with a history of PCOS found a significantly increased prevalence of NIDDM as well as of hypertension (see below) (53). We have continued to find prevalence rates of glucose intolerance as high as ~40% in obese PCOS women when the less stringent World Health Organization (WHO) criteria are used (49, 52, 54, 55, 56, 57). The majority of affected women are in their third and fourth decade of life, but we and others (58) have encountered PCOS adolescents with impaired glucose tolerance or NIDDM. These prevalence rates of 20–40% are substantially above prevalence rates for glucose intolerance reported in population-based studies in women of this age (5.3% by National Diabetes Data Group criteria and 10.3% by WHO criteria in women aged 20–44 yr) (59). We have found that the prevalence of glucose intolerance is significantly higher in obese PCOS women (~30%) than in concurrently studied age-, ethnicity-, and weight-matched ovulatory control women (~10%) (48). In contrast, we have found that nonobese PCOS women have impaired glucose tolerance only occasionally, consistent with the synergistic negative effect of obesity and PCOS on glucose tolerance (54, 55). Finally, based on the prevalence of glucose intolerance in women (59), the prevalence of glucose intolerance in PCOS (49), and on a conservative estimate of the prevalence of PCOS (~5%), it can be extrapolated that PCOS-related insulin resistance contributes to approximately 10% of cases of glucose intolerance in premenopausal women. The study in postmenopausal women with a history of PCOS found a 15% prevalence of NIDDM (53), consistent with our extrapolated prevalence estimates. It is thus clear that PCOS is a major risk factor for NIDDM in women, regardless of age.

B. Insulin action *in vivo* in PCOS

Although insulin has a number of actions, in addition to those regulating glucose metabolism, such as inhibition of lipolysis and stimulation of amino acid transport (51), the effects of insulin on glucose metabolism are usually examined in studies of insulin resistance (60). This can be studied quantitatively in humans with the euglycemic glucose clamp technique: a desired dose of insulin is administered and euglycemia is maintained by a simultaneous variable glucose infusion whose rate is adjusted based on frequent arterialized blood glucose determinations and a negative feedback principle (60, 61, 62). At steady state, the amount of glucose that is infused equals the amount of glucose taken up by the peripheral tissues and can be used as a measure of peripheral sensitivity to insulin, known as insulin-mediated glucose disposal (IMGD) or M (61, 62). The suppression of hepatic glucose production by insulin can be assessed by the use of a simultaneous infusion of isotopically labeled glucose. Insulin-mediated glucose disposal occurs only in muscle (skeletal and cardiac) and in fat; muscle accounts for about 85% of this (60).

Euglycemic glucose clamp studies have demonstrated significant and substantial decreases in insulin-mediated glucose disposal in PCOS (54, 55) (Fig. 5•). This decrease (~35–40%) is of a similar magnitude to that seen in NIDDM (Fig. 5•). Obesity (fat mass *per se*), body fat location (upper vs. lower body, *e.g.*, waist to hip girth ratio), and muscle mass all have important independent effects on insulin sensitivity (63, 64, 65, 66). Alterations in any of these parameters could potentially contribute to insulin

resistance in PCOS. PCOS women have an increased prevalence of obesity ([6](#), [47](#)), and women with upper, as opposed to lower body, obesity have an increased frequency of hyperandrogenism ([66](#)). Since muscle is the major site of insulin-mediated glucose use ([60](#)) and androgens can increase muscle mass ([67](#)), potential androgen-mediated changes in lean body (primarily muscle) mass must also be controlled for in PCOS ([54](#), [55](#)). Studies in which body composition, assessed by the most precise available method (hydrostatic weighing), has been matched to normal control women, and in which lean PCOS women, who had body composition and waist to hip girth ratios similar to controls, were studied, have confirmed that PCOS women are insulin resistant, independent of those potentially confounding parameters ([1](#), [55](#), [68](#)). The impact of hyperandrogenism on insulin sensitivity is discussed below, but studies in cultured cells have confirmed the impression from these *in vivo* studies that an intrinsic defect in insulin action is present in PCOS ([69](#)).

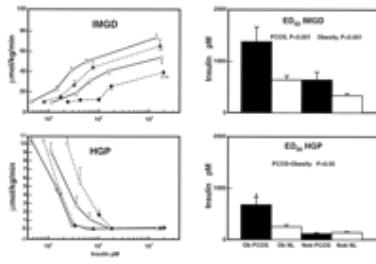

[View larger version \(22K\):](#)

[\[in this window\]](#)

[\[in a new window\]](#)

Figure 5. Insulin-mediated glucose disposal at steady-state insulin levels of ~600 pmol/liter (~100 μ U/ml) is decreased by 35–40% in PCOS women compared with age- and weight-matched control women. This decrease is similar in magnitude to that seen in NIDDM. [Figure is used with permission from A. **Dunaif**.]

Basal hepatic glucose production and the ED₅₀ value of insulin for suppression of hepatic glucose production are significantly increased only in obese PCOS women ([54](#), [55](#)) (Fig. 6•). This synergistic negative effect of obesity and PCOS on hepatic glucose production is an important factor in the pathogenesis of glucose intolerance ([49](#), [54](#), [55](#), [70](#)). This is analogous to NIDDM in general where defects in insulin action, presumably genetic, synergize with environmentally induced insulin resistance, primarily obesity-related, to produce glucose intolerance ([51](#), [60](#)). Sequential multiple-insulin-dose euglycemic clamp studies have indicated that the ED₅₀ insulin for glucose uptake is significantly increased, and that maximal rates of glucose disposal are significantly decreased in lean and in obese PCOS women ([55](#)) (Fig. 6•). It appears, however, that body fat has a more pronounced negative effect on insulin sensitivity in women with PCOS ([68](#), [71](#)).

[View larger version \(25K\):](#)

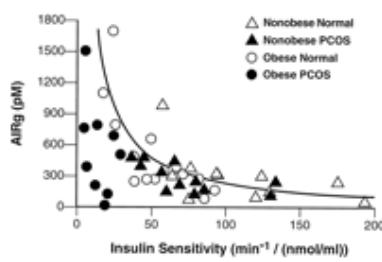

[\[in this window\]](#)

[\[in a new window\]](#)

Figure 6. Parameters of *in vivo* insulin action during sequential multiple-dose euglycemic glucose clamp studies in nonobese PCOS women (\blacktriangle , Nob PCOS); nonobese normal women (\triangle , Nob NL); obese PCOS women (\bullet , Ob PCOS); and obese normal women (\circ , Ob NL). The maximal response in the dose-response curves (*top left*) for insulin-mediated glucose disposal (IMGD) is significantly decreased in obesity ($*P < 0.001$) and in PCOS ($**P < 0.01$). The ED₅₀ insulin IMDG is significantly increased in PCOS women ($P < 0.001$) and in obese women ($P < 0.001$) (*top right*). Basal rates of hepatic glucose production (HGP) are not significantly different in the four groups (*bottom left*). The statistical interaction is significant between PCOS and obesity on the ED₅₀ insulin for suppression of HGP (*bottom right*), which is increased significantly in obese PCOS women ($*P < 0.001$) indicating a synergistic deleterious effect of obesity and PCOS on hepatic insulin sensitivity. [Reproduced with permission by A. Dunaif *et al. Diabetes* 41:1257–1266, 1992 (55).]

C. Insulin secretion in PCOS

In the presence of peripheral insulin resistance, pancreatic β -cell insulin secretion increases in a compensatory fashion. NIDDM develops when the compensatory increase in insulin levels is no longer sufficient to maintain euglycemia (72, 73). It is essential, therefore, to examine β -cell function in the context of peripheral insulin sensitivity. Under normal circumstances, this relationship is constant (72, 74) (Fig. 7*). β -Cell dysfunction is felt to be present for values falling below this hyperbolic curve (73, 74). This relationship can be quantitated as the product of insulin sensitivity and first-phase insulin release known as the disposition index (72).

[View larger version \(22K\):](#)

[\[in this window\]](#)

[\[in a new window\]](#)

Figure 7. The relationship between insulin sensitivity (SI) determined by frequently sampled intravenous glucose tolerance test and first-phase insulin secretion to an intravenous glucose load (AIRg). The majority of PCOS women fall below the normal curve determined in concurrently studied age- and weight-matched control women as well as normative data in the literature. [Derived from Ref. 57.]

Fasting hyperinsulinemia is present in obese PCOS women and this is, in part, secondary to increased basal insulin secretion rates (Fig. 4+ and Ref. 75). Insulin responses to an oral glucose load are increased in lean and obese PCOS women (Fig. 4+), but acute insulin responses to an intravenous glucose load (AIRg), first-phase insulin secretion, are similar to weight-matched control women (49, 57). When the relationship between insulin secretion and sensitivity is examined, lean and obese PCOS women fall below the relationship in weight-matched control women, and the disposition index is significantly decreased by PCOS as well as by obesity (57) (Fig. 7+). Further evidence for β -cell dysfunction in PCOS is provided by the elegant studies of Erhmann *et al.* (76), who have demonstrated defects in β -cell entrainment to an oscillatory glucose infusion and decreased meal-related insulin secretory responses (75). These defects are much more pronounced in PCOS women who have a first-degree relative with NIDDM, suggesting that such women may be at particularly high risk to develop glucose intolerance (76). There are reports of increased insulin secretion in PCOS, but these studies have not examined insulin secretion in the context of insulin sensitivity and/or have included women in whom the diagnosis was made on the basis of ovarian morphological changes rather than endocrine criteria (71, 77). In summary, the most compelling evidence suggests that β -cell dysfunction, in addition to insulin resistance, is a feature of PCOS. The ability to diagnose PCOS at the time of puberty will make possible prospective longitudinal studies of the ontogeny of these defects.

D. Insulin clearance in PCOS

Hyperinsulinemia can result from decreases in insulin clearance as well as from increased insulin secretion. Indeed, decreased insulin clearance is usually present in insulin-resistant states since insulin clearance is receptor-mediated, and acquired decreases in receptor number and/or function are often present in insulin resistance secondary to hyperinsulinemia and/or hyperglycemia (78, 79). Thus, PCOS would be expected to be associated with decreases in insulin clearance; however, relatively few studies have examined this question. Direct measurement of posthepatic insulin clearance during euglycemic clamp studies has not been abnormal in PCOS (54, 56). Circulating insulin to C-peptide molar ratios are increased in PCOS, suggesting decreased hepatic extraction of insulin, but such ratios also reflect insulin secretion (28, 80). Direct measurement of hepatic insulin clearance in non-PCOS hyperandrogenic women has found it to be decreased (81). The one study of this question in PCOS found decreased hepatic insulin extraction by model analysis of C-peptide levels (75). Therefore, in PCOS, hyperinsulinemia is probably the result of a combination of increased basal insulin secretion and decreased hepatic insulin clearance.

E. Cellular and molecular mechanisms of insulin resistance

1. *Molecular mechanisms of insulin action (Figs. 8+ and 9+).* Insulin acts on cells by binding to its cell surface receptor (51, 82, 83). The insulin receptor is a heterotetramer

made up of two α , β - dimers linked by disulfide bonds (84) (Fig. 8•). Each α , β -dimer is the product of one gene (85, 86). The α -subunit is extracellular and contains the ligand-binding domain whereas the β -subunit spans the membrane, and the cytoplasmic portion contains intrinsic protein tyrosine kinase activity, which is activated further by ligand-mediated autophosphorylation on specific tyrosine residues (87) (Fig. 8•). The insulin receptor belongs to a family of protein tyrosine kinase receptors that includes the insulin-like growth factor-I (IGF-I) receptor, with which it shares substantial sequence and structural homology, as well as the epidermal growth factor (EGF), fibroblast growth factor, platelet-derived growth factor, and colony-stimulating factor-1 receptors (88). A number of oncogene products are also protein tyrosine kinases (85, 89).

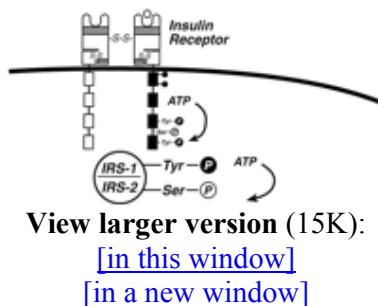

Figure 8. The insulin receptor is a heterotetramer consisting of two α , β -dimers linked by disulfide bonds. The α -subunit contains the ligand-binding site, and the β -subunit contains a ligand-activated tyrosine kinase. Tyrosine autophosphorylation increases the receptor's tyrosine kinase activity whereas serine phosphorylation inhibits it. [Adapted with permission from C. R. Kahn: *Diabetes* 43:1066–1084, 1994 (51).]

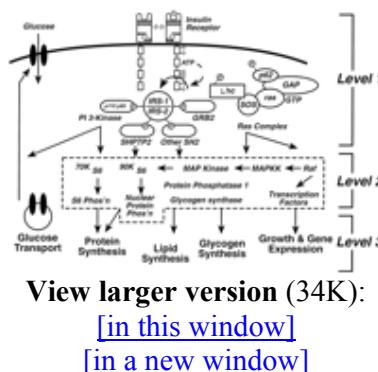

Figure 9. The tyrosine-phosphorylated insulin receptor phosphorylates intracellular substrates, such as insulin receptor substrate (IRS)-1 and IRS-2, initiating signal transduction and the pleiotropic actions of insulin. The activation of PI3-K (PI3-kinase) by tyrosine-phosphorylated IRS-1 appears to be the pathway for insulin-mediated glucose transport. The Ras-MAP kinase pathway appears to regulate cell

growth and glycogen synthesis. [Adapted with permission from C. R. Kahn: *Diabetes* 43:1066–1084, 1994 (51).]

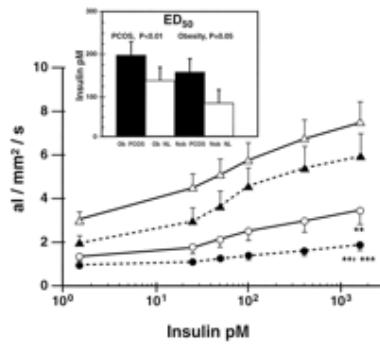

Ligand binding induces, probably via conformational changes, autophosphorylation of the insulin receptor on specific tyrosine residues and further activation of its intrinsic kinase activity (Fig. 8+) (90, 91, 92). The activated insulin receptor then tyrosine phosphorylates intracellular substrates to initiate signal transduction (Fig. 9+) (82). Over the last few years a number of these substrates have been characterized. The first was insulin receptor substrate-1 (IRS-1), which serves as a docking molecule for signaling and adaptor molecules (93, 94). The tyrosine-phosphorylated insulin receptor tyrosine phosphorylates IRS-1 on specific motifs, and these phosphorylated sites then bind signaling molecules, such as the SH2 domain of phosphatidylinositol 3-kinase (PI3-K), or the adaptor molecule, Nck (51, 82, 94). This leads to activation of downstream signaling pathways, such as that leading to insulin-mediated glucose transport, which appears to be modulated through the PI3-K signal cascade (82). More recently, insulin receptor substrate-2 (IRS-2), another substrate for the insulin receptor, has been identified (95, 96). Shc (an adaptor molecule) can also bind directly to the insulin receptor initiating signal transduction (82, 97).

Insulin has numerous target tissue actions, such as stimulation of glucose uptake, gene regulation, DNA synthesis, and amino acid uptake (51, 82). The mechanisms of insulin receptor signal specificity are currently a subject of intense investigation. It now appears that the Ras-Raf-MEK pathway is involved in the regulation of cell growth and metabolism whereas the PI3-K pathway is involved in glucose uptake (98, 99, 100, 101). The mechanisms by which the insulin signal is terminated remain incompletely understood. Receptor-mediated endocytosis and recycling are well known to occur and may be important to signal termination (83, 102). Serine phosphorylation has been shown to terminate signaling by the EGF receptor (103, 104), another tyrosine kinase growth factor receptor, and it can be shown under a variety of experimental conditions that insulin receptor serine phosphorylation decreases its tyrosine kinase activity (105, 106, 107, 108). It has been postulated that protein kinase C (PKC)-mediated serine phosphorylation of the insulin receptor is important in the pathogenesis of hyperglycemia-induced insulin resistance (102, 109). Recent evidence suggests that tumor necrosis factor- α (TNF- α)-mediated serine phosphorylation of IRS-1 inhibits insulin receptor signaling and is the mechanism of TNF- α -induced insulin resistance (110). Studies addressing this important question have been constrained by a lack of sensitive anti-phosphoserine antibodies. Identification of phosphoserine residues usually requires painstaking phosphoamino acid analysis of 32 P-labeled receptors (111). The use of fluorophore labeling of phosphoserine promises to provide a sensitive methodology for examining *in vivo* serine phosphorylation events (112).

In summary, insulin action is mediated through a ligand-activated tyrosine kinase receptor, similar to a number of other growth factors. A variety of phosphorylation-dephosphorylation signaling cascades are then activated, leading to the pleiotropic actions of insulin. The mechanisms of signal specificity and termination require further investigation.

2. Molecular insulin action defects in PCOS. Studies in adipocytes, a classic insulin target tissue, have failed to confirm earlier reports in blood cells of decreases in insulin receptor number and/or receptor affinity in PCOS (25, 26, 27, 113) when appropriately

weight-matched controls have been included. The one adipocyte study reporting a decrease in insulin receptor number used a control group consisting primarily of lean individuals (114). Studies of insulin action in isolated PCOS adipocytes have revealed marked decreases in insulin sensitivity together with less striking, but significant, decreases in maximal rates of insulin-stimulated glucose transport (55, 115) (Fig. 10+). There is evidence for decreases in adipocyte levels of adenosine in PCOS (116), but whether this is a primary defect or secondary to hyperinsulinemia is unclear. The decrease in maximal rates of adipocyte glucose uptake is secondary to a significant decrease in the abundance of GLUT4 glucose transporters (117). Similar defects are present in NIDDM and in obesity but are ameliorated by control of hyperglycemia and hyperinsulinemia as well as by weight reduction, suggesting acquired rather than intrinsic defects (65, 118, 119, 120). In contrast, in PCOS such defects can occur in the absence of obesity, glucose intolerance, or changes in waist to hip girth ratios (55, 117). Moreover, these abnormalities are not significantly correlated with sex hormone levels, suggesting that abnormalities of insulin action in PCOS may be intrinsic (55, 117).

Figure 10. Insulin-stimulated adipocyte U-[¹⁴C]glucose transport in nonobese PCOS women (\blacktriangle , Nob PCOS); nonobese normal women (\triangle , Nob NL); obese PCOS women (\bullet , Ob PCOS); and obese normal women (\circ , Ob NL). Basal rates of glucose transport are decreased significantly (*) in PCOS vs. normal women ($P < 0.01$) and in nonobese vs. obese women ($P < 0.001$). Maximal insulin-stimulated increments above basal are significantly decreased in PCOS vs. normal women (***, $P < 0.01$) and in obese vs. nonobese women (**, $P < 0.001$). The ED₅₀ insulin is increased significantly in PCOS vs. normal and in obese vs. nonobese women (inset). [Reproduced with permission from A. Dunaif *et al.*: *Diabetes* 41:1257–1266, 1992 (55).]

To further evaluate the postbinding defect in insulin action in PCOS, we examined insulin receptor function in receptors isolated from cultured skin fibroblasts. Because fibroblasts are removed from the *in vivo* environment for several generations, they provide a constant source of insulin receptors that are not influenced by the hormonal imbalance of PCOS. Consistent with our earlier results from the adipocyte studies, fibroblasts from PCOS women showed no change in insulin binding or receptor affinity

(69). However, in approximately 50% of PCOS fibroblasts (PCOS-ser), we observed decreased insulin receptor autophosphorylation (69). This was secondary to markedly increased basal autophosphorylation with minimal further insulin-stimulated autophosphorylation (Fig. 11+). Phosphoamino acid analysis revealed decreased insulin-dependent receptor tyrosine phosphorylation and increased insulin-independent receptor serine phosphorylation (69) (Fig. 11+). The ability of the PCOS-ser insulin receptors to phosphorylate an artificial substrate was also significantly reduced (Fig. 12+).

Serine phosphorylation of the insulin receptor has been shown in cell-free systems and *in vivo* to inhibit the receptor's tyrosine kinase activity, analogous to our findings in the PCOS-ser insulin receptors (69, 105, 106, 107, 108). Thus, this defect in the early steps of the insulin-signaling pathway may cause the insulin resistance in PCOS-ser women. Increased insulin-independent serine phosphorylation in PCOS-ser insulin receptors appears to be a unique disorder of insulin action since other insulin-resistant states, such as obesity, NIDDM, type A syndrome, and leprechaunism, do not exhibit this abnormality (1, 51, 65, 69) (Table 1+). The PCOS-ser phosphorylation abnormality appears to be physiologically relevant because it is present in insulin receptors partially purified from skeletal muscle, a classic insulin target tissue, and because the same pattern of abnormal phosphorylation occurs in insulin receptors phosphorylated in intact cells (69).

Fibroblasts from approximately 50% of PCOS women (PCOS-nl) have no detectable abnormality in insulin receptor phosphorylation (69) (Figs. 11+ and 12+). Although these women demonstrate the same PCOS phenotype and the same degree of insulin resistance as the PCOS-ser women with abnormal phosphorylation, insulin receptor phosphorylation in fibroblasts and skeletal muscle from these women is similar to that of control women (69). This observation suggests that a defect downstream of insulin receptor signaling, such as phosphorylation of IRS-1 or activation of PI3-K, is responsible for insulin resistance in PCOS-nl women (51, 69, 102). Indeed, our recent human studies demonstrate a significant decrease in muscle PI3-K activation during insulin infusion in PCOS women (121), consistent with a physiologically relevant defect in the early steps of insulin receptor signaling.

We found no insulin receptor mutations in two PCOS-ser women by direct sequencing of genomic DNA (120), and sequence analysis of the tyrosine kinase domain in the β -subunit of an additional eight PCOS-ser women also revealed no mutations (69). This finding has recently been confirmed by other investigators (122). Immunoprecipitation and mixing experiments suggest that a factor extrinsic to the insulin receptor is responsible for the excessive serine phosphorylation (69). PCOS-ser insulin receptors autophosphorylate normally, if they are first immunoprecipitated from wheat-germ agglutinin (WGA) lectin eluates. Furthermore, mixing control human insulin receptors and WGA eluates from PCOS-ser fibroblasts results in increased insulin-independent serine phosphorylation and decreased insulin-stimulated tyrosine phosphorylation of the normal receptors (69) (Fig. 13+). Both experiments suggest that a factor present in WGA eluates is responsible for the abnormal phosphorylation.

Figure 13. Phosphoamino acid analysis of immunopurified human insulin receptors (hIR) β -subunits basally and mixed with WGA-Sepharose eluates from control or PCOS-ser fibroblasts. hIRs were immunopurified from WGA-Sepharose eluates, mixed in a ratio of 10 fmol hIR:1 fmol PCOS-ser or control lectin eluate insulin-binding activity, and autophosphorylation \pm 1 μ M insulin was examined.

Phosphoamino acid analysis revealed a striking increase in phosphoserine content and a marked decrease in insulin-stimulated phosphotyrosine content after mixing hIR with PCOS-ser lectin eluates as compared with mixing hIR with control lectin eluates or in the absence of mixing. [Reproduced from A. Dunaif *et al.*: *J Clin Invest* 96: 801–810, 1995 (69) by copyright permission of The American Society for Clinical Investigation.]

The serine/threonine kinase, PKC, is a candidate for the putative serine phosphorylation factor (108). However, evidence against this possibility includes the observation that no phosphothreonine is detected in the PCOS-ser insulin receptors, and PKC has been shown to phosphorylate threonine 1336 of the insulin receptor (123). Furthermore, the IGF-I receptor, which is a known substrate of PKC under certain conditions, phosphorylates normally in PCOS-ser women (69, 124). Finally, preliminary Western blot analyses showed no significant differences in the abundance of PKC isoforms in PCOS-ser fibroblasts compared with controls (A. Dunaif, unpublished observations).

Other serine/threonine kinases that might cause the increased serine phosphorylation of PCOS-ser insulin receptors include a casein kinase I-like enzyme and cAMP-dependent protein kinase (125, 126). However, the casein kinase I-like enzyme has been shown to phosphorylate insulin-stimulated insulin receptors twice as well as unstimulated insulin receptors (125). This phosphorylation pattern differs from what we observe with PCOS-ser insulin receptors, namely excessive serine phosphorylation in the absence of insulin. cAMP-dependent protein kinase is a candidate because increases in cAMP cause serine phosphorylation of insulin receptors in cultured lymphocytes (127). However, insulin receptor phosphorylation by cAMP-dependent protein kinase is probably indirect because the human insulin receptor β -subunit does not contain the amino acid sequences classically recognized by this kinase (128).

Alternatively, a novel serine/threonine kinase or an inhibitor of a serine/threonine phosphatase may be responsible for the abnormal phosphorylation of PCOS-ser insulin receptors (69, 129). Because it is present in WGA eluates, the PCOS-ser factor is either a membrane glycoprotein or a protein associated with a glycoprotein. In some respects, our putative serine phosphorylation factor is similar to a recently identified inhibitor of insulin receptor tyrosine kinase, the membrane glycoprotein PC-1 (130) (Fig. 14•). Both

factors are extrinsic to the insulin receptor, both are present in WGA eluates from human skin fibroblasts, and both appear to inhibit insulin receptor tyrosine kinase activity. This represents an important new mechanism for human insulin resistance related to factors that modulate the tyrosine kinase activity of the insulin receptor (51) (Fig. 14+). The major difference between the two factors is that PC-1 is not associated with increased insulin-independent serine phosphorylation characteristic of the PCOS-ser insulin receptors (69, 130, 131). Recent studies suggest that TNF- α produces insulin resistance by a related mechanism: serine phosphorylation of IRS-1, which then inhibits insulin receptor tyrosine kinase activity (Fig. 7+). Isolation and characterization of the factor in PCOS-ser fibroblasts are now in progress, as is the mapping of phosphorylated serine residues in PCOS-ser insulin receptors.

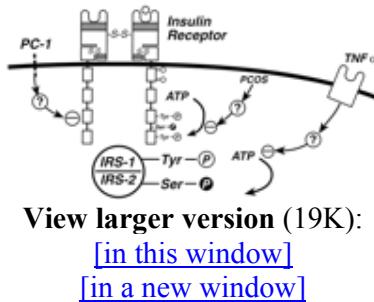

Figure 14. Insulin resistance in ~50% of PCOS women appears to be secondary to a cell membrane-associated factor, presumably a serine/threonine kinase, that serine-phosphorylates the insulin receptor-inhibiting signaling. Serine phosphorylation of IRS-1 appears to be the mechanism for TNF α -mediated insulin resistance. The membrane glycoprotein PC-1 also inhibits insulin receptor kinase activity, but it does not cause serine phosphorylation of the receptor. These are examples of a recently appreciated mechanism for insulin resistance secondary to factors regulating the receptor's tyrosine kinase activity. [Figure used with permission from A. Dunaif.]

Although fibroblasts are not classic insulin target cells, defects identified in insulin receptor number and/or kinase activity in them have reflected insulin receptor mutations (19). Thus, the presence of the putative serine phosphorylation factor in cultured cells of PCOS-ser women suggests that the abnormal insulin receptor phosphorylation is genetically programmed. In addition, we have found that some first degree relatives of PCOS women are insulin resistant, including brothers, consistent with a genetic defect (132). Recent twin (133) and family studies (134) have also suggested that insulin resistance is a genetic defect in PCOS. Our putative serine phosphorylation factor is a candidate gene for a mutation producing the insulin resistance associated with PCOS (see below).

F. Constraints of insulin action studies in PCOS

There is general consensus in the literature that obese PCOS women are insulin resistant. Controversy remains as to the pathogenesis of the insulin resistance, and there are studies that suggest that obesity *per se* or increased central adiposity are responsible

for the associated defects in insulin action (135, 136). Many of the conflicting studies can be explained by differing diagnostic criteria for PCOS and by the inclusion of both lean and obese women in the experimental sample. Our studies (49) and those in the United Kingdom (137, 138) strongly suggest that anovulation is associated with insulin resistance. We found insulin resistance only in women with hyperandrogenism and anovulation (Fig. 4•). Studies using ovarian morphology to ascertain women have found that only anovulatory women with PCO morphology are insulin resistant (137, 138). Women with regular ovulatory menses and hyperandrogenism [elevated plasma androgen levels (49)] (Fig. 4•) or with PCO detected by ovarian ultrasound (137, 138) are not insulin resistant. Therefore, studies that have defined PCOS by PCO morphology without further assessment of ovulation could have included women who were not insulin resistant. Similarly, studies that have included ovulatory hyperandrogenic women will bias the sample with insulin-sensitive subjects.

One reason for the general acceptance of the diagnostic criteria for PCOS of hyperandrogenism and anovulation (1) (Table 2•, see above) is that they define the insulin-resistant subset. Even with subjects so identified, not all are insulin resistant, despite using the relatively lenient criterion of 1 SD below the control mean value for insulin action. Moreover, the occasional PCOS woman can have insulin sensitivity more than 2 SDs (95% confidence interval) above the control mean (117). There is clearly heterogeneity in this feature of the syndrome. Obesity is another important factor, and it appears that it has a more pronounced effect on insulin action in PCOS than in control women (71). Ideally, lean and obese PCOS women should be studied separately (30, 49, 54, 55, 68). If groups are pooled, PCOS women should be matched to controls so that the spectrum of body weights are equally represented. This is often not the case so that, although mean body mass may be similar, the PCOS group often contains more obese individuals, thereby skewing the results (114). Moreover, there are very few studies in the literature in which lean PCOS woman have been separately studied (30, 54, 55, 68, 135). There are also major ethnic variations in insulin sensitivity, and this is another less well appreciated potential confounding factor (56). Recent studies from Denmark suggest that adiposity accounts for insulin resistance in their PCOS population in contrast to our US population (135, 136).

We have consistently found significant decreases in insulin-mediated glucose disposal in both lean and obese PCOS women (54, 55, 56). Similarly, our group (57) as well as Yen's group (68) have found significant decreases in insulin sensitivity (SI) determined by modified frequently sampled intravenous glucose tolerance test with minimal model analysis in such PCOS women (57). Insulin resistance has been found in PCOS women of many racial and ethnic groups including Japanese, Caribbean and Mexican Hispanics, non-Hispanic Whites, and African Americans (55, 56, 139, 140).

G. PCOS as a unique NIDDM subphenotype (Table 3•)

Our studies in premenopausal women, extrapolated data based on prevalence estimates of PCOS and glucose intolerance, and studies in postmenopausal women with a history of PCOS all suggest that PCOS-related insulin resistance confers a significantly increased risk for NIDDM (see above). Familial clustering of affected individuals as well as studies in monozygotic twins indicate that NIDDM has an important genetic component (51, 102, 141, 142, 143, 144). Insulin resistance is a major inherited abnormality, but studies in which insulin secretion has been examined in the context of insulin sensitivity demonstrate that β -cell dysfunction may also be an important contributing factor to the ultimate development of the NIDDM phenotype (51, 145,

[146](#)). There is clearly genetic heterogeneity with insulin resistance being absent in some affected individuals ([146](#), [147](#)).

View this table:

[\[in this window\]](#)

[\[in a new window\]](#)

Table 3. Adult NIDDM syndromes

The underlying genetic defects have been identified in fewer than 5% of NIDDM individuals and consist of mutations in genes such as the insulin receptor gene, mitochondrial DNA, or the glucokinase gene (Table 3+) ([19](#), [51](#), [102](#), [144](#), [148](#), [149](#)). Defects in a number of candidate genes, such as GLUT4, GLUT2, and hexokinase, have been excluded ([102](#), [150](#)). The major cause of insulin resistance in typical NIDDM is reduced insulin-stimulated muscle glycogen synthesis. Defects found in NIDDM in insulin receptor number and/or phosphorylation or glucose transport, however, are reversible with the control of hyperglycemia ([51](#), [65](#), [102](#), [151](#)), elevated free fatty acid levels ([152](#)), and/or hyperinsulinemia ([119](#)). Only one study has shown an intrinsic abnormality in NIDDM-cultured cells ([153](#)): decreased insulin-stimulated glycogen synthesis. Studies in NIDDM first-degree relatives, who are normoglycemic but insulin resistant, suggest that there is an inherited decrease in both insulin-stimulated muscle glucose transport/phosphorylation and glycogen synthase activity that results in the reduced glycogen synthesis ([154](#), [155](#), [156](#)). In contrast, in PCOS, intrinsic abnormalities in the early steps of insulin receptor signaling are present, making this the first common NIDDM subphenotype in which such defects have been identified ([69](#), [102](#), [151](#)). Moreover, the defective pattern of insulin receptor phosphorylation is unique, suggesting it should be possible to distinguish PCOS-related insulin resistance from that related to other NIDDM genotypes. This should make it possible to assign affected status accurately for linkage studies of the genetics of PCOS-related insulin resistance ([157](#)).

► **III. Hypotheses Explaining the Association of
Insulin Resistance and PCOS**

A. Causal association

1. *Do androgens cause insulin resistance?* If glucose utilization is expressed as a function of muscle mass rather than total body mass, women do appear to be more insulin sensitive than men (158, 159). Moreover, when isolated fat cells are compared, female adipocytes are more sensitive than male adipocytes to insulin-mediated glucose uptake (160). These are subtle differences, however, and do not approach the degree of impairment in insulin sensitivity observed in PCOS (54, 55). Finally, in the rare syndromes of extreme insulin resistance and hyperandrogenism, specific molecular defects in insulin action have been clearly identified as the cause of insulin resistance (19, 161).

It is possible, however, that androgens may produce mild insulin resistance. Women receiving oral contraceptives containing "androgenic" progestins can experience decompensations in glucose tolerance, as can individuals receiving synthetic anabolic steroids (162, 163). Prolonged testosterone administration to female-to-male transsexuals, which produced circulating testosterone levels in the normal male range, resulted in significant decreases in insulin-mediated glucose uptake in euglycemic clamp studies (164). These decreases were largest at lower doses of insulin (~25% at ~300 pM steady-state levels), not significant at moderate insulin doses (~1,000 pM steady-state levels), and minimal at higher doses (~7% at ~5,000 pM steady-state levels) (164) (Fig. 15•). Studies in testosterone-treated castrated female rats have suggested that androgen-mediated insulin resistance may be the result of an increase in the number of less insulin-sensitive type II b skeletal muscle fibers (165) and an inhibition of muscle glycogen synthase activity (166).

Figure 15. Hyperinsulinemic euglycemic clamp studies basally and during treatment with virilizing doses of testosterone in 13 female-to-male transsexuals. Insulin-mediated glucose disposal decreased significantly at low and at high doses of insulin. [Reproduced with permission from K. H. Polderman *et al.*: *J Clin Endocrinol Metab* 79:265–271, 1994 (164). © The Endocrine Society.]

It has been more difficult to demonstrate that decreasing androgen levels improve insulin sensitivity in PCOS. We found no significant changes in peripheral or hepatic

insulin action in profoundly insulin-resistant obese PCOS women by single-insulin dose (steady-state insulin levels \sim 600 pM) glucose clamp studies after prolonged androgen suppression produced by the administration of an agonist analog of GnRH (167). Diamanti-Kandarakis and colleagues (168) reported that antiandrogen therapy did not alter insulin sensitivity in PCOS. Other investigators have found modest improvements in insulin sensitivity in PCOS during androgen suppression or antiandrogen therapy (169, 170) (Fig. 16•). Such changes were apparent in less insulin-resistant, less obese, or nonobese PCOS women (169, 170). Moreover, insulin resistance was improved but not abolished (170) (Fig. 16•). It is of considerable interest that the effects of sex steroids on insulin sensitivity appear to be sexually dimorphic. Testosterone administration to obese males improves insulin sensitivity (171), and synthetic estrogen administration to male-to-female transsexuals produces insulin resistance (164).

Figure 16. Basal and insulin-mediated glucose disposal in 43 hyperandrogenic women and 12 control women. The hyperandrogenic women were studied before and after 3–4 months of antiandrogen therapy with spironolactone, flutamide, or Buserelin. Insulin-mediated glucose disposal increased significantly during treatment ($P < 0.01$). [Adapted with permission from P. Moghetti *et al.*: *J Clin Endocrinol Metab* 81:952–960, 1996 (170). © The Endocrine Society.]

Givens and colleagues (172) have proposed that androgens have differential effects on insulin action, with testosterone worsening insulin sensitivity and the adrenal androgen, dehydroepiandrosterone (DHEA), improving it. This hypothesis is based on differing correlations of these steroids with insulin-binding studies in blood cells and on their observation that women with elevated dehydroepiandrosterone sulfate (DHEAS) levels have normal insulin sensitivity (172). The one direct *in vitro* study supporting this hypothesis was constrained by a small sample size ($n = 3$), and the examination of testosterone and DHEA effects on insulin binding using blood cells rather than a more relevant insulin target tissue (172). Studies in which DHEA or DHEAS have been administered to humans have failed to support this hypothesis. Administration of supraphysiological amounts of DHEA (which also result in testosterone elevations since DHEA is a testosterone prehormone) has produced mild hyperinsulinemia in women, but had no effects on insulin sensitivity in men, as would be expected given the sexually dimorphic effects of androgens on insulin action (173, 174). Moreover, PCOS women with elevated DHEAS levels similar to those in ovulatory hyperandrogenic women are

significantly more insulin resistant, arguing against an insulin-sensitizing action of DHEA ([49](#), [175](#)).

In summary, the modest hyperandrogenism characteristic of PCOS may contribute to the associated insulin resistance. Additional factors are necessary to explain the insulin resistance, since suppressing androgen levels does not completely restore normal insulin sensitivity ([167](#), [170](#)). Further, androgen administration does not produce insulin resistance of the same magnitude as that seen in PCOS ([54](#), [55](#), [164](#)). Finally, there are clearly defects in insulin action that persist in cultured PCOS skin fibroblasts removed from the hormonal milieu for generations (see above) ([69](#)).

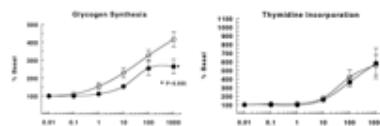

2. Does hyperinsulinemia cause hyperandrogenism? The syndromes of extreme insulin resistance are commonly associated with hyperandrogenism when they occur in premenopausal women ([19](#), [20](#)) (Table 1+). The cellular mechanisms of insulin resistance in these conditions range from antibodies that block insulin binding to its receptor (type B syndrome) to genetic defects in the receptor resulting in decreased numbers and/or depressed function of the receptor (type A syndrome, leprechaunism); the common biochemical feature is profound hyperinsulinemia ([19](#), [20](#)) (Table 1+). Accordingly, it has been proposed that hyperinsulinemia causes hyperandrogenism. Insulin can be shown experimentally to have a variety of direct actions on steroidogenesis in humans ([1](#), [9](#), [20](#)). Insulin can stimulate ovarian estrogen, androgen, and progesterone secretion *in vitro* ([1](#), [20](#), [176](#)). Although some of these actions have been observed at physiological insulin concentrations, most actions have been observed at higher concentrations ([1](#), [20](#)).

The presence of insulin receptors in crude ovarian membranes does not necessarily indicate a physiological role for insulin in the regulation of steroidogenesis since such receptors are widely distributed through the body ([51](#), [83](#)). Insulin is present in human follicular fluid but in concentrations most likely representing an ultrafiltrate of plasma rather than local production ([177](#)). In contrast, IGF-I is produced by human ovarian tissue, and IGF-I receptors are present in the ovary ([178](#), [179](#)). IGF-I and its receptor share considerable sequence, structural, and functional homology with insulin and its receptor, respectively ([180](#)). The IGF-I receptor is a heterotetramer with two $\alpha\beta$ -dimers assembled analogous to the insulin receptor ([85](#), [88](#), [181](#), [182](#), [183](#)) (see above). Insulin can bind to the ligand-binding domain of the IGF-I receptor and activate the tyrosine kinase activity of the β -subunit and the intracellular events normally mediated by IGF-I ([85](#), [88](#), [180](#), [181](#)). IGF-I can bind to and activate the insulin receptor, resulting in rapid effects on glucose metabolism ([85](#), [88](#), [181](#)). In general, the affinity of the IGF-I receptor for insulin is considerably less than it is for IGF-I and *vice versa* ([181](#)). However, this varies by tissue; thus data on receptor affinity cannot be extrapolated from one tissue to another. There are also so-called "atypical" IGF-I receptors that bind IGF-I and insulin with similar affinity ([184](#), [185](#)). $\alpha\beta$ -Dimers of the insulin and IGF-I receptor can assemble together to form hybrid heterotetramers ([11](#), [182](#), [186](#), [187](#)).

Insulin-like growth factor-binding proteins (IGFBPs) are major regulators of IGF action. IGFBPs can specifically bind IGF-I and modulate its cellular actions by altering its bioavailability ([182](#), [188](#)). Insulin decreases hepatic production of IGFBP-1 and may, thus, make IGF-I more biologically available ([182](#)). Growth factor regulation of ovarian steroidogenesis appears to be primarily a paracrine system with locally produced IGF-I and IGFBPs acting on neighboring cells in concert with gonadotropins ([1](#), [178](#), [179](#), [189](#)). A number of other growth factors, including IGF-II, EGF, and transforming growth factor- α and - β , appear to have a role in the regulation (both stimulatory and

inhibitory) of ovarian steroidogenesis (1, 188, 190). Insulin cannot interact directly with the receptors for these hormones (84, 88, 181, 182). However, the receptors for some of these growth factors, such as the EGF receptor (which binds both EGF and transforming growth factor- α), are also protein kinases (1, 84, 88). Thus the potential exists for communication between the insulin-IGF-I system and the other protein kinase growth factor systems through receptor "cross-talk" and/or by shared kinases or phosphatases that may regulate all of these receptors (51, 191). For example, serine phosphorylation of the EGF receptor also decreases its tyrosine kinase activity (103, 104). In rodents, hyperinsulinemia can result in up-regulation of ovarian IGF-I-binding sites, and this may provide yet another mechanism by which insulin can modulate growth factor action (192).

Insulin in high concentrations can mimic IGF-I actions by occupancy of the IGF-I receptor (1, 181, 182), and this has been a proposed mechanism for insulin-mediated hyperandrogenism (8, 9, 10). However, it has recently been shown that insulin has specific actions on steroidogenesis acting through its own receptor (193). Moreover, these actions appear to be preserved in insulin-resistant states (193, 194), presumably because of differences in receptor sensitivity to this insulin action or because of differential regulation of the receptor in this tissue. Our studies in cultured skin fibroblasts suggest that a mechanism for this may be selective defects in insulin action. Both insulin- and IGF-I-stimulated glycogen synthesis are significantly decreased in PCOS fibroblasts whereas thymidine incorporation is similar to control fibroblasts (Fig. 17+) (195). Thus only the signaling pathways regulating carbohydrate metabolism may be impaired in PCOS, while those involved in steroidogenesis are preserved. This would explain the paradox of persistent insulin-stimulated androgen production in insulin-resistant PCOS women. Insulin decreases hepatic IGFBP-1 production, the major circulating IGF-I-binding protein (183). Thus, bioavailable IGF-I levels are increased in insulin-resistant PCOS women, and this may contribute to the ovarian steroidogenic abnormalities via activation of the IGF-I receptor (68). In lean PCOS women, increases in GH release may also affect ovarian steroidogenesis (68).

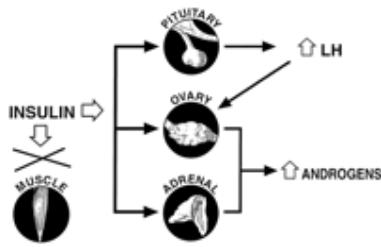

Figure 17. Dose-response curves for insulin-stimulated glycogen synthesis (*left panel*) and thymidine incorporation (*right panel*) in confluent skin fibroblasts from PCOS (•) and control (○, NL) women. Maximal responses for insulin-stimulated glycogen synthesis were significantly decreased ($P < 0.001$). There were no significant differences in thymidine incorporation in the PCOS fibroblasts (*right panel*). The dose-response curves for IGF-I were similar to those for insulin (data not shown). [Reproduced with permission from A. Dunaif (195).]

It has been more difficult to demonstrate insulin actions on steroidogenesis in humans *in vivo* because it is not feasible to administer insulin to nondiabetics for prolonged periods (1, 196, 197, 198). Relatively physiological levels of insulin (100 μU/ml or 600 pM), when infused over approximately 2 h, can slightly increase plasma androstenedione levels in normal women (1). However, these increases are minor and are not in the range seen in women with hyperandrogenism. Moreover, it is arguable whether insulin contributes to androgen production in normal women since insulin levels in the 100 μU/ml (~600 pM) range are generally seen only after meals (1, 196). Furthermore, such transient meal-related increases in insulin do not result in increased androgen levels, whereas the more sustained increases produced by continuous insulin infusion can slightly increase androgen levels (196).

Studies in which insulin levels have been lowered for prolonged periods have been much more informative. This has been accomplished for 7 days to 3 months with agents that either decrease insulin secretion, diazoxide (199) or somatostatin (200), or that improve insulin sensitivity, metformin (201) or troglitazone (202). Circulating androgen levels have decreased significantly in women with PCOS in these studies. Sex hormone binding globulin (SHBG) levels have increased (199, 202), compatible with a major role for insulin in regulating hepatic production of this protein (203, 204). Abnormalities in apparent 17,20-lyase activity have improved in parallel with reduced circulating insulin levels consistent with insulin-mediated stimulation of this enzyme (205). However, estrogen levels also decreased significantly, suggesting that insulin has diffuse effects on steroidogenesis (202). Changes in estrogen levels were seen only when insulin levels were lowered with troglitazone and thus, alternatively, these changes might be the result of troglitazone-mediated increases in sex steroid metabolism, a recently reported action of this agent (Rezulin Package Insert, Parke-Davis, Morris Plains, NJ). It is also possible that troglitazone has direct effects on steroidogenesis. Indeed, the thiazolidinediones have been shown to have such effects on granulosa cell steroidogenesis (206).

Most of the reported actions of insulin on steroidogenesis are observed only in women with PCOS (197, 198) and are greatly enhanced by the addition of gonadotropins when measured in *in vitro* experiments (1, 20, 176, 190, 207). In the one study in normal women in which insulin levels were lowered by diazoxide administration, no significant changes in androgen levels were noted (208). These observations suggest that, if insulin is to produce ovarian hyperandrogenism in women, polycystic ovarian changes (*e.g.*, theca cell hyperplasia) must be present that predispose the ovaries to secrete excess androgens. In normal women insulin does not appear to have any acute effects on ovarian function under physiological circumstances (196, 197, 208).

Although insulin has been shown to stimulate gonadotropin release in isolated rat pituitary cells (209), human studies of insulin action on gonadotropin release have yielded conflicting results. Acute insulin infusion has not changed pulsatile LH or FSH release or gonadotrope sensitivity to GnRH in normal or in PCOS women, despite direct effects on gonadal steroidogenesis in PCOS women (197). Long-term suppression of insulin levels with diazoxide, which resulted in decreases in circulating testosterone levels, did not alter circulating LH levels (199). In contrast, decreases in LH levels were observed after 7 days of somatostatin-mediated insulin lowering (201), after metformin for 8 weeks (205), or after troglitazone for 3 months (202). It is possible that insulin-mediated changes in gonadotropin release contribute to the changes of steroidogenesis produced by insulin in humans (Fig. 18*).

[\[in this window\]](#)

[\[in a new window\]](#)

Figure 18. Studies in which insulin levels have been lowered with the insulin-sensitizing agent, troglitazone, suggest that insulin is a general augmentor of steroidogenesis and LH release. [Figure is used with permission from A. **Dunaif**.]

Acute insulin infusions decrease DHEAS levels in men and women, suggesting that insulin is a negative modulator of adrenal androgen metabolism (176). When insulin levels are chronically lowered, however, circulating DHEA and DHEAS levels rise in men but not in women, suggesting that this regulation of adrenal androgen metabolism is sexually dimorphic (210). Lowering insulin levels with insulin-sensitizing agents, such as troglitazone, has resulted in decreases in DHEAS levels in PCOS women (202) (Fig. 18•). The mechanism of this appears to be a direct action of insulin to increase adrenal sensitivity to ACTH in hyperandrogenic women (211). Insulin can directly decrease hepatic SHBG production (203), explaining the frequently observed inverse correlation between peripheral insulin and SHBG levels (204). Indeed, insulin rather than sex steroids appears to be the major regulator of SHBG production (204).

In summary, studies in which insulin levels have been lowered by a variety of modalities indicate that hyperinsulinemia augments androgen production in PCOS (Fig. 18•). Moreover, this action appears to be directly mediated by insulin acting through its cognate receptor rather than by spillover occupancy of the IGF-I receptor. Intrinsic abnormalities in steroidogenesis appear to be necessary for this insulin action to be manifested since lowering insulin levels does not affect circulating androgen levels in normal women. Further, in many PCOS women, lowering insulin levels ameliorates but does not abolish hyperandrogenism.

B. Possible genetic association of PCOS and insulin resistance

1. Family studies of PCOS. Familial aggregation of PCOS suggesting a genetic etiology has been clearly established (1, 212, 213, 214). Cooper *et al.* (212) reported that a history of oligomenorrhea was more common in the mothers and sisters of PCOS women than in controls. Probands reported that male relatives had increased "pilosity" (212). The proposed mechanism of inheritance was autosomal dominant with decreased penetrance. Givens and colleagues have reported multiple kindreds showing affected women in several generations and have examined some males in considerable detail (1, 215). Diagnostic criteria for PCOS were hirsutism and enlarged ovaries. There was a high frequency of metabolic disorders, such as NIDDM and hyperlipidemia, in both male and female pedigree members. In one kindred there were several males with

oligospermia and one with Klinefelter's syndrome (47, XXY). Elevated LH/FSH ratios were present in some males and 89% of their daughters had PCOS. This would suggest inheritance in either an autosomal or X-linked dominant manner.

Ferriman and Purdie (216) studied 700 women; affected status was assigned on the basis of hirsutism and enlarged ovaries (assessed by gynecography). The frequency of various abnormalities in relatives was determined by history provided by the proband; no relatives were examined. Oligomenorrhea and infertility were most common in women who had both hirsutism and enlarged ovaries. Forty-six percent of female relatives were reported to be similarly affected. There was an increased incidence of baldness reported in male relatives. Similar results were found in a study of 132 Norwegian PCOS probands identified by ovarian wedge resection (217). Information on pedigree members was obtained by questionnaire. Female first-degree relatives had a significantly increased frequency of PCOS symptoms (*i.e.*, hirsutism, oligomenorrhea, infertility), and male first-degree relatives had a significantly increased frequency of early baldness or "excessive hairiness" compared with controls. Human leukocyte antigen typing in PCOS has had conflicting results; an initial report showed no human leukocyte antigen association, whereas a follow-up study reported an association with DQA1^L0501 (218, 219). There have been case reports of polyploidies and X-chromosome aneuploidies in PCOS (220, 221). Larger studies, however, have found normal karyotypes (222).

Studies from the United Kingdom have phenotyped women on the basis of polycystic ovarian morphology detected by ultrasound (223). Familial polycystic ovary morphology was observed in 51 of 62 pedigrees (92%). The proportion of females affected in all sibships was 80.5% (107 of 133), which would exceed the expected ratios for either an autosomal dominant or an X-linked dominant mode of inheritance. However, not all women in each kindred were examined and, thus, an accurate ratio of affected to unaffected women could not be established for segregation analysis. Further, the male phenotype was not sought.

A more recent study prospectively examined the families of probands consecutively identified on the basis of polycystic ovarian morphology on ultrasound (224). The first-degree relatives in 10 families were evaluated by history, measurement of physical indices, and hirsutism as well as serum levels of androgens, 17-hydroxyprogesterone, gonadotropins, and PRL. Transabdominal ultrasound was performed in female first-degree relatives. Only 54% of women with polycystic ovaries had an elevated total testosterone or LH level consistent with the endocrine *syndrome*. Glucose and insulin levels were assessed in obese but not lean probands. Twenty-two males were screened; eight had premature (before age 30 yr) fronto-parietal hair loss, 10 did not, and four were too young to assess. Female affected status was assigned on the basis of ultrasound evidence of polycystic ovaries. If male affected status was considered to be premature balding, and a history of menstrual irregularity was used to assign postmenopausal affected status, the segregation ratio for affected families, excluding the proband, was 51.4%, consistent with an autosomal dominant mode of inheritance with complete penetrance (224). Studies in monozygotic twins, however, have not found complete concordance of polycystic ovary morphology, arguing against this mode of inheritance (133). The study contained only 19 pairs of monozygotic twins as well as a sample of 15 dizygotic twins. The prevalence of polycystic ovary morphology was ~50% in these twins, who were recruited from a twin registry, which was twice the prevalence reported in other randomly selected groups of women (3). This raises concern about the accuracy of the detection of polycystic ovaries.

Family studies have been constrained by small sample sizes and/or failure to examine all available family members. In several studies, PCOS affected status has been assigned on the basis of ovarian morphology rather than hormonal abnormalities. Only one study has proposed a male phenotype on the basis of examination of male relatives, and this study was constrained by a small sample size (224). Nevertheless, these studies strongly suggest that PCOS has a genetic component, most likely with an autosomal dominant mode of transmission (220, 224). If this is true, are there other phenotypes in affected kindreds? The studies cited above have suggested that premature male balding may be a male phenotype (216, 224). This finding could be an artifact, since it is also possible that bald men choose to marry hirsute women. Recent studies in these families, however, suggesting linkage of this phenotype with a candidate gene in the steroidogenic enzyme pathway (Ref. 225; see below), if verified, would confirm genetically that this is a male phenotype.

Our studies have suggested that insulin resistance may be an additional male phenotype as well as a prepubertal and postmenopausal female phenotype (132, 220) (Table 4+). This has been also reported recently in a series of Australian PCOS kindreds. In the small number of families that we have studied (132, 220), when women of reproductive age are insulin resistant, they usually have possessed the other endocrine features of PCOS. The one insulin-resistant prepubertal girl was also hyperandrogenic and developed chronic anovulation after menarche consistent with the diagnosis of PCOS (132). That insulin resistance and hyperandrogenism may be a prepubertal phenotype is supported by recent studies suggesting that PCOS develops in insulin-resistant girls with premature adrenarche (58, 226, 227) (Table 4+). Our studies suggest that hyperandrogenism without insulin resistance is another phenotype in female PCOS kindred members of reproductive age (228) (Table 4+). Finally, we have found postmenopausal hyperandrogenic female family members with normal insulin sensitivity, which may represent an additional postmenopausal phenotype (132) (Table 4+). This possibility is supported by the study of Dahlgren and colleagues (53), which found that postmenopausal women with a history of PCOS had higher androgen levels than age-matched control women. We have found that hyperandrogenism and insulin resistance can segregate independently in PCOS kindreds (132). It is not yet possible to determine whether this reflects separate genetic traits or variable penetrance of a single defect. These studies also indicate that there is considerable phenotypic variation, even within kindreds.

Table 4. Additional familial phenotypes

2. Candidate genes for PCOS. The biochemical reproductive phenotype in PCOS is characterized by increased LH secretion and acyclic FSH release (2, 12). The ovaries (in response to LH) and, often, the adrenals secrete excessive androgens, and there is decreased ovarian aromatization of androgens to estrogens (12). The circulating androgens feed back on the hypothalamic-pituitary axis (directly or via their

exagonadal aromatization to estrogen) to increase LH relative to FSH release, producing a self-sustaining syndrome ([34](#), [35](#), [36](#), [37](#), [42](#)). The defect that initiates these reproductive disturbances in PCOS is unknown, but it can be shown experimentally that factors that increase either androgen secretion or LH release can reproduce these disturbances ([1](#), [2](#), [12](#), [38](#), [39](#)). Thus any factor regulating gonadotropin secretion or action, adrenal or ovarian steroidogenesis, and/or exagonadal aromatization could be a plausible candidate gene for the reproductive phenotype of PCOS. Indeed, polycystic o

Abstract:

Introduction:

Polycystic ovary syndrome (PCOS), an endocrine glands disorder, caused by hormonal imbalance, is featured by diverse potential effects for women; while individuals perpend to those that are affecting appearance and menstruation disorder. Our aim was to assess PCOS risk factors in working women.

Materials and Methods:

The study was carried out as a literature review work through searching databases including Scopus, PubMed, and ScienceDirect for papers published before December 2019. The databases were searched for the terms such as PCO, job stress, and risk factors of PCO. Risk factors for polycystic ovarian syndrome and occupational risk factors for working women were investigated.

Results and Discussion:

There are several reasons known for PCOS like obesity and insulin resistance along with the stressors that increase its risk. Working women tend to be exposed to several stressors and being in charge of home affairs creates a higher workload and intensified stresses. The risk of PCOS is higher in women with higher stressors at work.

Conclusions:

Working women experience many stressors and taking into account that stress is a precursor or intensifier of PCOS risk factors, working women are at a higher risk of PCOS compared with housewives.

Keywords: Polycystic ovary syndrome, Working women, Stress, Glucose, Risk, Polycystic.

1. INTRODUCTION

Polycystic ovary syndrome (PCOS), a disorder of endocrine glands, is caused by hormonal imbalance in women [1]. This syndrome is a silent and non-contagious disease [2] and appears as a sort of insulin resistance in women along with probable changes in cortisol and melatonin secretion; which are the key indicators of the hypothalamus, hypophyses, and adrenal function [2, 3]. According to the National Institute of Health (NIH) and Rotterdam Criteria, the prevalence of PCOS is about 6-10% and 15%, respectively [4]. The syndrome

causes a variety of diverse and notable complications such as infertility, hypoestrogenism, hirsutism, insulin resistance, glucose intolerance, diabetes type II, and cardiovascular disorder; in addition to causing anxiety, depression, and low quality of life [1]. Despite all these problems, there is no public awareness of PCOS [5]. Previous studies showed that women with PCOS suffer from higher social stress and other life stresses as well. One of them is occupational stress, which is the second occupational health related to work [6]. By definition, occupational stress refers to any non-useful psychological or physical response caused by a lack of fitness between the responsibility assigned at work and one's capabilities, which might lead to aggressive behaviors, work

* Address correspondence to this author at the Department of Occupational Health Engineering, School of Health, Ardabil University of Medical Sciences, Ardabil, Iran; E-mail: a.babaei@arums.ac.ir

accidents, psychological and mental disorders, or even death. It affects one's health and quality of life and increases the risk of work accidents. Moreover, stress might cause destructive effects on physical and psychological health including hypertension, heart attack, depression, and anxiety [7].

Chronic depression might cause changes in nutritional habits so that many find overeating a way to fight stress, which leads to obesity and abdominal fat – both as key risk factors for diabetes type II [8, 9]. In addition, unhealthy nutrition results in insulin resistance so there is a significant relationship between insulin resistance and clinical problems like non-alcoholic fatty liver and PCOS. On the other hand, some of the occupational risk factors like the inconsistency of circadian rhythm, overnight sleep disruption, the polluted environment at work (particles, solvents), exposure to heavy metals (arsenic, mercury) or stable organic pollutants increase the risk of insulin resistance [10]. Many jobs are featured with these risk factors. As shown by other studies, anxiety, depression, and lack of physical activity are very common in women with PCOS.^{3,9} In general, working women are under heavy stress in addition to their work since they are in charge of home affairs. Therefore, the hypothesis of the present study is that working women are at a higher risk of developing PCOS. Our aim was to assess PCOS risk factors in working women.

2. METHODS

The study was carried out as a literature review work through searching databases including Scopus, PubMed, and ScienceDirect for papers published before December 2019.

The databases were searched for the terms such as "Polycystic ovary syndrome", "PCOS", "stress", "job stress", "working women", and "risk factors of PCOS".

The other references were also reviewed to find the papers that might have been overlooked when searching the databases. Moreover, the studies published in English were selected for analysis. Studies, which investigated irrelevant outcomes and lacked sufficient information for analysis, were excluded. Finally, the search results were reviewed by two authors independently after removing duplicates. The information of the studies, which entered the final phase, was extracted and investigated. All procedures carried out in accordance with the ethical committee of Shoushtar Faculty of Medical Sciences (No. IR.SHOUSHTAR.REC.1399.04).

3. RESULTS

3.1. Risk Factors of PCOS

A variety of risk factors such as obesity, insulin resistance, and hormonal disorders play a role in the development of PCOS [7, 9]. According to the results of studies, stress can be influential as an intermediate factor in the development or intensification of these risk factors. These relationships are further discussed in the following sections:

3.2. Stress and Obesity

Chronic stress increases the risk of changes in nutritional habits and consequential obesity is a risk factor for diseases like diabetes, cardiovascular disease, and PCOS. Overeating is a strategy to fight stress, which results in obesity and abdominal fat – *i.e.* two main risk factors of diabetes type II

[9]. Social stresses like aggression, domination, and work pressure all may lead to diseases like diabetes type II. The prevalence of PCOS in underweight, normal, overweight, and obese women were 8.2, 9.8, 9.9, 9.0% respectively. Therefore, the risk of PCOS increases with obesity [4 - 6]. Studies have also shown that anxiety, depression, and lack of physical activity are common in women with PCOS.

3.3. Stress and Insulin Resistance

PCOS is a type of insulin resistance that is only developed by women. Some of the occupational risk factors like the inconsistency of circadian rhythm and overnight sleep disorders caused by overnight work shifts, exposure to pollution (particles, solvents), heavy metals (arsenic, mercury) or, organic pollutants increase the risk of developing insulin resistance. In turn, insulin resistance leads to cardiovascular diseases and diabetes. There is a significant relationship between insulin resistance and clinical problems like non-alcoholic fatty liver and PCOS [9]. Studies have shown that occupational stress creates unhealthy habits like unhealthy nutrition that results in insulin resistance. Tianwei Xu *et al.* showed that social stresses like aggression, domination, and work pressure may lead to diabetes type II [8], which is an outcome of insulin resistance.

3.4. Stress and Hormonal Disorders

In terms of pathology, PCOS includes hyperandrogenic and probable changes in cortisol and melatonin secretion that reflect the function of the hypophyses and adrenal hypothalamus. Each of the elements of stress paths can halt reproduction function. Severe stress and ovulation failure disrupt steroidogenesis and angiogenesis. Chronic stress intensifies general catabolic conditions; therefore, constant hyperactivity (HPA) might gradually lead to a reduction of lean body mass (muscle and bone) and an increase in visceral fat and insulin resistance, which in turn affects the HPO axis. In the case of PCOS, chronic stress is one of the hemostatic disorders that leads to an endocrine disorder. Functional hypothalamic amenorrhea (FHA) is a chronic annulation that is not diagnosable due to organic reasons. It is mostly associated with stress, weight loss, hyperactivity, or a combination of them. A decrease in GnRH outcome at LH and FSH levels is not enough to preserve folliculogenesis and ovary function [7]. Moreover, psychological stress intensifies hypothalamus amenorrhea through decreasing the HPS activity [7].

3.5. Work and PCOS

There is a relationship between the expansion of stress symptoms and demanding work, low decision-making skills, and low social support [11]. Studies have shown that female managers feel more stress than male ones and the source of this stress is the social roles and expectations of women. This explains the fact that female managers are still a minority [12].

Studies in the USA have shown that women in stressful jobs are twice at the risk of short menstruation in comparison to the ones in non-stressful jobs. The risk of breast cancer is higher in women with shorter menstruation cycles [13]; in addition, the rate of ovary and womb cancers is higher in these women [14].

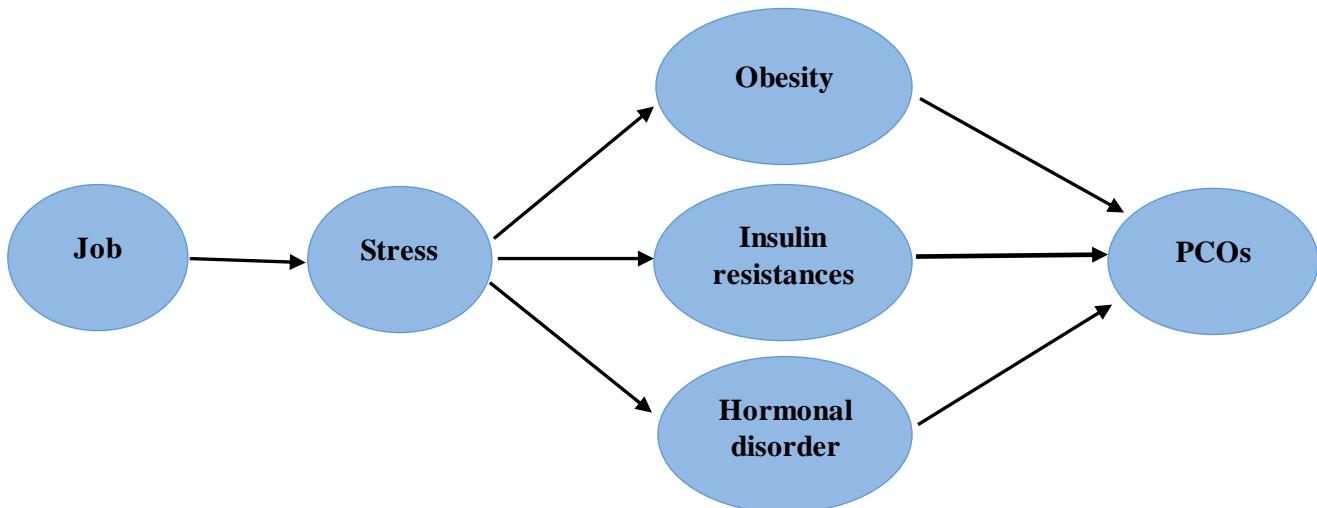

Fig (1). Relationship between job stress and PCO.

Occupational stress or other occupational risk factors have an indirect impact on PCOS in working women by creating insulin resistance, obesity, and hormonal distress (Fig. 1).

CONCLUSION

Working women experience many stressors depending on their job and being in charge of home affairs at the same time increases their stress and workload. Taking into account that stress is a precursor or intensifier of PCOS risk factors (*e.g.* obesity, insulin resistance, and hormonal disorder), working women are at a higher risk of PCOS compared with housewives.

Polycystic ovary syndrome (PCOS) is defined as a kind of endocrine and metabolic disorder that affects female individuals of reproductive age. Lifestyle modifications, including diet modifications, exercise, and behavioral modification, appear to alleviate the metabolic dysfunction and improve the reproductive disorders of PCOS patients (particularly in obese women). Therefore, lifestyle modifications have been gradually acknowledged as the first-line management for PCOS, especially in obese patients with PCOS. However, the mechanism of lifestyle modifications in PCOS, the appropriate composition of diet modifications, and the applicable type of exercise modifications for specific female populations are rarely reported. We conducted a systematic review and enrolled 10 randomized controlled trials for inclusion in a certain selection. In this review, we summarized the existing research on lifestyle modifications in PCOS. We aimed to illustrate the relationship between lifestyle modifications and PCOS (referring to hyperandrogenism, insulin resistance as well as obesity) and also considered the priorities for future research. These results might be an invaluable tool to serve as a guide in lifestyle modifications as the intervention for PCOS and other related endocrine disorders.

Keywords: polycystic ovarian syndrome (PCOS), lifestyle modifications, insulin resistance, hyperandrogenism, obesity

BACKGROUND

Polycystic ovary syndrome (PCOS) is a kind of common endocrine and metabolic disorder which disturbs reproductive-age female individuals (1). The symptoms of PCOS involved serious reproductive dysfunctions (including infertility and pregnancy complications) (2, 3), unbalanced metabolic functions (including insulin resistance, type 2 diabetes, and so on) as well as psychological disorders (mainly including depression and anxiety) and other implications (4), which disturb female patients whose ages range from adolescence to menopause. Recently, lifestyle modification is widely considered to be the cornerstone of many endocrine and metabolic disorders (5, 6). An increasing number of studies investigated the effectiveness and the frequency of lifestyle modification management in PCOS treatment (5). It is acknowledged that lifestyle plays a vital role in the development of PCOS, and lifestyle interventions are necessary. It seems that the lifestyle

modification for PCOS is an old story without any new tales; however, the kind of lifestyle modification that would be effective for PCOS, the difference between various modifications for different populations, and the underlying mechanism of the modifications are still uncertain. Herein we provide a comprehensive review of the influence of lifestyle modifications on the course of PCOS.

METHODS

Search Strategy and Design

We selected PubMed database for the systematic literature search. The search strategy included (i) “polycystic ovary syndrome” and its synonyms; (ii) “lifestyle”, “exercise therapy”, “behavior therapy”, “diet therapy”, and their synonyms; and (iii) “weight loss” and its synonyms. The outcome of the literature review was weight loss with different interventions (diverse lifestyle modifications).

Selection Criteria

We observed the inclusion criteria including (i) randomized controlled trials (RCTs), (ii) participants with polycystic ovary syndrome according to the Rotterdam criteria, (iii) intervention: lifestyle modification (with a clear description of methods) without pharmacological components, (iv) weight loss as outcome, and (v) follow-up of more than 24 weeks.

RESULTS

From the results in **Table 1**, a healthy eating diet and educational programs would lead to more weight loss. The outcomes after a diet modification, an exercise modification, and a combination of diet and exercise are significantly different. A high-protein diet also leads to weight loss when compared with a standard protein diet. However, there was no significant difference between a vegan diet and a caloric diet. No significant difference was also found between a low-glycemic-index (GI) diet and a hypocaloric healthy eating diet.

PCOS

PCOS is well acknowledged as a kind of disorder with both endocrine dysfunction and metabolic dysfunction (17), which impacts almost 20% of female patients of reproductive age. The symptoms of PCOS include androgen excess (hirsutism and/or hyperandrogenemia) and ovarian dysfunction (oligo-ovulation and/or polycystic ovarian morphology) (18). As studies focus on PCOS in-depth, insulin resistance and, subsequently, compensatory hyperinsulinism are regarded as two main mediators of hyperandrogenism in PCOS, both in animal models and in human bodies. It is widely acknowledged that hyperandrogenism and insulin resistance are common in PCOS. As an increasing number of studies focus on the phenotype and underlying mechanisms of PCOS, it is well demonstrated that insulin resistance and hyperinsulinism are responsible for the excessive androgen secretion in PCOS (19) since insulin could

react on the ovary as a cordonadotropin and trigger androgen secretion from the adrenal glands. Therefore, it is suggested that insulin resistance and hyperinsulinism are the pathophysiological factors in the development of PCOS. Many studies hypothesized that PCOS might be triggered by hyperandrogenism together with some pathophysiological factors and subsequently promote insulin resistance and hyperinsulinism (20). Insulin resistance and hyperinsulinism could induce androgen secretion by the ovaries and adrenal glands in PCOS patients in return (21). Thus, a large proportion of women with androgen excess and/or ovulatory dysfunction are also disturbed by insulin resistance, suggesting that hyperandrogenism and insulin resistance are in a vicious circle in PCOS. One of the characterizations of PCOS is heterogeneity. In view of pathophysiological characteristics, the factors accounting for PCOS heterogeneity mainly include obesity, insulin resistance, abdominal adiposity, and so on. Studies have reported that peripheral insulin resistance (insulin resistance exists in muscle tissues and adipose tissues) is actually a characteristic of PCOS patients with obesity (18). Moreover, insulin resistance might be present even in PCOS women who are not obese (22). However, many studies have reported that hyperandrogenism might be one of the common characteristics (23). Hyperandrogenism alone would induce PCOS without any other factors as shown in some case reports (24). In some cases, PCOS would also be noticed to fully manifest with both hyperandrogenism and the above-mentioned pathophysiological characteristics (obesity, insulin resistance, and abdominal adiposity) (25). Thus, excess androgen might be necessary for developing PCOS. Considering that the frequent familial aggregation of PCOS might also be relative to the primary steroidogenic abnormality and the pathophysiological characteristics, it is not complicated to understand the genetic predisposition of PCOS. Recently, it is well acknowledged that familial aggregation is one of the characteristics in PCOS, which indicates that PCOS might be a kind of disorder with a certain genetic basis (26). However, enormous genome-wide relevant studies reported that the associations of only a few genetic variants and mutations have been replicated in different populations in PCOS patients (27). Familial aggregation might be linked to certain environmental influences which only exist in the families affected, including lifestyle during fetal and childhood development, certain environmental exposure and certain drugs, aging process as well as dietary habits, most of which might contribute to the development of PCOS (28). Based on the characteristic of familial aggregation of PCOS, it is reasonable to speculate that lifestyle modification might benefit the PCOS patients.

Lifestyle Modifications

In recent years, lifestyle modifications are regarded as the cornerstone of all interventions against PCOS. Lifestyle modifications are regarded as the first-line management for patients disturbed by overweight or obesity (17). The most effective interventions include applicable diet modifications, increased physical activity and exercise modifications, and strategies to maintain adherence (29). Lifestyle modifications

TABLE 1 | Results of the 10 enrolled randomized controlled trial studies.

Year	Author	Grouping factors	Results Grouping 1	Grouping 2	Grouping 3	Control group	Significance
2018	Oberg E (7)	Behavioral intervention vs. minimal intervention	Mean weight loss -2.1%			Mean weight loss -1.0%	P = 0.002
2015	Wong J (8)	Low-glycemic-load diet vs. low-fat diet	Mean weight loss ± 0.8 kg (-1.2%)	-1.2	Mean weight loss -4.8 ± 1.6 kg (-5.5%)		P = 0.02
2015	Marzouk T (9)	Hypocaloric and healthy eating diet + educational program vs. healthy eating, no caloric restriction	Mean weight loss 90.8–83.7 kg (-3.9%)		Mean weight loss 90.5–90.1 kg (-0.4%)		P = 0.041
2014	Turner G (10)	Vegan diet vs. low-calorie diet	Mean weight loss 1.1%		Mean weight loss -0%		Not significant
2012	Sorensen L (11)	High-protein diet vs. standard protein diet	Mean weight loss 81.8–74.1 kg (7.7 kg) -9.4%			Mean weight loss 78.7–75.4 kg (3.3 kg) -4.2%	P = 0.002
2011	Egan N (12)	Low-glycemic-index diet vs. hypocaloric healthy eating diet	Median weight change -5.8 kg	Median weight change -4.5 kg			Not significant
2011	Nybacka A (13)	Diet vs. exercise vs. diet + exercise	Mean weight loss -6%	Mean weight loss -3%	Mean weight loss -5%		P < 0.001
2010	Marsh (14)	Low-glycemic-index diet vs. conventional healthy diet	Mean weight loss -5.2%, ITT: -3.2%	Mean weight loss -4.2%, ITT: -2.1%			Not significant
2008	Brown A (15)	Exercise vs. no exercise	Median weight change -1.29%			Median weight change +0.45%	P < 0.001
2008	Thomson R (16)	Diet vs. diet + aerobic exercise vs. diet + aerobic resistance exercise	Mean weight loss ± 1.6%	-8.9	Mean weight loss -10.6 ± 1.7%	Mean weight loss -8.7 ± 1.7%	Not significant

also appear to draw the ovulation function (30) as well as the menstrual cycle (31) into a regular level, which subsequently increases the successful pregnancy rates in PCOS patients. The studies reported that almost half of the PCOS patients would gain improvement both in regular menstrual cycle and ovulation function depending on the lifestyle modifications. In addition, lifestyle modifications could provide improvements such as alleviation of anxiety and improved quality of life, particularly in obese female patients with PCOS.

From the results shown in **Table 1**, a healthy eating diet and involvement in educational programs would lead to more weight loss—for example, Oberg E found that in terms of behavioral intervention, minimal intervention would help people attain weight loss (**Table 1**). The outcomes after diet modification, exercise modification, and the combination of diet with exercise are significantly different. A high-protein diet also leads to weight loss when compared with the standard protein diet. However, there was no significant difference between a vegan diet and a caloric diet. No significant difference was found between a low-GI diet and a hypocaloric healthy eating diet.

Mechanism of Lifestyle Modifications in PCOS

Lifestyle modifications (including diet, exercise, sleep, and so on) are regarded to play roles in the development of PCOS by regulating insulin sensitivity and keeping the weight balanced as well as governing normal androgen production. It was reported that lifestyle changes also appear to influence the restoration of ovulation and regular menstrual cycles and increased the pregnancy rates in overweight or obese anovulatory patients with PCOS. It is widely acknowledged that obesity is a vital

mediator in the development of PCOS. The level of sex-hormone-binding globulin is decreased in obese females (31), resulting in elevated androgen in the circulation and then in the target tissue, which disrupts normal ovulatory function (32). Additionally, obesity is associated with an elevated risk of metabolic syndrome, diabetes mellitus (type 2 diabetes), and insulin resistance in female bodies. Some studies compared the effects of lifestyle modifications with the effects of the combination of metformin and lifestyle modifications against PCOS and found that lifestyle modifications could reduce insulin resistance and increase the serum levels of sex-hormone-binding globulins when compared with metformin (33). Many studies also analyzed the effects of improved manifestations of PCOS by comparing the management of lifestyle modifications to the management of a combination of lifestyle modifications and other interventions (34). Negar reported their analysis based on 12 RCTs including 608 participants in which they witnessed a significant decrease in subcutaneous fat in subjects with “lifestyle (including daily physical activity, limited food intake, and so on) combined with metformin” compared with “lifestyle combined with placebo”. It was reported that both lifestyle modifications alone or a combination of lifestyle modifications and hormonal contraceptives have the potential to improve sexual function (35).

Exercise Modifications

As increasing studies focus on the roles of physical activities in human health, the evidence showed that in the management of PCOS, exercise activities would help female patients gain benefits, and this view is becoming accepted among doctors and patients (36, 37). When considering the appropriate exercise activities to alleviate the symptom of PCOS, it is always puzzling how to set the

appropriate exercise intensity and frequency. Recently, a meta-analysis reported that improvements in health outcomes are more likely to be linked to the exercise intensity rather than the exercise itself. An RCT study indicated exercise modifications with vigorous intensity (eight consecutive weeks and three sessions of supervised exercise training each week for the final four consecutive weeks). Each session lasts approximately 60 min and will involve 40 min of an individualized exercise protocol performed either on a cycle ergometer or a motorized treadmill preceded by a 10-min warm-up and followed by a 10-min cool-down) might have a better impact on the outcomes of PCOS (insulin resistance decreased significantly) (38). On the contrary, PCOS patients are found to be more likely to stay sedentary rather than perform vigorous exercises. Moderate aerobic exercise could also improve the insulin sensitivity of PCOS in the short term. Some other studies reported that women with PCOS could gain improvement, in terms of insulin sensitivity and abnormal androgen level, *via* vigorous aerobic exercise and resistance training (39). The minimum aerobic activity is recommended as more than 150 min per week, including intensive exercise for more than 90 min (2).

Diet Modifications

While it is recommended to reduce the calorie intake and induce weight loss among PCOS women with obesity, most of the current proposed recommendations regarding dietary modifications in PCOS are based on studies in obese women without PCOS. It was reported that there is limited evidence that any specific diet type is better than others (40). Some studies reported that once the intake of carbohydrates is less than 45% of the total daily calories, the low-carbohydrate diet might be helpful to decrease the body mass index as well as the serum levels of total cholesterol in PCOS subjects (41). Furthermore, studies indicate that maintaining the low-carbohydrate diet for more than 1 month could significantly increase the levels of follicle-stimulating hormone and sex-hormone-binding globulin (36). Even though some evidence indicates the effect of the low-carbohydrate diet on PCOS, the definitive mechanisms to explain the relationship are still unclear. It is well acknowledged that metformin has similar effects in decreasing body weight. Some studies compared the effects of diet modifications with the effects of the combination of metformin and lifestyle modifications against PCOS. It was reported that diet modifications could reduce insulin resistance and increase the serum levels of sex-hormone-binding globulins when compared with metformin (34).

What is more, weight loss could improve the features of PCOS patients regardless of dietary composition (42). Unfortunately, lifestyle modifications, including diet modifications, are seldom effective in the long run, which are in line with the results from the management of anti-obesity drugs. The unsatisfactory long-term results might be associated with the fact that the female subjects regain weight and fail to keep a normal body mass index (BMI).

Weight Modifications

While the complex clinical heterogeneity of PCOS brings up the lack of a clear understanding of obesity in PCOS, it is widely

accepted that obesity would increase insulin resistance and hyperandrogenism. It was reported that just a minor weight loss of 5–10% could play a role in significantly alleviating reproductive disorders (43), metabolic dysfunction, and even the psychological symptoms of PCOS patients (44). Thus, weight modification is recommended as a first step in the management of PCOS patients who are overweight or obese (45).

If the PCOS patient is disturbed by infertility, it is recommended that women with PCOS and obesity should delay therapy against infertility and achieve the weight modifications first because obesity is linked to a higher risk of increased rates of miscarriage and preeclampsia in perinatal PCOS women. It is believed that PCOS patients who are overweight/obese are more likely to face mood disorders, including anxiety, depression, and so on. However, the degree of the increased risk of excess weight and the impact on the prevalence and severity of the features of PCOS remains unclear. Anti-obesity drugs, including orlistat, could also be considered in PCOS patients who cannot achieve weight modification with diet modification and exercise modification (45, 46). Women with PCOS and normal weight and BMI also have an increased risk for metabolic disorders and chronic fatigue. A similar exercise program combined with diet modification is also recommended because these modifications could enhance insulin sensitivity (47, 48). Moreover, more studies are needed on the effects of weight modifications on normal-weight patients with PCOS. Thus, it is recommended that females with PCOS pursue weight modifications and prevent excessive weight gain by weight monitoring and maintaining appropriate BMI and waist circumference.

Mood Modifications

An increasing volume of evidence shows that both adolescent and adult females with PCOS are disturbed by mood disturbances, including depression and anxiety (49). It was reported that females with PCOS underwent a higher risk of depression, anxiety, and perceived stress when compared with women without PCOS (50). Since PCOS is linked to an increased risk of depression, anxiety, and some other mood disorders, screening and effective mood modifications for these disorders might be warranted.

There are several shared links and connections between depression- and PCOS-associated abnormalities, such as excessive androgen secretion, insulin resistance as well as obesity. These shared connections between depression and PCOS might help in finding potential therapies for depression in PCOS (51). A kind of appropriate and applicable mood modification for the two treatments is regarded as the potential modification which could help females with PCOS to lead a better life.

Sleep Modifications

It is important that psychological issues are considered as both a potential risk and a maintaining factor of illness, particularly in adolescent and young female subjects (52). As per the in-depth investigation and data analysis, a large proportion of psychological disorders with PCOS are sleep disorders. Since sleep disorders impact the development of PCOS, management relative to sleep modifications is considered an integral part of lifestyle modifications on females with PCOS. There is ample

evidence that sleep deprivation is associated with an increased risk of insulin resistance and obesity as well as type 2 diabetes (53). The mechanisms of the associations have been proven to be linked to relative autonomic pathways, endocrine disorders, and inflammatory status, which are responsible for the development of PCOS (54). Therefore, it is plausible that sleep modifications are of great significance among PCOS patients. Some studies reported that women are more likely to be disturbed by type 2 diabetes if the length of sleep is not more than 5 h per night when compared with women whose length of sleep ranges from 7 to 8 h per night. A study compared the quality of sleep by recording the percentage of rapid eye movement sleep via polysomnography and found that the percent sleep efficiency of obese females with PCOS is lower than that of not only normal-weight females but also obese adolescent females without PCOS (55). Ensuring adequate sleep with high quality would lead to a decreased risk of disturbance not only in obesity and insulin resistance but also in cardiovascular risk, suggesting that sleep modification could modify PCOS as an original modification.

SUMMARY AND PERSPECTIVES

PCOS is a kind of common endocrine and metabolic disorder which disturbs female subjects at reproductive ages. Since increasing evidence indicates that PCOS is frequently linked to abdominal adiposity, insulin resistance, obesity, metabolic disorders, and cardiovascular risk factors and becomes a complex disorder with environmental effects, such as diet and other lifestyle factors, lifestyle modification is therefore regarded as the first line of management for PCOS patients.

PCOS women who are overweight or obese not only are exposed to metabolic and cardiovascular risk but also suffer from potential mental problems and risk adverse obstetric and perinatal outcomes, such as gestational diabetes and preterm birth. Obesity leads to high healthcare costs, which means that it would increase the investment in lifestyle modification. In **Table 1**, our data suggested that a healthy diet and increased physical activity should be encouraged for weight loss, which was in line with many published suggestions or guidelines. The conclusion would undoubtedly propose new insights and promising strategies to support clinical practices.

We review the lifestyle modifications in PCOS, including diet modifications, exercise modifications, sleep modifications, mood modifications, and weight modifications. While physical modification, appropriate dietary modification, and maintaining healthy sleep modification and mood modification are recommended for the management of various PCOS conditions, more perspective studies are needed on the effects of lifestyle modifications on PCOS to figure out and develop accurate and individualized guidelines. Lifestyle modifications in PCOS are not old stories but also new tales.

Lifestyle management in polycystic ovary syndrome – beyond diet and physical activity

Stephanie Cowan^{1*} , Siew Lim², Chelsea Alycia¹, Stephanie Pirotta³, Rebecca Thomson⁴, Melanie Gibson-Helm^{1,5}, Rebecca Blackmore⁶, Negar Naderpoor¹, Christie Bennett⁷, Carolyn Ee⁸, Vibhuti Rao⁸, Aya Mousa¹, Simon Alesi¹ and Lisa Moran¹

Abstract

Polycystic ovary syndrome (PCOS) is a common condition affecting reproductive-aged women with reproductive, metabolic and psychological consequences. Weight and lifestyle (diet, physical activity and behavioural) management are first-line therapy in international evidence-based guidelines for PCOS. While these recommend following population-level diet and physical activity guidelines, there is ongoing interest and research in the potential benefit of including psychological and sleep interventions, as well as a range of traditional, complimentary and integrative medicine (TCIM) approaches, for optimal management of PCOS. There is limited evidence to recommend a specific diet composition for PCOS with approaches including modifying protein, carbohydrate or fat quality or quantity generally having similar effects on the presentations of PCOS. With regards to physical activity, promising evidence supports the provision of vigorous aerobic exercise, which has been shown to improve body composition, cardiorespiratory fitness and insulin resistance. Psychological and sleep interventions are also important considerations, with women displaying poor emotional wellbeing and higher rates of clinical and subclinical sleep disturbance, potentially limiting their ability to make positive lifestyle change. While optimising sleep and emotional wellbeing may aid symptom management in PCOS, research exploring the efficacy of clinical interventions is lacking. Uptake of TCIM approaches, in particular supplement and herbal medicine use, by women with PCOS is growing. However, there is currently insufficient evidence to support integration into routine clinical practice. Research investigating inositol supplementation have produced the most promising findings, showing improved metabolic profiles and reduced hyperandrogenism. Findings for other supplements, herbal medicines, acupuncture and yoga is so far inconsistent, and to reduce heterogeneity more research in specific PCOS populations, (e.g. defined age and BMI ranges) and consistent approaches to intervention delivery, duration and comparators are needed. While there are a range of lifestyle components in addition to population-recommendations for diet and physical activity of potential benefit in PCOS, robust clinical trials are warranted to expand the relatively limited evidence-base regarding holistic lifestyle management. With consumer interest in holistic healthcare rising, healthcare providers will be required to broaden their knowledge pertaining to how these therapies can be safely and appropriately utilised as adjuncts to conventional medical management.

Introduction

Polycystic ovary syndrome (PCOS) is a common condition affecting up to 13% of reproductive-aged women [1]. It is diagnosed through the European Society for Human Reproduction and Embryology/American Society for Reproductive Medicine (ESRHE/ASRM) criteria, requiring two of the following features: polycystic ovaries on ultrasound, oligoovulatory or anovulatory cycles and biochemical or clinical hyperandrogenism [2]. Women with PCOS experience a combination of reproductive (infertility, pregnancy complications) [3], metabolic (risk factors for and conditions of type 2 diabetes (T2DM) and cardiovascular disease (CVD)) [4, 5] and psychological (conditions including anxiety, depression, poor quality of life (QoL), disordered eating) comorbidities [6, 7].

Insulin resistance (IR) is defined as a key pathophysiological feature in PCOS, contributing to hyperandrogenism and worsening the clinical presentation of PCOS. While lean women present with IR in a form that is mechanistically different from IR caused by excess weight, overweight and obesity further exacerbate IR and consequent hyperinsulinaemia [8]. Women with PCOS also display a higher rate of weight gain over time [9] and a greater prevalence of overweight and obesity [10], which can further contribute to this worsening of IR and hence worsening of the presentation of PCOS [11]. The reason for this is unclear, but may be related to differences in intrinsic psychological and biological mechanisms [12–15], or extrinsic lifestyle factors such as diet and physical activity [16, 17]. Improving IR and excess adiposity are therefore key targets in PCOS management.

The International Evidence-Based Guideline for the Assessment and Management of PCOS [18], highlights lifestyle intervention as the primary early management strategy. Lifestyle interventions are traditionally defined as those designed to improve dietary intake or physical activity through appropriate behavioural support. In the 2018 PCOS guideline, lifestyle management is recommended for general health benefits [18]. Given that excess weight is associated with increased IR in PCOS [8], the guideline additionally promotes weight management, defined as: 1) weight gain prevention in all women with PCOS, and 2) achieving and maintaining modest weight loss in women with excess weight [18].

Lifestyle interventions in PCOS management can also be viewed as a broader construct beyond physical health. Since the emergence of the biopsychosocial model of healthcare in 1977, health disciplines have seen a gradual shift away from the classical biomedical model (where health is defined as the ‘absence of disease’) towards whole person or holistic care [19]. This is an approach that reflects many facets of the patient context, via integrating care that addresses biological, psychological, social, spiritual and ecological

aspects [20]. It therefore requires a range of different treatment strategies to improve health. Provision of whole person or holistic care has been identified as a core objective of healthcare reforms internationally [21–23]. In line with these reforms the PCOS guideline recognises the importance of emotional wellbeing to overall health and QoL in women living with PCOS [18]. It also highlights evidence which suggests that the psychological impact associated with PCOS is under-appreciated in clinical care [4, 5], and that few women are satisfied with the mental health support they receive [6, 7]. Recommendations for appropriate screening, assessment and treatment strategies for anxiety, depression, psychosexual dysfunction, eating disorders and poor body image are provided [18]. These specific areas of emotional wellbeing are of particular concern, with research showing a higher prevalence and severity of depression and anxiety [24, 25], lower scores for satisfaction with sex life and feeling sexually attractive [26] and a higher prevalence of disordered eating and eating disorders [7] in women with PCOS. Features of PCOS, in particular hirsutism and increased weight, have also been shown to negatively affect body image [27, 28], with poor body image being strongly related to depression in women with PCOS [29, 30].

While the current PCOS guideline is comprehensive, considering all available evidence at the time of development and providing best-practice recommendations for necessary screening, risk assessment and management, it could not possibly cover all aspects of PCOS care. An International Delphi process was used to prioritise clinical questions, with consensus reached through extensive consultation with both consumers and multidisciplinary clinicians with expertise in PCOS care. Therapies, such as traditional, complementary and integrative medicine (TCIM), supplement use, sleep and meditation interventions are either briefly considered or not at all included in the 2018 PCOS guideline. Many of these therapies are novel and there is a paucity of evidence to support intervention efficacy on PCOS outcomes. However, as patient interest in these types of non-pharmacological interventions are growing [31–35], it is prudent to provide more guidance to healthcare providers in this area on their potential efficacy in PCOS. Whole person or holistic care recognises that the doctor-patient relationship should be one of open dialogue, where healthcare providers involve the patient in negotiating their care and recognises patient’s autonomy to guide treatment (Figure 1) [36].

This review provides an extensive overview of evidence to date on lifestyle strategies used to optimise management of PCOS. Using a holistic definition of patient care, this review considers the traditional components of lifestyle change (diet, physical activity and behavioural change), psychological and sleep interventions, as well as TCIM approaches (supplements, herbal medicine,

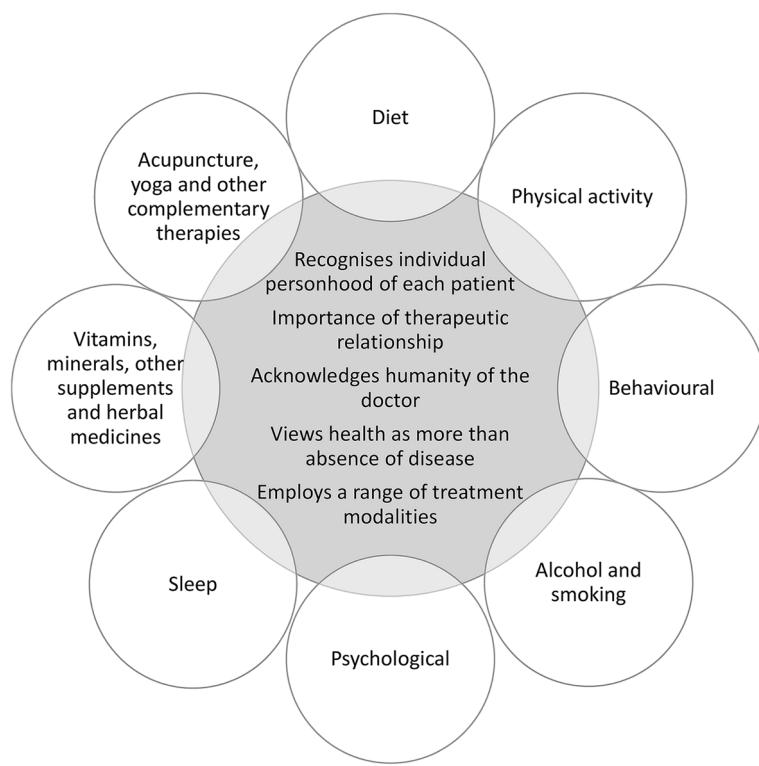

Fig. 1 Viewing lifestyle modifications through a whole person or holistic care lens. The key features of whole person or holistic care listed in the centre of the figure have been adapted from Thomas et al. [20]. ‘Recognises individual personhood’ relates to focusing on the unique needs of the person rather than the disease. ‘Importance of therapeutic relationship’ emphasises patient autonomy and responsibility. ‘Acknowledges humanity of the doctor’ considers the doctors’ ability to self-reflect on how they engage in the care of the patient. ‘Health as more than absence of disease’ incorporates the mental, emotional, physical, environmental and social needs of the patient. ‘Employs a range of treatment modalities’ promotes continuity of care across health disciplines, and while it may include traditional, complementary and integrative medicine (TCIM), TCIM is not holistic if used in isolation and without adequate integration into conventional healthcare

acupuncture and yoga). To improve translation of findings, evidence summaries are accompanied by an overview of relevant recommendations from the existing PCOS guideline. This highlights where emerging evidence supports current recommendations or provides new insights for research. As this is a narrative review, while evidence summaries include peer-reviewed journal articles identified from databases including Medline OVID, this is supplemented by expert opinion of the authors.

Traditional lifestyle and weight management

The PCOS guideline recommends the promotion of healthy lifestyle behaviours in all women with PCOS, to achieve and/or maintain a healthy weight and to optimise general health [18]. In women with excess weight, a weight loss of 5–10% is advised, aiming for an energy deficit of 30% or 500–750 kcal/day (1200–1500 kcal/day). While weight management is seen as a core component of lifestyle interventions, the guideline recognises that a healthy lifestyle provides benefits that occur independent of weight change.

A recent Cochrane review of 15 randomised controlled trials (RCT) and 498 participants, reported that lifestyle interventions compared with minimal intervention or usual care, significantly reduces weight (kg) and body mass index (BMI) and improves secondary reproductive outcomes such as free androgen index (FAI), testosterone (T), sex hormone-binding globulin (SHBG) and hirsutism (Ferriman-Gallwey score) [37]. In terms of metabolic outcomes, lifestyle intervention resulted in significant reductions in total cholesterol (TC), low density lipoprotein cholesterol (LDL-C) and fasting insulin (FINS). These findings are largely similar to that of other systematic reviews [38–41]. While no studies in the Cochrane review assessed clinical reproductive outcomes [37], individual trials that were not included in the review have reported that lifestyle interventions resulting in modest weight loss (2–5% total body weight) improve ovulation and menstrual regularity [42–45]. Losing >5% of weight is additionally associated with being able to conceive, having live births, reduction of ovarian volume and reduction in the number of follicles [46–52].

Table 1 Reviews and experimental studies investigating the effects of diet on polycystic ovary syndrome outcomes

Dietary intervention	N study design	N studies; N participants	Main findings ^a	References
Low CHO	2 SR/MA (27 RCT total - 18 RCT using low CHO diet) [56, 85] 1 SR (5 RCT total - 1 RCT using low CHO diet) [16]	14; 901	Low CHO compared with control diets [56]: ↓ BMI, HOMA-IR, TC, LDL-C ↑ SHBG ↔ LH, T, HDL-C Dietary intervention ↓ HOMA-IR, FINS, FGL, BMI, BW, WC compared with minimal intervention, and subgroup analysis showed no additional benefits for low CHO diets [85] Weight loss improved the presentation of PCOS regardless of dietary composition, with no subtle differences observed for low CHO diets [16]	Shang et al. 2020 [85] Zhang et al. 2019 [56] Moran et al. 2013 [16]
Low GI	1 SR/MA (10 RCT total - 8 RCT using low GI diet) [55] 1 SR (5 RCT total - 1 RCT using low GI diet) [16] 4 Pre-post prospective [61, 76, 77, 118] 1 RCT [78]	16 ^b ; 582	High GI compared with low GI diets [55]: ↓ HOMA-IR, FINS, TC, LDL-C, TAG, WC, T ↔ FGL, HDL-C, BW, FAI Low GI diets had greater improvements in IR, TC, HDL-C, fibrinogen, menstrual regularity and QoL [16] Low GI diets followed for ≥ 12 weeks: ↓ BW [76, 77], BMI [76, 77], BFM [77], WC [77], WHR [77], FINS [76, 77], FGL [77], TC [77], LDL-C [77], TAG [77], T [77], LH [77], androstenedione [77], prolactin [77] ↑ insulin sensitivity (HOMA2-IS) [61], synthesis of predominantly anti-inflammatory eicosanoid mediators (e.g. 16(R)/16(S)-HETE, 13(S)-HODE, 9(S)-HODE, 15(S)-HETE, 12(S)-HETE, 5(S)-oxoETE, 5(S)-HETE) [118], fasting glucagon (higher glucagon levels associated with lower levels of self-reported hunger) [78]	Kazemi et al. 2020 [55] Moran et al. 2013 [16] Shishrehgar et al. 2019 [76] Barr et al. 2016 [61] Szczuko et al. 2018 [77] Szczuko et al. 2017 [118] Hoover et al. 2021 [78]
High protein	1 SR (5 RCT total - 3 RCT using high protein diet) [16] 2 Pre-post prospective [73, 74] 6 RCT [92, 94–97]	11; 308	High protein diets improve depression and self-esteem [16] ↓ BFM [74, 97], BW [73, 74, 97], BMI [73, 74], WC [73, 74, 97], WHR [73], FINS [74, 98], FGL [97], HOMA-IR [73, 98], TAG [73], VLDL-C [73], T [73, 98], Ferriman-Gallwey scores [73] High protein and standard/low protein diet ↓ BW [92, 94, 95], BMI [92, 94, 95], BFM [95], WC [92, 94], WHR [94], FINS [95, 96], HOMA-IR [95], TAG [96], LDL-C [98] CRP [96], MPA [96], leptin [95], T [98], DHEAS [98], FAI [98] and there was ↔ between high and standard/low protein diets	Moran et al. 2013 [16] Moran et al. 2010 [96] Moran et al. 2004 [95] Sorensen et al. 2012 [97] Toscani et al. 2011 [92] Nadjarzadeh et al. 2021 [94] Phy et al. 2015 [73] Pohlmeier et al. 2014 [74] Mehrabani et al. 2012 [98]
Low fat	1 SR/MA (19 RCT total - 1 RCT using low fat diet) [85] 1 SR (5 RCT total - 1 RCT using low fat diet) [16] 1 RCT [107]	3; 137	Dietary intervention ↓ HOMA-IR, FINS, FGL, BMI, BW, WC compared with minimal intervention, and subgroup analysis showed no additional benefits for low fat diets [85] Weight loss improved the presentation of PCOS regardless of dietary composition, with no subtle differences observed for low fat diets [16] Low fat (25% E fat) ↓ BW, BFM, BMI though there was ↔ between low fat and standard fat (35% E fat) diets [107]	Shang et al. 2020 [85] Moran et al. 2013 [16] Wong et al. 2016 [107]

Table 1 (continued)

Dietary intervention	N study design	N studies; N participants	Main findings ^a	References
Fatty acids	1 SR (5 RCT total - 1 RCT using MUFA enriched diet) [16] 3 RCT [86, 102, 105] 1 controlled trial (not randomised) [103] ^c	5; 146	MUFA enriched diets may produce greater weight loss when compared to other dietary patterns [16] MUFA enriched compared with PUFA enriched diets ↓ FGL [103], glucose response to OGTT [103], HgBA1 [102] Diets with a higher alpha-linolenic acid, lower omega-6/omega-3 ratio and saturated fat content ↓ TAG, TC/HDL-C, LDL-C-/HDL-C, TAG/HDL-C, and HOMA-IR [105] High total and saturated fat meals compared with high fibre low fat meals produce prolonged ↓ in T [86]	Moran et al. 2013 [16] Yahay et al. 2021 [105] Kalgaonkar et al. 2011 [102] Kasim-Karakas et al. 2004 [103] Katcher et al. 2009 [86]
DASH	1 SR/MA (19 RCT total - 4 RCT using DASH diet) [85]	4; 228	Dietary intervention ↓ HOMA-IR, FINS, FGL, BMI, BW, WC compared with minimal intervention, and subgroup analysis showed DASH diet was more effective at improving insulin sensitivity [85]	Shang et al. 2020 [85]
Plant-based	3 RCT	3; 108	Plant-based (35% animal protein, 35% textured soy protein, 30% vegetable protein) compared to control (70% animal protein, 30% vegetable protein) ↓ BMI, FGL, FINS, TAG, HOMA-IR, T, MDA and ↑ QUICKI [67] Plant-based and control diets (calorie restriction [68] and general dietary recommendations [72]) ↓ BW [68], HOMA-IR [72], T [72], LH/FSH [72] and there was ↔ between plant-based and control diets	Turner-McGrievy et al. 2014 [68] Kazemi et al. 2020 [72] Karamali et al. 2018 [67]
Meal pattern	1 RCT	1; 40	6 meals/day compared with 3 meals/day: ↓ FINS ↑ post-OGTT insulin sensitivity	Papakonstantinou et al. 2016 [111]
Meal timing	1 RCT	1; 60	Consuming a high kilojoule breakfast compared with a high kilojoule dinner: ↓ FGL, FINS, HOMA-IR, T ↑ SHBG	Jakubowicz et al. 2013 [66]

^a Summarises commonly used measures in PCOS research and does not report on all measured outcomes. For prospective pre-post studies significant changes from baseline are reported. For RCTs significant changes between intervention(s) and control are reported. Only experimental studies not already summarised in included systematic reviews/meta-analysis are presented

^b Shishregar et al. 2019 total study population included 62 women though only findings for the women with PCOS ($n=28$) are included

^c While habitual diet (control) was not enriched with MUFA, nutritional analysis showed that it was rich in oleic acid

Although weight loss has shown clear benefits to PCOS outcomes, including not only on reproductive function, but also glucoregulatory status, androgen status and lipid profiles [42–52], there are varying degrees of responsiveness to weight loss in terms of improvement of PCOS symptoms. One study by Pasquali et al. [53] found that when women achieved similar levels of weight loss (>5% weight) only one-third displayed a full recovery from PCOS, with the remainder showing

only partial or no recovery. Higher waist circumference (WC), waist-hip-ratio (WHR) and androstenedione at baseline were associated with a poorer chance of successful outcomes [53], suggesting that central adiposity and more severe hyperandrogenism may predict responsiveness to weight loss interventions in PCOS. Huber-Buchholz et al. [45] also reported women who achieve greater reductions in central fat and insulin sensitivity show greater symptom improvement with

weight loss. This suggests that lifestyle interventions which simultaneously reduce IR and improve body composition (namely fat distribution), may help to optimise outcomes in PCOS management independent of changes in weight status.

Diet

The 2018 PCOS guideline recognises there is insufficient evidence to suggest that any specific dietary approaches provide greater benefits on health outcomes [18]. Dietary recommendations may take on a variety of balanced dietary strategies according to the individual's lifestyle needs and preferences, as per general population recommendations [18]. This advice is based on a systematic review comparing different dietary compositions (e.g. low carbohydrate, low glycaemic index (GI) and glycaemic load (GL), high protein, monounsaturated fatty acid (MUFA) enriched and fat counting diets) to best manage PCOS, identifying minimal differences between diets on anthropometric outcomes, concluding weight loss improves the presentation of PCOS regardless of dietary composition [16, 54]. There is now an emerging body of evidence that suggests a range of dietary strategies may produce favourable effects on PCOS features that occur independent of weight loss. It is important that the emerging findings from these studies are thoroughly considered to support consumer and health professional interests. To summarise current evidence this review has grouped diets in terms of those that modify carbohydrates, protein and fat, as well as specific dietary patterns.

Carbohydrates

The use of altered carbohydrate composition remains the most researched dietary approach for PCOS management. Two systematic reviews published after guideline inception support altered carbohydrate intake to improve intermediate markers of PCOS [55, 56], finding that altering carbohydrate type, as opposed to content, is preferable to better manage PCOS [55]. RCTs [57–72] and pre-post intervention studies [73–80] demonstrate that following a low GI/GL diet for at least eight weeks significantly reduces WC [55, 73, 74] and BMI when compared to high GI/GL [56] or a regular diet [73–76], although levels of weight loss are generally comparable to other dietary compositions [59, 60, 72, 74]. These reductions are proposed to be a result of decreased hunger, which may reduce energy intake and make it easier to follow dietary recommendations in the long-term [78, 81–84]. Low GI/GL diets also improve insulin sensitivity and reproductive hormones (T, SHBG, FAI) compared to high carbohydrate [16, 55, 57, 79, 85] or control diets [56, 59, 73–76], contributing to improvements in reproductive function, specifically menstrual regularly [60, 79]. Lastly, low GI/GL diets can improve risk factors for T2DM and CVD, including glucose

[86, 87], TC [55, 56, 59, 75, 77], LDL-C [55, 59, 75, 85], TAG [55, 59, 73] and HDL-C [75], when compared to a regular or high GI/GL diet. It must be noted that beneficial effects of low GI/GL diets may also be attributed to proportional increases in protein and/or fat loads.

Protein

In women with PCOS higher protein intakes may be superior at suppressing androgen levels when compared to high carbohydrate diets. Postprandial research has shown that high protein meals can reduce insulin and dehydroepiandrosterone stimulation compared to meals rich in glucose [88]. Research in the general population has also shown that reduced appetite and energy intakes from low GI/GL diets are related to increased protein intakes [89, 90]. RCTs and pre-post intervention studies found that high protein diets (defined here as protein constituting $\geq 25\%$ energy [91]) consumed for at least four weeks reduce weight [12, 73, 74, 92–96], BMI [73, 74, 92, 95], WC [73, 74, 92, 97], WHR [73] and fat mass [74, 92, 97]. These reductions in anthropometric measures are accompanied by improved FINS [12, 74, 95, 98] and HOMA-IR [12, 73, 95, 98], blood lipids [12, 96], T [73, 92, 94] and hirsutism (Ferriman-Gallwey score) [73]. However, only three of these studies were able to show significant improvements in anthropometric measures [97], insulin sensitivity [98] and blood lipids [12] when compared to low/standard protein [12, 97] or control diets [98]. Only one study investigated effects on mental health outcomes and found that a high protein diet reduced depression and improved self-esteem [99].

Fats

Fatty acid composition is also an important consideration as metabolic disorders associated with PCOS can benefit from increased MUFA and polyunsaturated fatty acid (PUFA) intakes [63–65]. Postprandial research in PCOS reported prolonged reductions in T for high fat compared to low fat meals, which likely results from delayed nutrient absorption [86]. Two acute meal studies in lean and obese women with and without PCOS reported that proatherogenic inflammatory markers [100] and oxidative stress [101] were elevated, independent of but augmented by obesity, following saturated fat ingestion with this associated with worsened IR and androgens. Two experimental studies in PCOS investigated the effects of habitual walnut (PUFA rich diet) [102, 103] and almond (MUFA rich diet) [102] intake for at least six weeks and reported no differences in glucoregulatory status, lipids or androgens with the exception of HbA1c significantly decreasing in the walnut relative to the almond group. Kasim-Karakas et al. [103] reported increased fasting and postprandial glucose

(oral glucose tolerance test (OGTT)) for increased walnut intake compared to habitual (control), which they postulated may be related to the control diet being rich in oleic acid. Together these findings suggest minimal benefit for improving dietary PUFA compared to MUFA content. Two RCTs in women with PCOS investigated the effects of diets rich in olive [104, 105], canola [105] and sunflower [105] oil. Yahay et al. [105] reported 25g/day canola oil caused reductions in TAG, TC/HDL-C, LDL-C/HDL-C, TAG/HDL-C and HOMA, but not androgens, compared to 25 g/day olive and sunflower oils [105]. This may be related to the more favourable fatty acid composition of canola oil, with comparable MUFA content to olive oil, higher alpha-linolenic acid, lower omega-6/omega-3 ratio and saturated fat than both olive and sunflower oils. Douglas et al. [104] reported weight and the acute insulin response (OGTT) were lower following a eucaloric low carbohydrate compared to a eucaloric MUFA-enriched olive oil diet, suggesting that reduced carbohydrate intake may have greater glucoregulatory benefits than increased MUFA intake [104]. Lastly, two RCTs compared hypocaloric low-fat diets to a low carbohydrate [106] or low GI [107] diets, with reductions in weight [106], WC [106], body fat [106, 107], FINS [106] and FAI [106] in both groups but no difference between groups.

Dietary and eating patterns

In addition to diets that focus on specific macronutrient manipulations, there are a range of dietary patterns which have been explored in PCOS management. A systematic review (including 19 studies and 1,193 participants) published after guideline development (2020) found that the Dietary Approaches to Stop Hypertension (DASH) diet (rich in fruit, vegetables, wholegrains, nuts, legumes and low-fat dairy and with a predominantly low-GI carbohydrate profile) was the optimal choice for reducing IR [85]. RCTs in PCOS also report beneficial effects on weight [63, 64], BMI [62, 63], IR [62] and hormonal profile, including SHBG [64], androstenedione [64] and FAI [62] for a DASH compared to a control diet after 8–12 weeks. A vegetarian diet also reduced inflammatory markers (CRP, resistin and adiponectin) compared to a meat inclusive diet [80]. A vegan diet improved weight loss at three, but not six months [68], and a pulse-based diet led to similar reductions in weight, insulin sensitivity and reproductive hormones compared to a healthy control diet [72]. All of these dietary patterns are high in fibre and plant proteins, producing favourable effects on microbial diversity and encouraging production of short-chain fatty acids that possess potential anti-inflammatory actions [108, 109]. With mechanistic animal studies suggesting a possible pathophysiological role of gut microbiota in IR and

ovarian dysfunction, it is possible that metabolic and hormonal benefits associated with plant-based dietary patterns in PCOS are related to increased intakes of dietary prebiotics [110]. However, further mechanistic studies exploring the role of gut microbiota in PCOS and RCTs investigating effects of dietary prebiotics on PCOS outcomes are required.

Lastly, particular eating patterns, such as eating smaller more frequent meals across the day [111] and eating a larger breakfast and smaller dinner [66], have also been found to be beneficial for insulin sensitivity [66, 111] and androgen reductions [66]. This is an important finding, as women with PCOS are more likely to either skip breakfast or consume their breakfast and lunch later in the day [112].

Studies examining specific food items in relation to PCOS outcomes, including raw onions [65], concentrated pomegranate juice [69, 113–115] and flaxseed powder [70, 116] have yielded largely inconsistent results. A core limitation of these single food studies is that foods are never consumed alone within the diet, omitting the influence of the dietary matrix and the interactions that occur amongst dietary constituents within meals. These studies provide limited applicability in the context of formulating practical dietary recommendations [117]. Please see Table 1 for a summary of available evidence from reviews and experimental studies investigating the effects of different types of diets on PCOS outcomes.

Physical activity

The 2018 PCOS guideline recommends ≥150 minutes per week of moderate or ≥75 minutes per week of vigorous intensity exercise for weight gain prevention, and ≥250 minutes per week of moderate or ≥150 minutes per week of vigorous intensity exercise for weight loss and weight regain prevention [18]. Minimising sedentary time and the inclusion of strength training exercise for two days per week is also recommended [18].

To date the most comprehensive review in PCOS (including 27 papers from 18 trials up until June 2017) reported that exercise improved FINS, HOMA-IR, TC, LDL-C, TAG, body composition (body fat percentage and WC) and aerobic fitness ($\text{VO}_{2\text{max}}$) [119] compared with usual care or control groups. In regards to exercise type, subgroup analysis reported aerobic exercise improved BMI, WC, body fat percentage, FINS, HOMA-IR, TC, TAG and $\text{VO}_{2\text{max}}$. In contrast, while resistance training produced unfavourable effects on HDL-C (decrease) and BMI (increase), it improved other measures of anthropometry, including WC. Combined interventions (using both aerobic and resistance training) had no effect on any of the measured markers. Subgroup analysis also found that more outcomes improved when

^a Significant findings from meta-analyses when comparing exercise groups to control

^b Subgroup analyses compared different types of exercise; only 1 study included for combined exercise

interventions were supervised, of a shorter duration (≤ 12 weeks) and were conducted in women who were above a healthy weight [119].

Three more recent systematic reviews have looked at the effects of specific types of exercise on PCOS outcomes [120–122]. These reviews found that vigorous aerobic exercise can improve measures of insulin responsiveness and resistance, including HOMA-IR [121] and the insulin sensitivity index [120]; body composition, including WC [121] and BMI [122]; and cardiorespiratory fitness (VO_{2max}) [121]. High intensity interval training (HIIT) alone may be effective for improving IR and BMI [123], however this has not been consistently shown [124]. Interventions involving a combination of aerobic and resistance exercise [122] or resistance training only [120] did not result in improvements in BMI [122] or weight status [120]. Exercise involving resistance training did result in other beneficial improvements to body composition (reduced body fat, WC and increased lean mass) and strength. This is important, as the degree of

central adiposity predicts responsiveness to weight loss interventions in PCOS [53], and women who achieve greater reductions in central fat show greater symptom improvement with weight loss [45]. Resistance training may also improve androgen levels, though findings are inconsistent and more research is needed to draw definite conclusions [120]. There was insufficient evidence from available data to assess the effects of exercise type on reproductive function [122]. Please see Table 2 for a summary of available evidence from meta-analyses investigating the effects of different types of exercise on PCOS outcomes.

When comparing the effects of exercise and diet combined with diet alone, a systematic review and meta-analysis (three studies) found no differences for any measured outcomes (glucose, insulin HOMA-IR, weight, BMI, WC, body fat, fat free mass, T, SHBG and FAI) [119]. In regards to exercise and diet combined compared to exercise alone, subgroup analysis (including 17 studies) from a large systematic review found that the addition of diet to exercise,

^a Qualitative analysis only

^b Statistical analysis compares order of intervention arms (e.g. counselling followed by exercise versus exercise followed by counselling) and doesn't compare effects of counselling versus exercise

particularly vigorous intensity aerobic exercise, resulted in greater reduction to BMI, WC, FAI and HOMA-IR than exercise only [121]. In regards to exercise (aerobic) alone versus diet alone, one intervention study found that exercise induced weight loss produced greater improvements

in menstrual frequency and ovulation rates [125], with no differences in pregnancy rates [125]. However, this study was not randomised and treatments were self-selected, which may have biased the results and precludes firm conclusions [125].

Table 4 Key observational studies that report non-clinical sleep disruption in polycystic ovary syndrome

Reference	Sample size	Sleep methodology used	Main findings
Moran et al. 2015 [182]	PCOS: n=87 Non-PCOS: n=637	Modified version of the Jenkins Sleep Questionnaire	Women with PCOS were twice as likely to experience sleep disturbance PCOS was associated with difficulty falling asleep and maintaining sleep
Mo et al 2019 [140] ^a	PCOS: n=484 Non-PCOS: n=6094	Sleep duration was self-reported on a work day and non-work day Sleep quality was self-reported through frequency questions about difficulty falling asleep, restless sleep, difficulty sleeping and severe tiredness	Women with/without PCOS had similar sleep duration Women with PCOS had higher prevalence of sleep disturbance, and this relationship maintained even after controlling for BMI, depression, income, marital status, occupation, education status and COB
Bennett et al. 2021 [183] ^a	PCOS: n=464 Non-PCOS: n=5603	Sleep duration was self-reported on a work day and non-work day Sleep quality was self-reported through frequency questions about difficulty falling asleep, restless sleep, difficulty sleeping and severe tiredness	Overall women with PCOS had greater adverse sleep symptoms and higher DGI However, subgroup analysis revealed PCOS was only associated with a higher DGI in women with adequate sleep There was no association between PCOS and DGI in women with poor sleep The higher DGI observed in women with PCOS may only be maintained in women who achieve adequate amounts of good quality sleep
Shreeve et al. 2013 [167]	PCOS: n=15 Non-PCOS: n=18	Actigraphy, PSQI and ESS	Women with PCOS had higher night time melatonin levels Women with PCOS had reduced sleep when compared to controls
Kutanaee et al. 2019 [181]	PCOS: n=201 Non-PCOS: n=199	PSQI	Women with PCOS had lower sleep quality and daytime function Women with PCOS were more likely to utilise medication to assist with sleep

^a Mo et al. [140] and Bennett et al. [183] share the same cohort

Behavioural

The 2018 PCOS guideline promotes the use of behavioural interventions that foster self-efficacy [18]. These include the use of SMART (specific, measurement, achievable, realistic and timely) goals, self-monitoring, stimulus control, problem solving and relapse prevention [18].

Behavioural and cognitive interventions are required to improve sustainability of lifestyle changes, through considering not only the specific behaviour, but also their antecedents, consequences and cognition [126, 127]. Given that women with PCOS show higher rates of weight gain over time [9] and high attrition rates in clinical weight management research [37], there is a clear need to improve adherence to diet and physical activity interventions. However, the majority of research investigating lifestyle change in PCOS involve short-term dietary interventions with/without an exercise element, and there is a paucity of research on behavioural change strategies. As such, guideline development relied heavily on evidence taken from the general population. Only three RCTs in women with PCOS included a ‘behavioural intervention’ [128–130]. While

these studies showed enhanced weight loss [128, 130] and improved androgen and lipid profiles [129] when compared with placebo, the interventions were not well defined, with negligible context provided regarding the theoretic framework or behavioural strategies utilised.

More recently, a cross-sectional study in 501 women with PCOS [131] and two RCTs [44, 132] explored the use of self-management strategies [131] and behavioural modification interventions [44, 132] in PCOS. In the cross-sectional study, implementation of physical activity self-management strategies improved the likelihood of meeting physical activity recommendations, but had no association with BMI. Dietary self-management strategies were associated with reductions in BMI, though were not related to weight or nutritional intake [131]. In the RCTs, only the behavioural modification programme and not the control (general healthy lifestyle recommendations) produced significant weight loss after four months. A significantly greater proportion of women in the intervention group also improved menstrual regularity [44] and psychological well-being (lower anxiety and depressive

symptoms) [132] when compared to the control group. The women who achieved greater weight loss reported higher social desirability and lower embitterment scores on a personality trait assessment measure [132]. These findings are particularly novel, as they provide insight into the influence of personality traits and their contribution to success in following behavioural modifications [132].

Alcohol and smoking

In the clinical setting, smoking and alcohol consumption are often addressed alongside dietary and physical activity changes, employing the same behavioural and cognitive interventions to promote adherence. Hence, alcohol and cigarette use are considered here under traditional lifestyle strategies. The PCOS international guideline highlights the importance of assessing alcohol consumption and cigarette smoking when improving fertility and reproductive outcomes in women with PCOS [18]. Assessment of cigarette use is also recommended when evaluating CVD risk factors and thromboembolism risk associated with oral contraceptive pills [18]. These recommendations are based on existing practice guidelines used for the general population.

There is a paucity of observational research characterising alcohol consumption in women with PCOS. One Swedish study comparing women with PCOS ($n=72$) to healthy controls ($n=30$), demonstrated a lower alcohol intake in the PCOS group [133]. A larger study in Australia comparing women with ($n=409$) and without ($n=7,057$) PCOS, reported no significant difference in alcohol intake [134]. Similarly, a Spanish study ($n=22$ PCOS and $n=59$ controls) and a Chinese study ($n=2,217$ PCOS and $n=279$ controls), found no significant difference in alcohol intake between PCOS and non-PCOS groups [135, 136].

Current evidence on the impact of alcohol intake on anovulatory infertility (a common feature of PCOS) is controversial, with some studies showing adverse effects and others reporting no significant correlation [136, 137]. One prospective study including 18,555 married women from The Nurses' Health Study II, who had no history of infertility, found no clinically significant impact of alcohol intake on anovulatory infertility, after adjusting for parity and other factors [138]. Similarly, a Danish study ($n=6,120$ women aged 21 to 45 years) found no fertility effect with alcohol consumption of less than 14 standard drinks per week [137]. In contrast, a study on 3,833 women who recently gave birth and 1,050 women with infertility, reported an increased risk of anovulatory infertility and endometriosis with increasing alcohol intake [139].

Current observational evidence does not reveal any significant difference in smoking between women with and without PCOS [135, 136, 140], with the exception of one

study in pregnant women which showed a lower smoking rate in women with PCOS ($n=354$) compared to women without PCOS at 15 weeks gestation [3]. However, a significantly higher rate of smoking (including passive and active) is reported in women with PCOS and oligo-anovulation and/or reduced fertility compared to women with PCOS and normal menstruations or healthy controls [141, 142]. Smoking is also associated with PCOS risk independent of BMI and age [142]. A Mendelian randomisation study supports these findings, demonstrating a 38% higher risk of PCOS development in genetically predicted smokers (based on single-nucleotide polymorphisms associated with smoking initiation) compared with those who never smoked [143]. In PCOS, smoking is associated with increased levels of T, DHEAS, TC, LDL-C and FINS [141, 144, 145]. However, the underlying mechanisms are not fully understood and there are inconsistencies in findings from different studies. Furthermore, smoking is associated with lower conception and live birth rates and less favourable ART outcomes in women with PCOS [141, 146].

Psychological

The current guideline highlights the need for awareness, and appropriate assessment (such as stepwise screening) and management, of QoL, depression and anxiety, psychosexual dysfunction, negative body image and disordered eating [18]. The guideline emphasises the importance of clinicians and women working in partnership to address women's individual priorities; understanding that the impact of PCOS on an individual's QoL is key to delivering meaningful outcomes [147, 148]. To assist women to communicate with clinicians about what is important to them, the PCOS Question Prompt List [149] was developed and is consistent with the 2018 guideline. The 2018 guideline recommends screening for risk factors and symptoms of depression and anxiety at time of diagnosis. Women with positive screening results should be supported with further assessment and treatment by appropriately qualified clinicians. To screen for psychosexual dysfunction tools such as the Female Sexual Function Index [150] should be utilised. If negative body image, disordered eating or eating disorders are suspected, the PCOS guideline outlines a stepped approach for screening, and where appropriate promotes the use of psychological therapy offered by trained health professionals, which should be guided by regional clinical practice guidelines [18].

While the PCOS guideline provides justification and summarises evidence for mental health screening and diagnostic assessment, there is also a need for consideration of additional aspects, such as the efficacy of different types of psychological interventions and how

Table 5 Reviews and experimental studies investigating the effects of traditional, complimentary and integrative medicine on polycystic ovary syndrome outcomes

^a Summarises commonly used measures in PCOS research and does not report on all measured outcomes. For prospective pre-post studies significant changes from baseline are reported. For RCTs significant changes between intervention(s) and control are reported

^b Not all participants are included in the findings reported here (e.g. where findings from subgroup analysis are reported)

psychological interventions influence engagement with lifestyle change. This is important, as poorer mental health outcomes at baseline are positively associated with higher rates of attrition in lifestyle interventions [13]. Cognitive behavioural interventions could be considered to improve engagement and adherence to healthy lifestyle in women with PCOS. Research has shown support for a range of different psychological interventions, such as counselling [151], cognitive behavioural therapy (CBT) [152–154] and mindfulness meditation [155, 156], helping to change the way clinicians' approach and deliver optimal PCOS management.

CBT is one of the most widely-researched psychological interventions, and is well-recognised as the most effective psychological treatment for depression and anxiety [157]. One RCT showed that eight weekly group CBT sessions were effective in improving QoL ratings and reducing psychological fatigue in women with PCOS [152]. Another more recent RCT investigated the outcome of a 1 year three-component intervention focusing on CBT, diet and exercise [154] and reported improvements in self-esteem and depressive symptoms as compared to usual care [154]. Similarly, an RCT by Cooney et al. [153], comparing the effects of CBT and lifestyle modification versus lifestyle modification alone, reported the CBT/lifestyle modification group lost more than twice as much weight per week

and had greater improvements in QoL compared to lifestyle only. Depression scores decreased in the overall group and there was no difference between the two groups [153]. Lastly, a pilot intervention study of adolescents with PCOS has shown promising results for the use of CBT in the reduction of weight and improvement in depressive symptoms [158].

Mindfulness meditation programs have gained increasing popularity over the past few decades, and are being included as part of clinical trials to reduce stress and improve psychological wellbeing across a range of medical conditions [159]. Mindfulness meditation can be used to reduce the production of adrenal androgens, activated via the adrenal glands as a direct result of psychological distress [156]. Despite the proposed benefits, there are very few studies investigating the use of mindfulness meditation as a treatment for psychological symptoms associated with PCOS. One RCT ($n=86$) compared the provision of an eight week mindfulness-based stress reduction (MBSR) program, and found that when compared to the control group (health education), the MBSR group produced greater reductions in perceived stress, depressive symptoms and fasting blood glucose [160]. Similarly, another RCT investigating the impact of mindfulness meditation for eight weeks in PCOS showed reduced stress, depression and anxiety symptoms, and increased life satisfaction and QoL in the intervention

group compared to no treatment [156]. In adolescents with PCOS ($n=37$), a pilot RCT reported higher levels of nutrition and physical activity self-efficacy following a mindfulness and self-management program [161]. Mindfulness-based cognitive therapy (MBCT) combines both elements of MBSR and CBT, but as yet there are no trials investigating this intervention in PCOS.

In addition to CBT and mindfulness meditation, there is some evidence to support group counselling sessions as beneficial in conjunction with exercise programs to increase and support weight loss [151]. In one RCT ($n=17$) participants followed a high-intensity aerobic exercise program for eight weeks, followed by eight weeks of group counselling [151]. Qualitative analysis of data taken from the group counselling and physical exercise sessions revealed that development of supportive relationships was important for successful behavioural change. By fostering the exchange of narratives relating to their illness (e.g. effects of PCOS on aspects of everyday life), and generating feedback between group members, counselling sessions helped to reduce social isolation and improve adherence to the exercise intervention [151]. Please see Table 3 for a summary of experimental studies investigating effects of psychological interventions on PCOS outcomes.

Sleep

Women with PCOS have an increased risk of both clinical sleep disorders and non-clinical sleep disturbance, which is mediated by hormone derangement, in particular reduced oestrogen, progesterone and melatonin levels [164]. Oestrogen is required for the metabolism of neurotransmitters (norepinephrine and serotonin) involved in regulating sleep patterns, and plays an important role in maintaining a low body temperature at night [165]. Progesterone has sedative and anxiolytic actions that can support sleep quality, and acts as a respiratory stimulant that lessens airway resistance in obstructive sleep apnoea (OSA) [166]. Melatonin is a neuroendocrine hormone that is widely recognised as crucial in maintaining circadian rhythm regulation. However, melatonin is also involved in ovarian function, with actions including delaying ovarian senescence, promoting follicle formation and improving oocyte quality [167–173].

The current PCOS guideline recognises that OSA is 6.5–8.3 times more likely in women with PCOS [164, 174–177], and promotes routine screening to identify and treat associated symptoms, such as snoring, excessive sleepiness and the potential for fatigue to worsen mood disorders [18]. Screening should include a simple questionnaire, such as the Berlin tool [178], and where appropriate women should be referred onto a specialist for further assessment and

treatment [18]. The guidelines also highlight that treatment of OSA in PCOS should not be used to improve metabolic features. Since guideline inception evidence has emerged reporting weight, PCOS and sleep are interrelated factors that can each contribute to the worsening presentation of one another, whereby sleep disorders and disturbance may worsen the presentation of PCOS related metabolic outcomes and vice versa [179].

Hypersomnia and insomnia are also common clinical sleep disorders in PCOS [164, 177, 180], with prevalence estimated at 11% versus 1% in women with versus those without PCOS [180]. Even in the absence of clinically diagnosed sleep disorders, women with PCOS have a higher prevalence of sleep disturbances, including poor sleep quality [181], issues with sleep initiation [182], severe fatigue [140], restless sleep [140] and difficulty sleeping overnight [140]. The prevalence of sleep disturbances may be up to 20% higher in women with PCOS compared to women without PCOS [183]. Emerging research also suggests that social restrictions arising from the COVID-19 pandemic have worsened sleep disturbances in women with PCOS [177]. Findings from key studies of non-clinical sleep disturbance can be found in Table 4.

In the general population short and disturbed sleep is consistently associated with excess weight [184], IR [185], T2DM [185] and CVD [186]. Similar relationships are observed in PCOS, where OSA and sleep disordered breathing exacerbates risk of IR and metabolic consequences of abnormal glucose tolerance [187, 188]. A cross-sectional study in adolescents with PCOS ($n=103$) reported those with sleep disordered breathing had significantly higher BMI Z-scores, and a higher prevalence of metabolic syndrome (METS) [188]. Similar metabolic consequences are seen in women with PCOS who suffer from non-clinical sleep disturbance [164]. Underlying mechanisms linking sleep disorders and disturbance with worsened metabolic outcomes include amplified sympathetic tone and oxidative stress [164], reduced adipose tissue lipolysis, and an increase in energy intake stemming from heightened hedonic and endocrine appetite signals [189].

Unfavourable effects on energy metabolism and appetite regulation, may explain why women with PCOS who display sleep disturbance have a reduced capacity to maintain dietary interventions [183]. Moreover, depression and anxiety share a bidirectional relationship with disrupted and reduced sleep [190], and as stated previously, interventions that improve mental health can help to increase engagement with dietary and physical activity recommendations [131]. Optimising sleep may therefore be an important consideration when promoting healthy lifestyle change in women with PCOS [183].

Table 6 Current recommendations for clinical practice and research gaps identified by this review

Recommendation(s) from current guidelines ^a	Category of recommendation ^b	Research gaps
Effectiveness of lifestyle interventions		
Healthy lifestyle behaviours encompassing healthy eating and regular physical activity should be recommended in all those with PCOS to achieve and/or maintain healthy weight and to optimise hormonal outcomes, general health, and QoL across the life course.	CCR	<ul style="list-style-type: none"> • Improves sustainability of weight loss interventions. • Identifies subgroups who respond to weight loss with clinically relevant metabolic and reproductive improvements (this requires the inclusion of more clinical reproductive outcomes in RCTs). • Defines weight loss thresholds for improvements in different PCOS features (metabolic, reproductive and psychological). • Characterises the degree of metabolic and reproductive improvements related to different lifestyle factors (diet, physical activity and behavioural) independent of weight changes. • Considers effects of weight gain prevention on limiting the progression/worsening of PCOS features. • Investigates how different dietary, physical activity and behavioural interventions affect engagement, adherence and sustainability of lifestyle change. • Investigates efficacy and effectiveness of healthy lifestyle changes independent of weight change.

Table 6 (continued)

Recommendation(s) from current guidelines ^a	Category of recommendation ^b	Research gaps
Dietary interventions		
A variety of balanced dietary approaches could be recommended to reduce dietary energy intake and induce weight loss in women with PCOS and overweight and obesity, as per general population recommendations.	CCR	<ul style="list-style-type: none"> Low GI/GL diets may provide benefits in reducing weight and IR in women with PCOS. Further research needs to assess additional risk factors including reproductive function and CVD risk. Identify and define the optimal diet for PCOS management by comparing a range of different dietary approaches (e.g. DASH, Mediterranean or low GI/GL).
General healthy eating principles should be followed for all women with PCOS across the life course, as per general population recommendations.	CCR	
To achieve weight loss in those with excess weight, an energy deficit of 30% or 500 - 750 kcal/day (1,200 to 1,500 kcal/day) could be prescribed for women, also considering individual energy requirements, body weight and physical activity levels.	CPP	
In women with PCOS, there is no or limited evidence that any specific energy equivalent diet type is better than another, or that there is any differential response to weight management intervention, compared to women without PCOS.	CPP	
Tailoring of dietary changes to food preferences, allowing for a flexible and individual approach to reducing energy intake and avoiding unduly restrictive and nutritionally unbalanced diets, are important, as per general population recommendations.	CPP	
Physical activity interventions		
Health professionals should encourage and advise the following for prevention of weight gain and maintenance of health:	CCR	While evidence supports the provision of supervised vigorous aerobic exercise, which may provide greater benefits on PCOS symptoms than other types of exercise (e.g. resistance training), additional larger and longer-term studies are required to: <ul style="list-style-type: none"> Characterise optimal exercise prescription for PCOS management. Identify factors that improve adherence to exercise interventions. Identify subgroups who respond to exercise with clinical improvements.
• in adults from 18 – 64 years; a minimum of 150 min/week of moderate intensity physical activity or 75 min/week of vigorous intensities or an equivalent combination of both, including muscle strengthening activities on 2 non-consecutive days/week;		
• in adolescents, at least 60 minutes of moderate to vigorous intensity physical activity/day, including those that strengthen muscle and bone at least 3 times weekly;		
• activity be performed in at least 10-minute bouts or around 1000 steps, aiming to achieve at least 30 minutes daily on most days.		
Health professionals should encourage and advise the following for modest weight-loss, prevention of weight-regain and greater health benefits:	CCR	
• a minimum of 250 min/week of moderate intensity activities or 150 min/week of vigorous intensity or an equivalent combination of both, and muscle strengthening activities involving major muscle groups on 2 non-consecutive days/week;		
• minimised sedentary, screen or sitting time.		
Physical activity includes leisure time physical activity, transportation such as walking or cycling, occupational work, household chores, games, sports or planned exercise, in the context of daily, family and community activities.	CPP	
Daily, 10000 steps is ideal, including activities of daily living and 30 minutes of structured physical activity or around 3000 steps.		
Structuring of recommended activities need to consider women's and family routines as well as cultural preferences.		

Table 6 (continued)

Recommendation(s) from current guidelines ^a	Category of recommendation ^b	Research gaps
Behavioural interventions		
Lifestyle interventions could include behavioural strategies such as goal-setting, self-monitoring, stimulus control, problem solving, assertiveness training, slower eating, reinforcing changes and relapse prevention, to optimise weight management healthy lifestyle and emotional wellbeing in women with PCOS.	CCR	<ul style="list-style-type: none"> To identify behavioural and cognitive strategies that should be targeted in women with PCOS, more observational research that characterises women's use of self-management strategies is needed. To aid replication and interpretation of findings, RCTs must clearly define the theoretical frameworks and behavioural components used in intervention design.
Comprehensive health behavioural or cognitive behavioural interventions could be considered to increase support, engagement, retention, adherence and maintenance of healthy lifestyle and improve health outcomes in women with PCOS.	CPP	
Assessment and treatment of infertility (as it relates to alcohol and smoking use)		
Cardiovascular disease risk (as it relates to alcohol and smoking use)	CPP	<ul style="list-style-type: none"> Determine whether women with PCOS are at a higher risk of alcohol and smoking-related infertility complications (with a focus on anovulatory infertility) when compared to women without PCOS. Determine whether women with PCOS are at a higher risk of smoking-related CVD complications when compared to women without PCOS.
Factors such as blood glucose, weight, blood pressure, smoking, alcohol, diet, exercise, sleep and mental, emotional and sexual health need to be optimised in women with PCOS, to improve reproductive and obstetric outcomes, aligned with recommendations in the general population.	CCR	
If screening reveals CVD risk factors including obesity, cigarette smoking, dyslipidaemia, hypertension, impaired glucose tolerance and lack of physical activity, women with PCOS should be considered at increased risk of CVD.	CCR	
Quality of life		
Health professionals and women should be aware of the adverse impact of PCOS on quality of life.	CCR	<ul style="list-style-type: none"> Validate QoL tools longitudinally to identify clinically meaningful differences in QoL scores.
Health professionals should capture and consider perceptions of symptoms, impact on quality of life and personal priorities for care to improve patient outcomes.	CCR	
The PCOS quality of life tool (PCOSQ), or the modified PCOSQ, may be useful clinically to highlight PCOS features causing greatest distress, and to evaluate treatment outcomes on women's subjective PCOS health concerns.	CPP	

Table 6 (continued)

Recommendation(s) from current guidelines ^a	Category of recommendation ^b	Research gaps
Depression and anxiety symptoms, screening and treatment		
Psychosexual function		
Body image		
Eating disorders and disordered eating		
Health professionals should be aware that in PCOS, there is a high prevalence of moderate to severe anxiety and depressive symptoms in adults; and a likely increased prevalence in adolescents.	CCR	<ul style="list-style-type: none"> To determine accurate prevalence of psychological conditions in PCOS, more adequately powered cross-sectional studies using structured diagnostic interviews administered by appropriately qualified professionals are required. Future research should consider the efficacy of different types of psychological interventions in PCOS, with a focus on how changes to mental health symptoms influence engagement with lifestyle change. In particular, the development of a PCOS specific CBT program, tailored to meet the specific mental health needs of women with PCOS is warrant.
Anxiety and depressive symptoms should be routinely screened in all adolescents and women with PCOS at diagnosis. If the screen for these symptoms and/or other aspects of emotional wellbeing is positive, further assessment and/or referral for assessment and treatment should be completed by suitably qualified health professionals, informed by regional guidelines.	CCR	
If treatment is warranted, psychological therapy and/or pharmacological treatment should be offered in PCOS, informed by regional clinical practice guidelines.	CCR	
Factors including obesity, infertility, hirsutism need consideration along with use of hormonal medications in PCOS, as they may independently exacerbate depressive and anxiety symptoms and other aspects of emotional wellbeing.	CPP	
All health professionals should be aware of the increased prevalence of psychosexual dysfunction and should consider exploring how features of psychohirsutism and body image, impact on sex life and relationships in PCOS.	CCR	
If psychosexual dysfunction is suspected, tools such as the Female Sexual Function Index can be considered.	CCR	
Health professionals and women should be aware that features of PCOS can impact on body image.	CCR	
All health professionals and women should be aware of the increased prevalence of eating disorders and disordered eating associated with PCOS.	CCR	
If eating disorders and disordered eating are suspected, further assessment, referral and treatment, including psychological therapy, could be offered by appropriately trained health professionals, informed by regional clinical practice guidelines.	CCR	

Table 6 (continued)

Recommendation(s) from current guidelines^a

Recommendation(s) from current guidelines ^a	Category of recommendation ^b	Research gaps
Obstructive sleep apnoea (OSA)		
Screening should only be considered for OSA in PCOS to identify and alleviate related symptoms, such as snoring, waking unrefreshed from sleep, daytime sleepiness, and the potential for fatigue to contribute to mood disorders. Screening should not be considered with the intention of improving cardiometabolic risk, with inadequate evidence for metabolic benefits of OSA treatment in PCOS and in general populations.	CCR	<ul style="list-style-type: none"> To determine accurate prevalence of subclinical sleep disturbances in PCOS, more adequately powdered cross-sectional studies using validated subjective and objective sleep measures are required. While emerging evidence suggests that disturbed sleep may exacerbate IR via decreasing energy expenditure and increasing adipose tissue deposition, more research in women with PCOS is needed to confirm this hypothesis. Investigate effects of CBT interventions in women with PCOS who have disturbed sleep (outcomes of interest include food intake, metabolic rate, appetite hormones, weight, adherence to lifestyle changes and PCOS features).
A simple screening questionnaire, preferably the Berlin tool [178], could be applied and if positive, referral to a specialist is considered.	CPP	
A positive screen raises the likelihood of OSA, however it does not quantify symptom burden and alone does not justify treatment. If women with PCOS have OSA symptoms and a positive screen, consideration can be given to be referral to a specialist centre for further evaluation.		
Inositol		
Inositol (in any form) should currently be considered an experimental therapy in PCOS, with emerging evidence on efficacy highlighting the need for further research. Women taking inositol and other complementary therapies are encouraged to advise their health professional.	EBR	<ul style="list-style-type: none"> To reduce heterogeneity across studies investigating supplements or herbal medicine, RCTs should focus on specific populations within PCOS (i.e. age, BMI or phenotype) and adopt more consistent approaches to formulation (i.e. limit co-supplementation), dosage, intervention duration and the type of comparator used. Mechanistic studies are needed to investigate herb- or nutrient-drug interactions (with common pharmacological treatments used in PCOS) and other possible interactions with the biological processes underpinning PCOS. Research that characterises the uptake of CIM approaches by women with PCOS, including where they are sourcing information on this topic, will aid health professionals understanding of how to safely navigate the use of adjunct therapies in PCOS management.

Abbreviations: BMI Body mass index, CBT Cognitive behavioural therapy, CI/D Cardiovascular disease, DASH Dietary approaches to stop hypertension, GI Glycaemic index, GL Glycaemic load, IR Insulin resistance, NAC N-acetyl-cysteine, PCOS Polycystic ovary syndrome, RCT Randomised controlled trial, QoL Quality of life

^a Recommendations are taken directly from the 2018 International Evidence-Based Guideline for the Assessment and Management of PCOS [18]. Does not include all recommendations, only those relevant to the findings of this review are presented

^b EBR Evidence based recommendations: Evidence sufficient to inform a recommendation made by the guideline development group. CCR Clinical Consensus Recommendations: In the absence of evidence, a clinical consensus recommendation has been made by the guideline development group. CPP Clinical Practice Points: Evidence not sought. A practice point has been made by the guideline development group where important issues arose from discussion of evidence-based or clinical consensus recommendations

Traditional, complementary and integrative medicine

The 2018 PCOS guideline includes recommendations on inositol supplementation, though do not include evidence regarding the use of other supplements, herbal medicine or other TCIM approaches, including acupuncture and yoga [18].

Vitamins, vitamin-like supplements, minerals and other supplements

The 2018 guideline highlights that inositol (including myo-inositol (MI) and di-chiro inositol) is a nutritional supplement that may be involved in insulin signalling transduction [191]. MI in particular is a key endocrine regulator that displays impaired metabolism in PCOS [191]. MI supplementation has been explored in a meta-analysis of nine RCTs ($n=496$), which showed improved metabolic profiles and reduced hyperandrogenism [191]. These findings are supported by two earlier meta-analyses, reporting improved ovulation, menstrual cyclicity, and hormonal profiles following MI supplementation [192, 193]. The 2018 PCOS guideline recommends that inositol (in any form) should be considered as an experimental therapy in PCOS management. The guideline also recognises that women participating in any form of TCIM should be encouraged to advise their health professional. However, it does not consider emerging evidence for the use of other types of TCIM in PCOS treatment as this was outside of the scope of the 2018 guideline.

Vitamins

B-group vitamins (B₁, B₆ and B₁₂), folic acid (B₉) and vitamins D, E, and K are critical for several biological processes that can affect metabolic and reproductive features of PCOS. B-group vitamins work alongside folic acid (the synthetic form of folate) to regulate homocysteine (Hcy) via re-methylation of Hcy to methionine [194]. Hcy is an amino acid that confers an increased risk of CVD at high levels, and which is often deranged in women with PCOS [195], likely related to a higher prevalence of folate deficiency [196–198]. One RCT explored the use of B-group vitamins combined with folic acid in 60 women with PCOS, and reported a reduction in the Hcy increasing effect of metformin [198]. Folic acid alone has also been examined in two RCTs of women with PCOS ($n=69$ [199] and $n=81$ [200]), improving FINS, HOMA-IR, C-reactive protein, total antioxidant capacity (TAC) and glutathione with doses ≥ 5 mg/day when compared with placebo [199, 200]. Regarding vitamin D supplementation, three large-scale meta-analyses reported improvements in measures of IR (HOMA-IR [201, 202], FINS [201]), fasting glucose [201]), lipid profiles (LDL-C [201–203], TC [203] and TAG [203]) and androgens (T) [202], when compared

with placebo. While vitamin E (or tocopherol) has various reported benefits on fertility outcomes in other populations [204], and has improved androgen profiles when co-supplemented with coenzyme Q10 (CoQ10) in women with PCOS [205], to date no RCTs have examined the use of vitamin E supplements alone in PCOS. Vitamin K also has limited available literature in PCOS, with only one RCT ($n=84$) demonstrating improvements in anthropometry, insulin and androgen profiles following supplementation (90 µg/day Menaquinone-7 for eight weeks), compared with placebo [206].

Vitamin-like supplements

Vitamin-like supplements including bioflavonoids, carnitine and alpha-lipoic acid (α-LA) have well-recognised antioxidant properties and play a role in fatty acid and glucose metabolism, providing possible metabolic benefits in PCOS [207]. Bioflavonoids consist of plant-derived polyphenolic compounds, some of which have been inversely associated with METS in women with PCOS [207]. In a pilot prospective study of 12 women with PCOS, 36 mg/day of the soy isoflavone genistein for six months improved lipid profiles but not anthropometry, IR, hormonal profiles or menstrual cyclicity [208]. Carnitine, particularly the active form L-carnitine, is reported to be lower in women with PCOS and linked with hyperandrogenism, hyperinsulinaemia and reduced oocyte quality [209, 210]. One RCT explored L-carnitine use in PCOS and found beneficial effects on mental health parameters and markers of oxidative stress [211], although the integrity of these have come under scrutiny and hence should be interpreted with caution [122212]. Regarding α-LA, a small pre-post study ($n=6$) administered 1200 mg/day for 16 weeks, and reported improved IR, LDL-C and TAG, though no effects on TAC or plasma oxidation metabolites [213]. Another RCT reported improved anthropometric (BMI), metabolic (FINS and HDL-C) and reproductive (menstrual cyclicity) features in 46 women with PCOS receiving α-LA supplementation (600 mg/day for 180 days) compared with controls [214]. However, as these women were co-supplemented with 1000 mg/day D-chiro-inostiol, findings are not isolated to the effects of α-LA alone [214].

Minerals

Minerals such as calcium, zinc, selenium, magnesium and chromium picolinate (CrP) have been explored in PCOS due to their reported insulin sensitising, antioxidant and anti-inflammatory properties [215–217]. A small number of studies have also reported women with PCOS are at higher risk of being deficient in calcium [218], zinc [215, 217] and selenium [195]. A recent systematic

review (six RCTs) reported that vitamin D and calcium co-supplementation in women with PCOS improved lipid and androgen profiles, follicular health and menstrual cyclicity [219]. While these findings are promising, it is difficult to attribute benefits to calcium alone, given calcium is often co-supplemented with vitamin D due to their complementary mechanisms of action. One systematic review (five RCTs) in PCOS reported zinc (often co-supplemented with other nutrients such as calcium, vitamin D and magnesium), improved HOMA-IR, lipids, T, FSH and DHEAS [220] compared to placebo. Another systematic review (five RCTs) examining selenium supplementation reported reduced IR, oxidative stress and inflammation, while results for anthropometry, lipids, androgens and hirsutism were inconsistent [221]. Regarding magnesium (an intracellular cation involved in insulin metabolism), while supplementation in PCOS has been associated with reduced IR in observational research [222], these findings are not supported by data from RCTs, with considerable inconsistencies between studies [222]. Two meta-analyses examined CrP in women with PCOS [223, 224]. While one reported that CrP supplementation reduced BMI, FINS and free testosterone [223], the other reported decreased IR, but not BMI, and increased levels of T [224].

Other supplements

Other supplements purported to provide a range of antioxidant and anti-inflammatory benefits, including omega-3 fatty acids, N-acetyl-cysteine (NAC), CoQ10, probiotics, quercetin, resveratrol and melatonin have been explored in PCOS. A meta-analysis (nine RCTs) of women with PCOS ($n=591$) receiving omega-3 supplementation reported reductions in HOMA-IR, TC, TAG and LDL-C, though showed no effect on other metabolic parameters or T [225]. In a meta-analysis of eight RCTs ($n=910$) examining NAC supplementation (the acylated form of L-cysteine), researchers reported improved glucose regulation and a greater likelihood of conception and livebirths in women with PCOS compared with placebo [226]. In a single RCT ($n=60$) CoQ10 supplementation (100 mg/day for 12 weeks) improved fasting glucose and insulin, HOMA-IR, insulin sensitivity index and TC, compared with the placebo group [227]. Two meta-analyses reported probiotics improved FAI, SHBG, IR and blood lipids, with no differences in weight or hirsutism between intervention and placebo groups [228, 229]. These findings may be linked to lower microbial diversity and increased intestinal permeability in women with PCOS [230, 231]. In regards to quercetin and resveratrol, which are both food derived polyphenols with a strong antioxidant capacity, one systematic review (three experimental studies, $n=246$ women with PCOS) reported

quercetin supplementation improved measures of IR and testosterone levels, but not anthropometry compared with placebo [232]. Similarly, one RCT in women with PCOS ($n=61$) reported resveratrol (800–1500 mg/day for four days) improved androgen and metabolic profiles and oocyte and embryo quality compared with placebo [233]. Finally, a systematic review (two RCTs and one cell-culture study) investigating the effects of melatonin supplementation in women with PCOS using assisted reproductive technologies reported melatonin significantly increased clinical pregnancy rates but not live birth rates [172]. A more recent RCT ($n=56$) reported improved levels of T, hirsutism, inflammatory and oxidative stress profiles in women receiving 10 g melatonin/day for 12 weeks, compared with placebo [234].

Herbal medicine

To date the most recent and comprehensive review (Cochrane review including five RCTs and $n=414$ women with PCOS) investigating the effects of herbal medicine on reproductive outcomes, reported no difference between the use of Chinese herbal medicine (CHM) and clomiphene for pregnancy rates, and limited evidence of increased pregnancy rate for CHM with clomiphene compared with clomiphene alone [235]. This review concluded that there was inadequate evidence to promote the use of CHM for the treatment of subfertility in women with PCOS [235]. Similarly, a smaller systematic review (five studies) investigating the effects of four herbal medicines (green tea, cinnamon, spearmint and black cohosh) on menstrual regularity in PCOS, found limited high-quality evidence from RCTs to support their clinical use and concluded that evidence for safety was lacking [236].

More recently, a number of small RCTs investigating metabolic and reproductive effects of a range of herbal medicines have been published. Curcumin, an active compound in turmeric (*Curcuma longa*), may exert hypoglycemic effects via a number of mechanisms, including attenuation of circulating levels of tumor necrosis factor- α [237]. One RCT ($n=67$) reported decreased levels of fasting glucose following supplementation compared with placebo [238], while another ($n=51$) which used a lower dose (1000 mg/day versus 1500 mg/day) and shorter duration (six weeks versus 12 weeks), reported no between group differences for fasting glucose, HOMA-IR or lipids [239]. *Salvia officinalis* or sage contains multiple active compounds that display antioxidant effects and therefore effects on glucose metabolism and insulin sensitivity [240]. One RCT ($n=72$) reported consuming sage extract for eight weeks improved IR and reduced BMI, with no effects on WHR or blood pressure [241]. *Foeniculum vulgare*

or fennel may provide protective effects on hormonal abnormalities in PCOS via its actions as a phytoestrogen [242]. One RCT ($n=55$) reported that six months of fennel tea and dry cupping was as effective as metformin for reducing BMI and menstrual cycle length [243]. *Glycyrrhiza glabra* or licorice contains active phytochemicals including isoflavane and glabridin, which have been shown to have antiandrogenic effects [244]. Two experimental studies in healthy women ($n=9$) [245] and women with PCOS ($n=32$) [246] reported that 3.5 g/day of licorice extract decreased T [245] and reduced side effects of spironolactone [246]. *Mentha spicata* (spearmint), *Zingiber officinale Roscoe* (ginger), *Cinnamomum cassia* (cinnamon) and *Citrus sinensis* (citrus) have been shown to exert anti-inflammatory and hypoglycemic effects [247–250]. One RCT in infertile women with PCOS ($n=60$) comparing the effects of a herbal mixture (citrus, ginger, cinnamon and spearmint) with clomiphene citrate (CC), herbal mixture alone, or CC alone reported that the herbal mixture, with or without CC, improved circulating antioxidant levels, IR and fasting blood glucose, but not menstrual regularity when compared to CC alone [251]. While observations from emerging research are promising, to support the safe translation of findings into the clinical setting there is a clear need for larger clinical trials investigating the efficacy and safety of herbal medicine use in PCOS.

Other traditional, complimentary and integrative medicine approaches

Acupuncture may provide beneficial impacts on sympathetic function [252] and ovarian blood flow [253] in women with PCOS. A recent meta-analysis of 22 RCTs ($n=2315$ women with PCOS) reported recovery of the menstrual period in the acupuncture group when compared with placebo, but no evidence for differences between groups in terms of live birth, pregnancy and ovulation [254]. While an earlier meta-analysis reported a significant reduction in BMI following acupuncture use, this was mainly due to one RCT ($n=80$) which compared acupuncture and the oral contraceptive pill to the oral contraceptive pill alone [255]. When this study was removed, the pooled analysis was no longer significant [255].

Yoga gymnastics have been recommended as an example of moderate physical activity in the 2018 evidence-based PCOS guideline [18]. However, as yoga is considered a mind-body therapy that incorporates aspects of meditation, it may provide additional benefits beyond those gained through other forms of exercise [256]. While one systematic review (16 observational and experimental studies, $n=365$ women with

PCOS) reported yoga may provide a range of psychological, reproductive and metabolic benefits, no meta-analysis was performed and a limited summary of included studies made it difficult to confirm findings [257]. A more recent systematic review (11 experimental studies) included a meta-analysis of two RCTs and found that yoga significantly decreased clinical hyperandrogenism, menstrual irregularity and fasting glucose and insulin [258]. Lastly, findings from a recent RCT ($n=67$ women with PCOS) suggests that 90 minutes of yoga per day for six weeks can significantly reduce hirsutism, waist and hip circumference when compared to controls [259]. Please see Table 5 for a summary of available evidence from meta-analyses and experimental studies investigating the effects of TCIM on PCOS outcomes.

Summary of findings and research gaps

The 2018 International Evidence-Based Guideline for the Assessment and Management of PCOS highlights lifestyle (diet, physical activity and/or behavioural) management as the primary initial treatment strategy [18]. It is important to consider that the definition of lifestyle management may warrant expansion consistent with the whole person model of healthcare provision, which may include care addressing psychological and sleep interventions, as well as a range of TCIM approaches [20]. In line with patient interest [31–35], and to assist women and healthcare providers in understanding the evidence to aid safe implementation of adjunct therapies, rigorous assessment of the evidence for these alternative lifestyle strategies in PCOS management is warranted. Using a holistic definition of patient care, this review has summarised evidence to date on the traditional components of lifestyle change (diet, physical activity and behavioural change), psychological interventions and non-pharmacological strategies (sleep, supplements, herbal medicine and other TCIM approaches). Table 6 provides a overview of current guideline recommendations alongside the key findings from this review, summarising the identified research gaps that need to be addressed before evidence-based recommendations for clinical practice can be updated.

With regards to traditional lifestyle treatment, the majority of studies focussed on weight loss as a primary treatment goal. This indicates more research is warranted to understand the role of diet and exercise in lean women and/or in weight gain prevention. RCTs using lifestyle interventions under isocaloric conditions that investigate effects on IR, body composition and androgens independent of weight loss are needed. Given the high risk of failure with long-term weight management [9, 37, 40, 261] and high attrition in weight loss trials in

PCOS [13], exploring interventions that focus on weight neural messaging around dietary quality and physical activity may also aid in optimising engagement, adherence and sustainability of lifestyle interventions. Future research should also identify subgroups who respond more favourably to weight loss [45, 53], to aid provision of a more targeted and personalised treatment approach.

With regards to diet strategies, there is a need for more research understanding the impact of low GI/GL diets on androgen status, as well as the biological mechanisms by which low GI/GL diets may impact reproductive and cardiometabolic outcomes associated with PCOS. With regards to physical activity, additional longer-term studies are required to guide exercise prescription in PCOS, although promising evidence supports the provision of vigorous aerobic exercise performed under supervised conditions (i.e. through referral to an exercise physiologist). While behavioural interventions are essential for long term sustainability of dietary and physical activity change, research in PCOS is scarce and interventions are not well defined. Future research should incorporate appropriate theoretical frameworks and clearly outline behavioural components utilised. This will aid intervention duplication and tailoring of active elements to ensure relevance in women with PCOS.

There is currently a lack of research investigating whether women with PCOS are at a higher risk of alcohol and smoking-related complications. This is particularly relevant given the well-established relationship between higher alcohol and cigarette use and rates of depression and anxiety in the general population [262–265]. There is also a need to better understand the relationship between alcohol intake and reproductive outcomes (particularly anovulatory infertility) [139], as safe alcohol limits in PCOS is currently unknown [139].

With regards to psychological interventions, the current evidence base for prevalence of mental health concerns in PCOS relies heavily on symptom prevalence. More adequately powered, gold standard prevalence studies using structured diagnostic interviews administered by appropriately qualified professionals are needed. While QoL has recently been highlighted as a core outcome in PCOS research [266], the application of QoL tools in clinical care is still unclear, with research yet to validate QoL tools longitudinally or identify clinically meaningful differences in QoL scores. The emerging evidence showing support for the use of CBT in PCOS [152–154] highlights an opportunity for tailoring of this psychological intervention to meet the specific mental health needs of women with PCOS, with a focus on how management of mental health symptoms affect lifestyle modifications. CBT that incorporates elements of

mindfulness-based stress reduction also warrants further investigation.

Future research in PCOS and sleep disorders should include more high-quality research in subclinical disorders using objective sleep measures (polysomnography and actigraphy). Future work should also consider emerging evidence showing that disturbed sleep can detrimentally effect energy expenditure, which may increase adipose tissue deposition and exacerbate IR [164, 184, 186, 267–271], thereby worsening the presentation of PCOS. Further, a consideration of how sleep disturbance can reduce engagement with positive lifestyle changes, for example through the disruption of appetite regulation [272, 273] or via contributing to poor mental health outcomes [190, 274], is warranted. CBT interventions including elements of stimulus control and psychoeducation are effective non-pharmacological treatments for both clinical sleep disorders and sleep disturbances in the general population [275–277]. RCTs in women with PCOS that investigate effects of CBT on dietary intake, energy metabolism, appetite regulation, anthropometry, adherence to lifestyle changes and PCOS features are required.

With regards to TCIM, there is a vast array of literature suggesting some beneficial effects of vitamins (B-group vitamins, folate, vitamins D, E and K), vitamin-like nutrients (bioflavonoids, carnitine and α-LA), minerals (calcium, zinc, selenium, and CrP) and other formulations (such as melatonin, omega-3 fatty acids, probiotics, NAC and cinnamon) in PCOS [278]. However, the quality of evidence across studies ranges from meta-analyses of RCTs (vitamin D, omega-3 fatty acids and NAC) to single retrospective observational studies (vitamin K and carnitine). In addition, heterogeneity in results related to factors including variable PCOS presentation and study methodology make it difficult to draw definite conclusions. Future research should focus on specific populations within PCOS, for example age, BMI or phenotype (factors which substantially affect nutrient sufficiency), and outline more consistent approaches to supplement formulation, dosage, intervention duration and type of comparator used. Mechanistic studies are also needed to investigate herb- or nutrient-drug interactions (with common pharmacological treatments used in PCOS) and other possible interactions with the biological processes underpinning PCOS. In regards to acupuncture and yoga, more sufficiently powered RCTs are needed to determine clinical relevance and integration into PCOS management is not yet warranted.

While current research is not sufficiently robust to support integration of TCIM into routine clinical practice, healthcare providers should broaden their knowledge pertaining to how these therapies can be safely and

appropriately utilised as adjuncts to conventional medical management [279–281]. TCIM is frequently used by women, with uptake of TCIM approaches increasing steadily over the past 10 years [31–35]. In women with PCOS, one cross-sectional study ($n=493$) found that 70% reported use of TCIM, namely nutritional and herbal supplements [282]. The most common reasons for use were to treat PCOS symptoms, improve general wellbeing and reduce depression. Of the women using TCIM, 77% had consulted with a complementary practitioner (acupuncturists, chiropractors, naturopaths and massage therapists) [282]. While the study did not report participants engagement with medical physicians, research in the general population has shown that patients are resistant to discuss TCIM use with their consulting physician [283–288]. Qualified health-care providers should be involved in TCIM discussions to help ensure appropriate use, maximise possible benefits and minimize potential harm [289]. For example, to sustain patient engagement in women who express the desire to experiment with supplementation, health-care providers could consider inositol supplementation, using a nuanced and case-specific approach that encapsulates the variety of pathologies in PCOS.

When considering all of the research summarised here, across traditional lifestyle, psychological, sleep and TCIM interventions, there is a clear need for more real-world PCOS research. This involves the translation of findings from clinical trials (where highly selected populations, intensive treatment protocols and expert multidisciplinary teams provide an ideal research setting), into the heterogeneous situations that face clinicians [290–292]. Health professionals provide care to women from diverse social contexts, are often restrained by finite resources and are required to juggle many competing demands for their time [290–292]. While some barriers to implementation, including time, resource and access issues are considered in the current PCOS guideline, they were generated by the guideline development groups and research is needed to validate and clarify their proposed concerns. Real-world research is required to: a) fully understand whether lifestyle recommendations can be practically integrated into current healthcare settings; b) tailor interventions to meet the unique needs of women with PCOS; and c) generate evidence on clinical outcomes that are of great relevance to patients and clinicians, such as live birth, miscarriage and menstrual regularity, which can be collected through routine care.

It is also important to highlight that while lifestyle management is a first-line treatment for PCOS, the addition of pharmacological therapies to further improve clinical features of hyperandrogenism, menstrual irregularity and infertility are often indicated [293]. In these instances,

prescribing physicians should consider how medical management and lifestyle change can be used in adjunct to optimise treatment. For example, the use of combined oral contraceptive pills may have detrimental effects on weight gain [294] and mental health [295], which can be mitigated by appropriate lifestyle intervention. Further, the combination of lifestyle modification and metformin has been shown to lower BMI, subcutaneous adipose tissue and improve menstruation compared with lifestyle modification alone, and hence may have an additive effect on improving cardio-metabolic outcomes in high risk groups [296].

Conclusion

Using the whole person or holistic definition of health, this review has highlighted emerging areas of research that could be considered for integration into future classifications of lifestyle management in PCOS. When developing lifestyle recommendations for PCOS management, interpreting and communicating evidence not only for diet, physical activity and behavioural interventions, but also psychological, sleep and TCIM approaches, will aid clinicians to deliver patient-centred care by affording women more choice and therefore autonomy over their treatment options. This sentiment aligns with the core objectives underpinning the 2018 PCOS guideline, which sought to understand the unmet needs of women with PCOS through continuing to engage consumers in co-design of guideline development, implementation, translation and dissemination.

Abbreviations

α -LA	Alpha-lipoic acid
BMI	Body mass index
CVD	Cardiovascular disease
CHM	Chinese herbal medicine
CrP	Chromium picolinate
CoQ10	Coenzyme Q10
CBT	Cognitive behavioural therapy
DASH	Dietary Approaches to Stop Hypertension
FINS	Fasting insulin level
FSH	Follicle stimulating hormone
FAI	Free androgen index
GI	Glycaemic index
GL	Glycaemic load
HDL-C	High density lipoprotein cholesterol
Hcy	Homocysteine
IR	Insulin resistance
LDL-C	Low density lipoprotein cholesterol
LH	Luteinizing hormone
$VO_{2\max}$	Maximal rate of oxygen
METS	Metabolic syndrome
MUFA	Monounsaturated fatty acid
MI	Myo-inositol
NAC	N-acetyl-cysteine
OGTT	Oral glucose tolerance test
PCOS	Polycystic ovary syndrome
PUFA	Polyunsaturated fatty acid
RCT	Randomised controlled trial
SHBG	Sex hormone-binding globulin
TAC	Total antioxidant capacity

TC	Total cholesterol
T	Testosterone
TCIM	Traditional, complementary and integrative medicine
TAG	Triglycerides
T2DM	Type 2 diabetes
WC	Waist circumference
WHR	Waist-hip-ratio

Lifestyle management in polycystic ovary syndrome – beyond diet and physical activity

Stephanie Cowan^{1*} , Siew Lim², Chelsea Alycia¹, Stephanie Pirotta³, Rebecca Thomson⁴, Melanie Gibson-Helm^{1,5}, Rebecca Blackmore⁶, Negar Naderpoor¹, Christie Bennett⁷, Carolyn Ee⁸, Vibhuti Rao⁸, Aya Mousa¹, Simon Alesi¹ and Lisa Moran¹

Abstract

Polycystic ovary syndrome (PCOS) is a common condition affecting reproductive-aged women with reproductive, metabolic and psychological consequences. Weight and lifestyle (diet, physical activity and behavioural) management are first-line therapy in international evidence-based guidelines for PCOS. While these recommend following population-level diet and physical activity guidelines, there is ongoing interest and research in the potential benefit of including psychological and sleep interventions, as well as a range of traditional, complimentary and integrative medicine (TCIM) approaches, for optimal management of PCOS. There is limited evidence to recommend a specific diet composition for PCOS with approaches including modifying protein, carbohydrate or fat quality or quantity generally having similar effects on the presentations of PCOS. With regards to physical activity, promising evidence supports the provision of vigorous aerobic exercise, which has been shown to improve body composition, cardiorespiratory fitness and insulin resistance. Psychological and sleep interventions are also important considerations, with women displaying poor emotional wellbeing and higher rates of clinical and subclinical sleep disturbance, potentially limiting their ability to make positive lifestyle change. While optimising sleep and emotional wellbeing may aid symptom management in PCOS, research exploring the efficacy of clinical interventions is lacking. Uptake of TCIM approaches, in particular supplement and herbal medicine use, by women with PCOS is growing. However, there is currently insufficient evidence to support integration into routine clinical practice. Research investigating inositol supplementation have produced the most promising findings, showing improved metabolic profiles and reduced hyperandrogenism. Findings for other supplements, herbal medicines, acupuncture and yoga is so far inconsistent, and to reduce heterogeneity more research in specific PCOS populations, (e.g. defined age and BMI ranges) and consistent approaches to intervention delivery, duration and comparators are needed. While there are a range of lifestyle components in addition to population-recommendations for diet and physical activity of potential benefit in PCOS, robust clinical trials are warranted to expand the relatively limited evidence-base regarding holistic lifestyle management. With consumer interest in holistic healthcare rising, healthcare providers will be required to broaden their knowledge pertaining to how these therapies can be safely and appropriately utilised as adjuncts to conventional medical management.

Introduction

Polycystic ovary syndrome (PCOS) is a common condition affecting up to 13% of reproductive-aged women [1]. It is diagnosed through the European Society for Human Reproduction and Embryology/American Society for Reproductive Medicine (ESRHE/ASRM) criteria, requiring two of the following features: polycystic ovaries on ultrasound, oligoovulatory or anovulatory cycles and biochemical or clinical hyperandrogenism [2]. Women with PCOS experience a combination of reproductive (infertility, pregnancy complications) [3], metabolic (risk factors for and conditions of type 2 diabetes (T2DM) and cardiovascular disease (CVD)) [4, 5] and psychological (conditions including anxiety, depression, poor quality of life (QoL), disordered eating) comorbidities [6, 7].

Insulin resistance (IR) is defined as a key pathophysiological feature in PCOS, contributing to hyperandrogenism and worsening the clinical presentation of PCOS. While lean women present with IR in a form that is mechanistically different from IR caused by excess weight, overweight and obesity further exacerbate IR and consequent hyperinsulinaemia [8]. Women with PCOS also display a higher rate of weight gain over time [9] and a greater prevalence of overweight and obesity [10], which can further contribute to this worsening of IR and hence worsening of the presentation of PCOS [11]. The reason for this is unclear, but may be related to differences in intrinsic psychological and biological mechanisms [12–15], or extrinsic lifestyle factors such as diet and physical activity [16, 17]. Improving IR and excess adiposity are therefore key targets in PCOS management.

The International Evidence-Based Guideline for the Assessment and Management of PCOS [18], highlights lifestyle intervention as the primary early management strategy. Lifestyle interventions are traditionally defined as those designed to improve dietary intake or physical activity through appropriate behavioural support. In the 2018 PCOS guideline, lifestyle management is recommended for general health benefits [18]. Given that excess weight is associated with increased IR in PCOS [8], the guideline additionally promotes weight management, defined as: 1) weight gain prevention in all women with PCOS, and 2) achieving and maintaining modest weight loss in women with excess weight [18].

Lifestyle interventions in PCOS management can also be viewed as a broader construct beyond physical health. Since the emergence of the biopsychosocial model of healthcare in 1977, health disciplines have seen a gradual shift away from the classical biomedical model (where health is defined as the ‘absence of disease’) towards whole person or holistic care [19]. This is an approach that reflects many facets of the patient context, via integrating care that addresses biological, psychological, social, spiritual and ecological

aspects [20]. It therefore requires a range of different treatment strategies to improve health. Provision of whole person or holistic care has been identified as a core objective of healthcare reforms internationally [21–23]. In line with these reforms the PCOS guideline recognises the importance of emotional wellbeing to overall health and QoL in women living with PCOS [18]. It also highlights evidence which suggests that the psychological impact associated with PCOS is under-appreciated in clinical care [4, 5], and that few women are satisfied with the mental health support they receive [6, 7]. Recommendations for appropriate screening, assessment and treatment strategies for anxiety, depression, psychosexual dysfunction, eating disorders and poor body image are provided [18]. These specific areas of emotional wellbeing are of particular concern, with research showing a higher prevalence and severity of depression and anxiety [24, 25], lower scores for satisfaction with sex life and feeling sexually attractive [26] and a higher prevalence of disordered eating and eating disorders [7] in women with PCOS. Features of PCOS, in particular hirsutism and increased weight, have also been shown to negatively affect body image [27, 28], with poor body image being strongly related to depression in women with PCOS [29, 30].

While the current PCOS guideline is comprehensive, considering all available evidence at the time of development and providing best-practice recommendations for necessary screening, risk assessment and management, it could not possibly cover all aspects of PCOS care. An International Delphi process was used to prioritise clinical questions, with consensus reached through extensive consultation with both consumers and multidisciplinary clinicians with expertise in PCOS care. Therapies, such as traditional, complementary and integrative medicine (TCIM), supplement use, sleep and meditation interventions are either briefly considered or not at all included in the 2018 PCOS guideline. Many of these therapies are novel and there is a paucity of evidence to support intervention efficacy on PCOS outcomes. However, as patient interest in these types of non-pharmacological interventions are growing [31–35], it is prudent to provide more guidance to healthcare providers in this area on their potential efficacy in PCOS. Whole person or holistic care recognises that the doctor-patient relationship should be one of open dialogue, where healthcare providers involve the patient in negotiating their care and recognises patient’s autonomy to guide treatment (Figure 1) [36].

This review provides an extensive overview of evidence to date on lifestyle strategies used to optimise management of PCOS. Using a holistic definition of patient care, this review considers the traditional components of lifestyle change (diet, physical activity and behavioural change), psychological and sleep interventions, as well as TCIM approaches (supplements, herbal medicine,

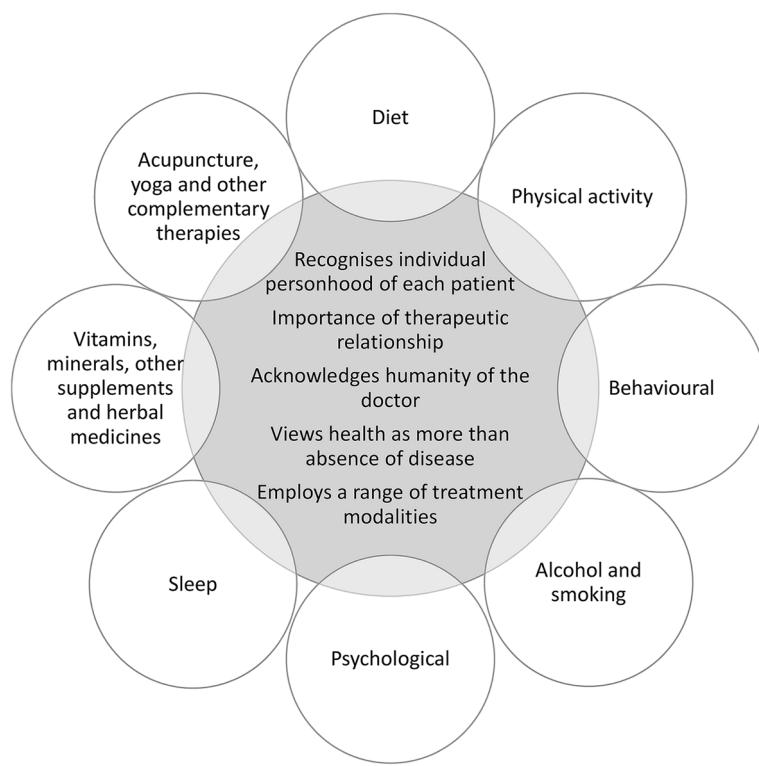

Fig. 1 Viewing lifestyle modifications through a whole person or holistic care lens. The key features of whole person or holistic care listed in the centre of the figure have been adapted from Thomas et al. [20]. ‘Recognises individual personhood’ relates to focusing on the unique needs of the person rather than the disease. ‘Importance of therapeutic relationship’ emphasises patient autonomy and responsibility. ‘Acknowledges humanity of the doctor’ considers the doctors’ ability to self-reflect on how they engage in the care of the patient. ‘Health as more than absence of disease’ incorporates the mental, emotional, physical, environmental and social needs of the patient. ‘Employs a range of treatment modalities’ promotes continuity of care across health disciplines, and while it may include traditional, complementary and integrative medicine (TCIM), TCIM is not holistic if used in isolation and without adequate integration into conventional healthcare

acupuncture and yoga). To improve translation of findings, evidence summaries are accompanied by an overview of relevant recommendations from the existing PCOS guideline. This highlights where emerging evidence supports current recommendations or provides new insights for research. As this is a narrative review, while evidence summaries include peer-reviewed journal articles identified from databases including Medline OVID, this is supplemented by expert opinion of the authors.

Traditional lifestyle and weight management

The PCOS guideline recommends the promotion of healthy lifestyle behaviours in all women with PCOS, to achieve and/or maintain a healthy weight and to optimise general health [18]. In women with excess weight, a weight loss of 5–10% is advised, aiming for an energy deficit of 30% or 500–750 kcal/day (1200–1500 kcal/day). While weight management is seen as a core component of lifestyle interventions, the guideline recognises that a healthy lifestyle provides benefits that occur independent of weight change.

A recent Cochrane review of 15 randomised controlled trials (RCT) and 498 participants, reported that lifestyle interventions compared with minimal intervention or usual care, significantly reduces weight (kg) and body mass index (BMI) and improves secondary reproductive outcomes such as free androgen index (FAI), testosterone (T), sex hormone-binding globulin (SHBG) and hirsutism (Ferriman-Gallwey score) [37]. In terms of metabolic outcomes, lifestyle intervention resulted in significant reductions in total cholesterol (TC), low density lipoprotein cholesterol (LDL-C) and fasting insulin (FINS). These findings are largely similar to that of other systematic reviews [38–41]. While no studies in the Cochrane review assessed clinical reproductive outcomes [37], individual trials that were not included in the review have reported that lifestyle interventions resulting in modest weight loss (2–5% total body weight) improve ovulation and menstrual regularity [42–45]. Losing >5% of weight is additionally associated with being able to conceive, having live births, reduction of ovarian volume and reduction in the number of follicles [46–52].

Table 1 Reviews and experimental studies investigating the effects of diet on polycystic ovary syndrome outcomes

Dietary intervention	N study design	N studies; N participants	Main findings ^a	References
Low CHO	2 SR/MA (27 RCT total - 18 RCT using low CHO diet) [56, 85] 1 SR (5 RCT total - 1 RCT using low CHO diet) [16]	14; 901	Low CHO compared with control diets [56]: ↓ BMI, HOMA-IR, TC, LDL-C ↑ SHBG ↔ LH, T, HDL-C Dietary intervention ↓ HOMA-IR, FINS, FGL, BMI, BW, WC compared with minimal intervention, and subgroup analysis showed no additional benefits for low CHO diets [85] Weight loss improved the presentation of PCOS regardless of dietary composition, with no subtle differences observed for low CHO diets [16]	Shang et al. 2020 [85] Zhang et al. 2019 [56] Moran et al. 2013 [16]
Low GI	1 SR/MA (10 RCT total - 8 RCT using low GI diet) [55] 1 SR (5 RCT total - 1 RCT using low GI diet) [16] 4 Pre-post prospective [61, 76, 77, 118] 1 RCT [78]	16 ^b ; 582	High GI compared with low GI diets [55]: ↓ HOMA-IR, FINS, TC, LDL-C, TAG, WC, T ↔ FGL, HDL-C, BW, FAI Low GI diets had greater improvements in IR, TC, HDL-C, fibrinogen, menstrual regularity and QoL [16] Low GI diets followed for ≥ 12 weeks: ↓ BW [76, 77], BMI [76, 77], BFM [77], WC [77], WHR [77], FINS [76, 77], FGL [77], TC [77], LDL-C [77], TAG [77], T [77], LH [77], androstenedione [77], prolactin [77] ↑ insulin sensitivity (HOMA2-IS) [61], synthesis of predominantly anti-inflammatory eicosanoid mediators (e.g. 16(R)/16(S)-HETE, 13(S)-HODE, 9(S)-HODE, 15(S)-HETE, 12(S)-HETE, 5(S)-oxoETE, 5(S)-HETE) [118], fasting glucagon (higher glucagon levels associated with lower levels of self-reported hunger) [78]	Kazemi et al. 2020 [55] Moran et al. 2013 [16] Shishrehgar et al. 2019 [76] Barr et al. 2016 [61] Szczuko et al. 2018 [77] Szczuko et al. 2017 [118] Hoover et al. 2021 [78]
High protein	1 SR (5 RCT total - 3 RCT using high protein diet) [16] 2 Pre-post prospective [73, 74] 6 RCT [92, 94–97]	11; 308	High protein diets improve depression and self-esteem [16] ↓ BFM [74, 97], BW [73, 74, 97], BMI [73, 74], WC [73, 74, 97], WHR [73], FINS [74, 98], FGL [97], HOMA-IR [73, 98], TAG [73], VLDL-C [73], T [73, 98], Ferriman-Gallwey scores [73] High protein and standard/low protein diet ↓ BW [92, 94, 95], BMI [92, 94, 95], BFM [95], WC [92, 94], WHR [94], FINS [95, 96], HOMA-IR [95], TAG [96], LDL-C [98] CRP [96], MPA [96], leptin [95], T [98], DHEAS [98], FAI [98] and there was ↔ between high and standard/low protein diets	Moran et al. 2013 [16] Moran et al. 2010 [96] Moran et al. 2004 [95] Sorensen et al. 2012 [97] Toscani et al. 2011 [92] Nadjarzadeh et al. 2021 [94] Phy et al. 2015 [73] Pohlmeier et al. 2014 [74] Mehrabani et al. 2012 [98]
Low fat	1 SR/MA (19 RCT total - 1 RCT using low fat diet) [85] 1 SR (5 RCT total - 1 RCT using low fat diet) [16] 1 RCT [107]	3; 137	Dietary intervention ↓ HOMA-IR, FINS, FGL, BMI, BW, WC compared with minimal intervention, and subgroup analysis showed no additional benefits for low fat diets [85] Weight loss improved the presentation of PCOS regardless of dietary composition, with no subtle differences observed for low fat diets [16] Low fat (25% E fat) ↓ BW, BFM, BMI though there was ↔ between low fat and standard fat (35% E fat) diets [107]	Shang et al. 2020 [85] Moran et al. 2013 [16] Wong et al. 2016 [107]

Table 1 (continued)

Dietary intervention	N study design	N studies; N participants	Main findings ^a	References
Fatty acids	1 SR (5 RCT total - 1 RCT using MUFA enriched diet) [16] 3 RCT [86, 102, 105] 1 controlled trial (not randomised) [103] ^c	5; 146	MUFA enriched diets may produce greater weight loss when compared to other dietary patterns [16] MUFA enriched compared with PUFA enriched diets ↓ FGL [103], glucose response to OGTT [103], HgBA1 [102] Diets with a higher alpha-linolenic acid, lower omega-6/omega-3 ratio and saturated fat content ↓ TAG, TC/HDL-C, LDL-C-/HDL-C, TAG/HDL-C, and HOMA-IR [105] High total and saturated fat meals compared with high fibre low fat meals produce prolonged ↓ in T [86]	Moran et al. 2013 [16] Yahay et al. 2021 [105] Kalgaonkar et al. 2011 [102] Kasim-Karakas et al. 2004 [103] Katcher et al. 2009 [86]
DASH	1 SR/MA (19 RCT total - 4 RCT using DASH diet) [85]	4; 228	Dietary intervention ↓ HOMA-IR, FINS, FGL, BMI, BW, WC compared with minimal intervention, and subgroup analysis showed DASH diet was more effective at improving insulin sensitivity [85]	Shang et al. 2020 [85]
Plant-based	3 RCT	3; 108	Plant-based (35% animal protein, 35% textured soy protein, 30% vegetable protein) compared to control (70% animal protein, 30% vegetable protein) ↓ BMI, FGL, FINS, TAG, HOMA-IR, T, MDA and ↑ QUICKI [67] Plant-based and control diets (calorie restriction [68] and general dietary recommendations [72]) ↓ BW [68], HOMA-IR [72], T [72], LH/FSH [72] and there was ↔ between plant-based and control diets	Turner-McGrievy et al. 2014 [68] Kazemi et al. 2020 [72] Karamali et al. 2018 [67]
Meal pattern	1 RCT	1; 40	6 meals/day compared with 3 meals/day: ↓ FINS ↑ post-OGTT insulin sensitivity	Papakonstantinou et al. 2016 [111]
Meal timing	1 RCT	1; 60	Consuming a high kilojoule breakfast compared with a high kilojoule dinner: ↓ FGL, FINS, HOMA-IR, T ↑ SHBG	Jakubowicz et al. 2013 [66]

^a Summarises commonly used measures in PCOS research and does not report on all measured outcomes. For prospective pre-post studies significant changes from baseline are reported. For RCTs significant changes between intervention(s) and control are reported. Only experimental studies not already summarised in included systematic reviews/meta-analysis are presented

^b Shishregar et al. 2019 total study population included 62 women though only findings for the women with PCOS ($n=28$) are included

^c While habitual diet (control) was not enriched with MUFA, nutritional analysis showed that it was rich in oleic acid

Although weight loss has shown clear benefits to PCOS outcomes, including not only on reproductive function, but also glucoregulatory status, androgen status and lipid profiles [42–52], there are varying degrees of responsiveness to weight loss in terms of improvement of PCOS symptoms. One study by Pasquali et al. [53] found that when women achieved similar levels of weight loss (>5% weight) only one-third displayed a full recovery from PCOS, with the remainder showing

only partial or no recovery. Higher waist circumference (WC), waist-hip-ratio (WHR) and androstenedione at baseline were associated with a poorer chance of successful outcomes [53], suggesting that central adiposity and more severe hyperandrogenism may predict responsiveness to weight loss interventions in PCOS. Huber-Buchholz et al. [45] also reported women who achieve greater reductions in central fat and insulin sensitivity show greater symptom improvement with

weight loss. This suggests that lifestyle interventions which simultaneously reduce IR and improve body composition (namely fat distribution), may help to optimise outcomes in PCOS management independent of changes in weight status.

Diet

The 2018 PCOS guideline recognises there is insufficient evidence to suggest that any specific dietary approaches provide greater benefits on health outcomes [18]. Dietary recommendations may take on a variety of balanced dietary strategies according to the individual's lifestyle needs and preferences, as per general population recommendations [18]. This advice is based on a systematic review comparing different dietary compositions (e.g. low carbohydrate, low glycaemic index (GI) and glycaemic load (GL), high protein, monounsaturated fatty acid (MUFA) enriched and fat counting diets) to best manage PCOS, identifying minimal differences between diets on anthropometric outcomes, concluding weight loss improves the presentation of PCOS regardless of dietary composition [16, 54]. There is now an emerging body of evidence that suggests a range of dietary strategies may produce favourable effects on PCOS features that occur independent of weight loss. It is important that the emerging findings from these studies are thoroughly considered to support consumer and health professional interests. To summarise current evidence this review has grouped diets in terms of those that modify carbohydrates, protein and fat, as well as specific dietary patterns.

Carbohydrates

The use of altered carbohydrate composition remains the most researched dietary approach for PCOS management. Two systematic reviews published after guideline inception support altered carbohydrate intake to improve intermediate markers of PCOS [55, 56], finding that altering carbohydrate type, as opposed to content, is preferable to better manage PCOS [55]. RCTs [57–72] and pre-post intervention studies [73–80] demonstrate that following a low GI/GL diet for at least eight weeks significantly reduces WC [55, 73, 74] and BMI when compared to high GI/GL [56] or a regular diet [73–76], although levels of weight loss are generally comparable to other dietary compositions [59, 60, 72, 74]. These reductions are proposed to be a result of decreased hunger, which may reduce energy intake and make it easier to follow dietary recommendations in the long-term [78, 81–84]. Low GI/GL diets also improve insulin sensitivity and reproductive hormones (T, SHBG, FAI) compared to high carbohydrate [16, 55, 57, 79, 85] or control diets [56, 59, 73–76], contributing to improvements in reproductive function, specifically menstrual regularly [60, 79]. Lastly, low GI/GL diets can improve risk factors for T2DM and CVD, including glucose

[86, 87], TC [55, 56, 59, 75, 77], LDL-C [55, 59, 75, 85], TAG [55, 59, 73] and HDL-C [75], when compared to a regular or high GI/GL diet. It must be noted that beneficial effects of low GI/GL diets may also be attributed to proportional increases in protein and/or fat loads.

Protein

In women with PCOS higher protein intakes may be superior at suppressing androgen levels when compared to high carbohydrate diets. Postprandial research has shown that high protein meals can reduce insulin and dehydroepiandrosterone stimulation compared to meals rich in glucose [88]. Research in the general population has also shown that reduced appetite and energy intakes from low GI/GL diets are related to increased protein intakes [89, 90]. RCTs and pre-post intervention studies found that high protein diets (defined here as protein constituting $\geq 25\%$ energy [91]) consumed for at least four weeks reduce weight [12, 73, 74, 92–96], BMI [73, 74, 92, 95], WC [73, 74, 92, 97], WHR [73] and fat mass [74, 92, 97]. These reductions in anthropometric measures are accompanied by improved FINS [12, 74, 95, 98] and HOMA-IR [12, 73, 95, 98], blood lipids [12, 96], T [73, 92, 94] and hirsutism (Ferriman-Gallwey score) [73]. However, only three of these studies were able to show significant improvements in anthropometric measures [97], insulin sensitivity [98] and blood lipids [12] when compared to low/standard protein [12, 97] or control diets [98]. Only one study investigated effects on mental health outcomes and found that a high protein diet reduced depression and improved self-esteem [99].

Fats

Fatty acid composition is also an important consideration as metabolic disorders associated with PCOS can benefit from increased MUFA and polyunsaturated fatty acid (PUFA) intakes [63–65]. Postprandial research in PCOS reported prolonged reductions in T for high fat compared to low fat meals, which likely results from delayed nutrient absorption [86]. Two acute meal studies in lean and obese women with and without PCOS reported that proatherogenic inflammatory markers [100] and oxidative stress [101] were elevated, independent of but augmented by obesity, following saturated fat ingestion with this associated with worsened IR and androgens. Two experimental studies in PCOS investigated the effects of habitual walnut (PUFA rich diet) [102, 103] and almond (MUFA rich diet) [102] intake for at least six weeks and reported no differences in glucoregulatory status, lipids or androgens with the exception of HbA1c significantly decreasing in the walnut relative to the almond group. Kasim-Karakas et al. [103] reported increased fasting and postprandial glucose

(oral glucose tolerance test (OGTT)) for increased walnut intake compared to habitual (control), which they postulated may be related to the control diet being rich in oleic acid. Together these findings suggest minimal benefit for improving dietary PUFA compared to MUFA content. Two RCTs in women with PCOS investigated the effects of diets rich in olive [104, 105], canola [105] and sunflower [105] oil. Yahay et al. [105] reported 25g/day canola oil caused reductions in TAG, TC/HDL-C, LDL-C/HDL-C, TAG/HDL-C and HOMA, but not androgens, compared to 25 g/day olive and sunflower oils [105]. This may be related to the more favourable fatty acid composition of canola oil, with comparable MUFA content to olive oil, higher alpha-linolenic acid, lower omega-6/omega-3 ratio and saturated fat than both olive and sunflower oils. Douglas et al. [104] reported weight and the acute insulin response (OGTT) were lower following a eucaloric low carbohydrate compared to a eucaloric MUFA-enriched olive oil diet, suggesting that reduced carbohydrate intake may have greater glucoregulatory benefits than increased MUFA intake [104]. Lastly, two RCTs compared hypocaloric low-fat diets to a low carbohydrate [106] or low GI [107] diets, with reductions in weight [106], WC [106], body fat [106, 107], FINS [106] and FAI [106] in both groups but no difference between groups.

Dietary and eating patterns

In addition to diets that focus on specific macronutrient manipulations, there are a range of dietary patterns which have been explored in PCOS management. A systematic review (including 19 studies and 1,193 participants) published after guideline development (2020) found that the Dietary Approaches to Stop Hypertension (DASH) diet (rich in fruit, vegetables, wholegrains, nuts, legumes and low-fat dairy and with a predominantly low-GI carbohydrate profile) was the optimal choice for reducing IR [85]. RCTs in PCOS also report beneficial effects on weight [63, 64], BMI [62, 63], IR [62] and hormonal profile, including SHBG [64], androstenedione [64] and FAI [62] for a DASH compared to a control diet after 8–12 weeks. A vegetarian diet also reduced inflammatory markers (CRP, resistin and adiponectin) compared to a meat inclusive diet [80]. A vegan diet improved weight loss at three, but not six months [68], and a pulse-based diet led to similar reductions in weight, insulin sensitivity and reproductive hormones compared to a healthy control diet [72]. All of these dietary patterns are high in fibre and plant proteins, producing favourable effects on microbial diversity and encouraging production of short-chain fatty acids that possess potential anti-inflammatory actions [108, 109]. With mechanistic animal studies suggesting a possible pathophysiological role of gut microbiota in IR and

ovarian dysfunction, it is possible that metabolic and hormonal benefits associated with plant-based dietary patterns in PCOS are related to increased intakes of dietary prebiotics [110]. However, further mechanistic studies exploring the role of gut microbiota in PCOS and RCTs investigating effects of dietary prebiotics on PCOS outcomes are required.

Lastly, particular eating patterns, such as eating smaller more frequent meals across the day [111] and eating a larger breakfast and smaller dinner [66], have also been found to be beneficial for insulin sensitivity [66, 111] and androgen reductions [66]. This is an important finding, as women with PCOS are more likely to either skip breakfast or consume their breakfast and lunch later in the day [112].

Studies examining specific food items in relation to PCOS outcomes, including raw onions [65], concentrated pomegranate juice [69, 113–115] and flaxseed powder [70, 116] have yielded largely inconsistent results. A core limitation of these single food studies is that foods are never consumed alone within the diet, omitting the influence of the dietary matrix and the interactions that occur amongst dietary constituents within meals. These studies provide limited applicability in the context of formulating practical dietary recommendations [117]. Please see Table 1 for a summary of available evidence from reviews and experimental studies investigating the effects of different types of diets on PCOS outcomes.

Physical activity

The 2018 PCOS guideline recommends ≥150 minutes per week of moderate or ≥75 minutes per week of vigorous intensity exercise for weight gain prevention, and ≥250 minutes per week of moderate or ≥150 minutes per week of vigorous intensity exercise for weight loss and weight regain prevention [18]. Minimising sedentary time and the inclusion of strength training exercise for two days per week is also recommended [18].

To date the most comprehensive review in PCOS (including 27 papers from 18 trials up until June 2017) reported that exercise improved FINS, HOMA-IR, TC, LDL-C, TAG, body composition (body fat percentage and WC) and aerobic fitness ($VO_{2\max}$) [119] compared with usual care or control groups. In regards to exercise type, subgroup analysis reported aerobic exercise improved BMI, WC, body fat percentage, FINS, HOMA-IR, TC, TAG and $VO_{2\max}$. In contrast, while resistance training produced unfavourable effects on HDL-C (decrease) and BMI (increase), it improved other measures of anthropometry, including WC. Combined interventions (using both aerobic and resistance training) had no effect on any of the measured markers. Subgroup analysis also found that more outcomes improved when

^a Significant findings from meta-analyses when comparing exercise groups to control

^b Subgroup analyses compared different types of exercise; only 1 study included for combined exercise

interventions were supervised, of a shorter duration (≤ 12 weeks) and were conducted in women who were above a healthy weight [119].

Three more recent systematic reviews have looked at the effects of specific types of exercise on PCOS outcomes [120–122]. These reviews found that vigorous aerobic exercise can improve measures of insulin responsiveness and resistance, including HOMA-IR [121] and the insulin sensitivity index [120]; body composition, including WC [121] and BMI [122]; and cardiorespiratory fitness (VO_{2max}) [121]. High intensity interval training (HIIT) alone may be effective for improving IR and BMI [123], however this has not been consistently shown [124]. Interventions involving a combination of aerobic and resistance exercise [122] or resistance training only [120] did not result in improvements in BMI [122] or weight status [120]. Exercise involving resistance training did result in other beneficial improvements to body composition (reduced body fat, WC and increased lean mass) and strength. This is important, as the degree of

central adiposity predicts responsiveness to weight loss interventions in PCOS [53], and women who achieve greater reductions in central fat show greater symptom improvement with weight loss [45]. Resistance training may also improve androgen levels, though findings are inconsistent and more research is needed to draw definite conclusions [120]. There was insufficient evidence from available data to assess the effects of exercise type on reproductive function [122]. Please see Table 2 for a summary of available evidence from meta-analyses investigating the effects of different types of exercise on PCOS outcomes.

When comparing the effects of exercise and diet combined with diet alone, a systematic review and meta-analysis (three studies) found no differences for any measured outcomes (glucose, insulin HOMA-IR, weight, BMI, WC, body fat, fat free mass, T, SHBG and FAI) [119]. In regards to exercise and diet combined compared to exercise alone, subgroup analysis (including 17 studies) from a large systematic review found that the addition of diet to exercise,

^a Qualitative analysis only

^b Statistical analysis compares order of intervention arms (e.g. counselling followed by exercise versus exercise followed by counselling) and doesn't compare effects of counselling versus exercise

particularly vigorous intensity aerobic exercise, resulted in greater reduction to BMI, WC, FAI and HOMA-IR than exercise only [121]. In regards to exercise (aerobic) alone versus diet alone, one intervention study found that exercise induced weight loss produced greater improvements

in menstrual frequency and ovulation rates [125], with no differences in pregnancy rates [125]. However, this study was not randomised and treatments were self-selected, which may have biased the results and precludes firm conclusions [125].

Table 4 Key observational studies that report non-clinical sleep disruption in polycystic ovary syndrome

Reference	Sample size	Sleep methodology used	Main findings
Moran et al. 2015 [182]	PCOS: n=87 Non-PCOS: n=637	Modified version of the Jenkins Sleep Questionnaire	Women with PCOS were twice as likely to experience sleep disturbance PCOS was associated with difficulty falling asleep and maintaining sleep
Mo et al 2019 [140] ^a	PCOS: n=484 Non-PCOS: n=6094	Sleep duration was self-reported on a work day and non-work day Sleep quality was self-reported through frequency questions about difficulty falling asleep, restless sleep, difficulty sleeping and severe tiredness	Women with/without PCOS had similar sleep duration Women with PCOS had higher prevalence of sleep disturbance, and this relationship maintained even after controlling for BMI, depression, income, marital status, occupation, education status and COB
Bennett et al. 2021 [183] ^a	PCOS: n=464 Non-PCOS: n=5603	Sleep duration was self-reported on a work day and non-work day Sleep quality was self-reported through frequency questions about difficulty falling asleep, restless sleep, difficulty sleeping and severe tiredness	Overall women with PCOS had greater adverse sleep symptoms and higher DGI However, subgroup analysis revealed PCOS was only associated with a higher DGI in women with adequate sleep There was no association between PCOS and DGI in women with poor sleep The higher DGI observed in women with PCOS may only be maintained in women who achieve adequate amounts of good quality sleep
Shreeve et al. 2013 [167]	PCOS: n=15 Non-PCOS: n=18	Actigraphy, PSQI and ESS	Women with PCOS had higher night time melatonin levels Women with PCOS had reduced sleep when compared to controls
Kutanaee et al. 2019 [181]	PCOS: n=201 Non-PCOS: n=199	PSQI	Women with PCOS had lower sleep quality and daytime function Women with PCOS were more likely to utilise medication to assist with sleep

^a Mo et al. [140] and Bennett et al. [183] share the same cohort

Behavioural

The 2018 PCOS guideline promotes the use of behavioural interventions that foster self-efficacy [18]. These include the use of SMART (specific, measurement, achievable, realistic and timely) goals, self-monitoring, stimulus control, problem solving and relapse prevention [18].

Behavioural and cognitive interventions are required to improve sustainability of lifestyle changes, through considering not only the specific behaviour, but also their antecedents, consequences and cognition [126, 127]. Given that women with PCOS show higher rates of weight gain over time [9] and high attrition rates in clinical weight management research [37], there is a clear need to improve adherence to diet and physical activity interventions. However, the majority of research investigating lifestyle change in PCOS involve short-term dietary interventions with/without an exercise element, and there is a paucity of research on behavioural change strategies. As such, guideline development relied heavily on evidence taken from the general population. Only three RCTs in women with PCOS included a ‘behavioural intervention’ [128–130]. While

these studies showed enhanced weight loss [128, 130] and improved androgen and lipid profiles [129] when compared with placebo, the interventions were not well defined, with negligible context provided regarding the theoretic framework or behavioural strategies utilised.

More recently, a cross-sectional study in 501 women with PCOS [131] and two RCTs [44, 132] explored the use of self-management strategies [131] and behavioural modification interventions [44, 132] in PCOS. In the cross-sectional study, implementation of physical activity self-management strategies improved the likelihood of meeting physical activity recommendations, but had no association with BMI. Dietary self-management strategies were associated with reductions in BMI, though were not related to weight or nutritional intake [131]. In the RCTs, only the behavioural modification programme and not the control (general healthy lifestyle recommendations) produced significant weight loss after four months. A significantly greater proportion of women in the intervention group also improved menstrual regularity [44] and psychological well-being (lower anxiety and depressive

symptoms) [132] when compared to the control group. The women who achieved greater weight loss reported higher social desirability and lower embitterment scores on a personality trait assessment measure [132]. These findings are particularly novel, as they provide insight into the influence of personality traits and their contribution to success in following behavioural modifications [132].

Alcohol and smoking

In the clinical setting, smoking and alcohol consumption are often addressed alongside dietary and physical activity changes, employing the same behavioural and cognitive interventions to promote adherence. Hence, alcohol and cigarette use are considered here under traditional lifestyle strategies. The PCOS international guideline highlights the importance of assessing alcohol consumption and cigarette smoking when improving fertility and reproductive outcomes in women with PCOS [18]. Assessment of cigarette use is also recommended when evaluating CVD risk factors and thromboembolism risk associated with oral contraceptive pills [18]. These recommendations are based on existing practice guidelines used for the general population.

There is a paucity of observational research characterising alcohol consumption in women with PCOS. One Swedish study comparing women with PCOS ($n=72$) to healthy controls ($n=30$), demonstrated a lower alcohol intake in the PCOS group [133]. A larger study in Australia comparing women with ($n=409$) and without ($n=7,057$) PCOS, reported no significant difference in alcohol intake [134]. Similarly, a Spanish study ($n=22$ PCOS and $n=59$ controls) and a Chinese study ($n=2,217$ PCOS and $n=279$ controls), found no significant difference in alcohol intake between PCOS and non-PCOS groups [135, 136].

Current evidence on the impact of alcohol intake on anovulatory infertility (a common feature of PCOS) is controversial, with some studies showing adverse effects and others reporting no significant correlation [136, 137]. One prospective study including 18,555 married women from The Nurses' Health Study II, who had no history of infertility, found no clinically significant impact of alcohol intake on anovulatory infertility, after adjusting for parity and other factors [138]. Similarly, a Danish study ($n=6,120$ women aged 21 to 45 years) found no fertility effect with alcohol consumption of less than 14 standard drinks per week [137]. In contrast, a study on 3,833 women who recently gave birth and 1,050 women with infertility, reported an increased risk of anovulatory infertility and endometriosis with increasing alcohol intake [139].

Current observational evidence does not reveal any significant difference in smoking between women with and without PCOS [135, 136, 140], with the exception of one

study in pregnant women which showed a lower smoking rate in women with PCOS ($n=354$) compared to women without PCOS at 15 weeks gestation [3]. However, a significantly higher rate of smoking (including passive and active) is reported in women with PCOS and oligo-anovulation and/or reduced fertility compared to women with PCOS and normal menstruations or healthy controls [141, 142]. Smoking is also associated with PCOS risk independent of BMI and age [142]. A Mendelian randomisation study supports these findings, demonstrating a 38% higher risk of PCOS development in genetically predicted smokers (based on single-nucleotide polymorphisms associated with smoking initiation) compared with those who never smoked [143]. In PCOS, smoking is associated with increased levels of T, DHEAS, TC, LDL-C and FINS [141, 144, 145]. However, the underlying mechanisms are not fully understood and there are inconsistencies in findings from different studies. Furthermore, smoking is associated with lower conception and live birth rates and less favourable ART outcomes in women with PCOS [141, 146].

Psychological

The current guideline highlights the need for awareness, and appropriate assessment (such as stepwise screening) and management, of QoL, depression and anxiety, psychosexual dysfunction, negative body image and disordered eating [18]. The guideline emphasises the importance of clinicians and women working in partnership to address women's individual priorities; understanding that the impact of PCOS on an individual's QoL is key to delivering meaningful outcomes [147, 148]. To assist women to communicate with clinicians about what is important to them, the PCOS Question Prompt List [149] was developed and is consistent with the 2018 guideline. The 2018 guideline recommends screening for risk factors and symptoms of depression and anxiety at time of diagnosis. Women with positive screening results should be supported with further assessment and treatment by appropriately qualified clinicians. To screen for psychosexual dysfunction tools such as the Female Sexual Function Index [150] should be utilised. If negative body image, disordered eating or eating disorders are suspected, the PCOS guideline outlines a stepped approach for screening, and where appropriate promotes the use of psychological therapy offered by trained health professionals, which should be guided by regional clinical practice guidelines [18].

While the PCOS guideline provides justification and summarises evidence for mental health screening and diagnostic assessment, there is also a need for consideration of additional aspects, such as the efficacy of different types of psychological interventions and how

Table 5 Reviews and experimental studies investigating the effects of traditional, complimentary and integrative medicine on polycystic ovary syndrome outcomes

^a Summarises commonly used measures in PCOS research and does not report on all measured outcomes. For prospective pre-post studies significant changes from baseline are reported. For RCTs significant changes between intervention(s) and control are reported

^b Not all participants are included in the findings reported here (e.g. where findings from subgroup analysis are reported)

psychological interventions influence engagement with lifestyle change. This is important, as poorer mental health outcomes at baseline are positively associated with higher rates of attrition in lifestyle interventions [13]. Cognitive behavioural interventions could be considered to improve engagement and adherence to healthy lifestyle in women with PCOS. Research has shown support for a range of different psychological interventions, such as counselling [151], cognitive behavioural therapy (CBT) [152–154] and mindfulness meditation [155, 156], helping to change the way clinicians' approach and deliver optimal PCOS management.

CBT is one of the most widely-researched psychological interventions, and is well-recognised as the most effective psychological treatment for depression and anxiety [157]. One RCT showed that eight weekly group CBT sessions were effective in improving QoL ratings and reducing psychological fatigue in women with PCOS [152]. Another more recent RCT investigated the outcome of a 1 year three-component intervention focusing on CBT, diet and exercise [154] and reported improvements in self-esteem and depressive symptoms as compared to usual care [154]. Similarly, an RCT by Cooney et al. [153], comparing the effects of CBT and lifestyle modification versus lifestyle modification alone, reported the CBT/lifestyle modification group lost more than twice as much weight per week

and had greater improvements in QoL compared to lifestyle only. Depression scores decreased in the overall group and there was no difference between the two groups [153]. Lastly, a pilot intervention study of adolescents with PCOS has shown promising results for the use of CBT in the reduction of weight and improvement in depressive symptoms [158].

Mindfulness meditation programs have gained increasing popularity over the past few decades, and are being included as part of clinical trials to reduce stress and improve psychological wellbeing across a range of medical conditions [159]. Mindfulness meditation can be used to reduce the production of adrenal androgens, activated via the adrenal glands as a direct result of psychological distress [156]. Despite the proposed benefits, there are very few studies investigating the use of mindfulness meditation as a treatment for psychological symptoms associated with PCOS. One RCT ($n=86$) compared the provision of an eight week mindfulness-based stress reduction (MBSR) program, and found that when compared to the control group (health education), the MBSR group produced greater reductions in perceived stress, depressive symptoms and fasting blood glucose [160]. Similarly, another RCT investigating the impact of mindfulness meditation for eight weeks in PCOS showed reduced stress, depression and anxiety symptoms, and increased life satisfaction and QoL in the intervention

group compared to no treatment [156]. In adolescents with PCOS ($n=37$), a pilot RCT reported higher levels of nutrition and physical activity self-efficacy following a mindfulness and self-management program [161]. Mindfulness-based cognitive therapy (MBCT) combines both elements of MBSR and CBT, but as yet there are no trials investigating this intervention in PCOS.

In addition to CBT and mindfulness meditation, there is some evidence to support group counselling sessions as beneficial in conjunction with exercise programs to increase and support weight loss [151]. In one RCT ($n=17$) participants followed a high-intensity aerobic exercise program for eight weeks, followed by eight weeks of group counselling [151]. Qualitative analysis of data taken from the group counselling and physical exercise sessions revealed that development of supportive relationships was important for successful behavioural change. By fostering the exchange of narratives relating to their illness (e.g. effects of PCOS on aspects of everyday life), and generating feedback between group members, counselling sessions helped to reduce social isolation and improve adherence to the exercise intervention [151]. Please see Table 3 for a summary of experimental studies investigating effects of psychological interventions on PCOS outcomes.

Sleep

Women with PCOS have an increased risk of both clinical sleep disorders and non-clinical sleep disturbance, which is mediated by hormone derangement, in particular reduced oestrogen, progesterone and melatonin levels [164]. Oestrogen is required for the metabolism of neurotransmitters (norepinephrine and serotonin) involved in regulating sleep patterns, and plays an important role in maintaining a low body temperature at night [165]. Progesterone has sedative and anxiolytic actions that can support sleep quality, and acts as a respiratory stimulant that lessens airway resistance in obstructive sleep apnoea (OSA) [166]. Melatonin is a neuroendocrine hormone that is widely recognised as crucial in maintaining circadian rhythm regulation. However, melatonin is also involved in ovarian function, with actions including delaying ovarian senescence, promoting follicle formation and improving oocyte quality [167–173].

The current PCOS guideline recognises that OSA is 6.5–8.3 times more likely in women with PCOS [164, 174–177], and promotes routine screening to identify and treat associated symptoms, such as snoring, excessive sleepiness and the potential for fatigue to worsen mood disorders [18]. Screening should include a simple questionnaire, such as the Berlin tool [178], and where appropriate women should be referred onto a specialist for further assessment and

treatment [18]. The guidelines also highlight that treatment of OSA in PCOS should not be used to improve metabolic features. Since guideline inception evidence has emerged reporting weight, PCOS and sleep are interrelated factors that can each contribute to the worsening presentation of one another, whereby sleep disorders and disturbance may worsen the presentation of PCOS related metabolic outcomes and vice versa [179].

Hypersomnia and insomnia are also common clinical sleep disorders in PCOS [164, 177, 180], with prevalence estimated at 11% versus 1% in women with versus those without PCOS [180]. Even in the absence of clinically diagnosed sleep disorders, women with PCOS have a higher prevalence of sleep disturbances, including poor sleep quality [181], issues with sleep initiation [182], severe fatigue [140], restless sleep [140] and difficulty sleeping overnight [140]. The prevalence of sleep disturbances may be up to 20% higher in women with PCOS compared to women without PCOS [183]. Emerging research also suggests that social restrictions arising from the COVID-19 pandemic have worsened sleep disturbances in women with PCOS [177]. Findings from key studies of non-clinical sleep disturbance can be found in Table 4.

In the general population short and disturbed sleep is consistently associated with excess weight [184], IR [185], T2DM [185] and CVD [186]. Similar relationships are observed in PCOS, where OSA and sleep disordered breathing exacerbates risk of IR and metabolic consequences of abnormal glucose tolerance [187, 188]. A cross-sectional study in adolescents with PCOS ($n=103$) reported those with sleep disordered breathing had significantly higher BMI Z-scores, and a higher prevalence of metabolic syndrome (METS) [188]. Similar metabolic consequences are seen in women with PCOS who suffer from non-clinical sleep disturbance [164]. Underlying mechanisms linking sleep disorders and disturbance with worsened metabolic outcomes include amplified sympathetic tone and oxidative stress [164], reduced adipose tissue lipolysis, and an increase in energy intake stemming from heightened hedonic and endocrine appetite signals [189].

Unfavourable effects on energy metabolism and appetite regulation, may explain why women with PCOS who display sleep disturbance have a reduced capacity to maintain dietary interventions [183]. Moreover, depression and anxiety share a bidirectional relationship with disrupted and reduced sleep [190], and as stated previously, interventions that improve mental health can help to increase engagement with dietary and physical activity recommendations [131]. Optimising sleep may therefore be an important consideration when promoting healthy lifestyle change in women with PCOS [183].

Table 6 Current recommendations for clinical practice and research gaps identified by this review

Recommendation(s) from current guidelines ^a	Category of recommendation ^b	Research gaps
Effectiveness of lifestyle interventions		
Healthy lifestyle behaviours encompassing healthy eating and regular physical activity should be recommended in all those with PCOS to achieve and/or maintain healthy weight and to optimise hormonal outcomes, general health, and QoL across the life course. Lifestyle intervention (preferably multicomponent including diet, exercise and behavioural strategies) should be recommended in all those with PCOS and excess weight, for reductions in weight, central obesity and IR.	CCR EBR	<ul style="list-style-type: none"> • Improves sustainability of weight loss interventions. • Identifies subgroups who respond to weight loss with clinically relevant metabolic and reproductive improvements (this requires the inclusion of more clinical reproductive outcomes in RCTs). • Defines weight loss thresholds for improvements in different PCOS features (metabolic, reproductive and psychological). • Characterises the degree of metabolic and reproductive improvements related to different lifestyle factors (diet, physical activity and behavioural) independent of weight changes. • Considers effects of weight gain prevention on limiting the progression/worsening of PCOS features. • Investigates how different dietary, physical activity and behavioural interventions affect engagement, adherence and sustainability of lifestyle change. • Investigates efficacy and effectiveness of healthy lifestyle changes independent of weight change.

Table 6 (continued)

Recommendation(s) from current guidelines ^a	Category of recommendation ^b	Research gaps
Dietary interventions		
A variety of balanced dietary approaches could be recommended to reduce dietary energy intake and induce weight loss in women with PCOS and overweight and obesity, as per general population recommendations.	CCR	<ul style="list-style-type: none"> Low GI/GL diets may provide benefits in reducing weight and IR in women with PCOS. Further research needs to assess additional risk factors including reproductive function and CVD risk. Identify and define the optimal diet for PCOS management by comparing a range of different dietary approaches (e.g. DASH, Mediterranean or low GI/GL).
General healthy eating principles should be followed for all women with PCOS across the life course, as per general population recommendations.	CCR	
To achieve weight loss in those with excess weight, an energy deficit of 30% or 500 - 750 kcal/day (1,200 to 1,500 kcal/day) could be prescribed for women, also considering individual energy requirements, body weight and physical activity levels.	CPP	
In women with PCOS, there is no or limited evidence that any specific energy equivalent diet type is better than another, or that there is any differential response to weight management intervention, compared to women without PCOS.	CPP	
Tailoring of dietary changes to food preferences, allowing for a flexible and individual approach to reducing energy intake and avoiding unduly restrictive and nutritionally unbalanced diets, are important, as per general population recommendations.	CPP	
Physical activity interventions		
Health professionals should encourage and advise the following for prevention of weight gain and maintenance of health:	CCR	While evidence supports the provision of supervised vigorous aerobic exercise, which may provide greater benefits on PCOS symptoms than other types of exercise (e.g. resistance training), additional larger and longer-term studies are required to: <ul style="list-style-type: none"> Characterise optimal exercise prescription for PCOS management. Identify factors that improve adherence to exercise interventions. Identify subgroups who respond to exercise with clinical improvements.
• in adults from 18 – 64 years; a minimum of 150 min/week of moderate intensity physical activity or 75 min/week of vigorous intensities or an equivalent combination of both, including muscle strengthening activities on 2 non-consecutive days/week;		
• in adolescents, at least 60 minutes of moderate to vigorous intensity physical activity/day, including those that strengthen muscle and bone at least 3 times weekly;		
• activity be performed in at least 10-minute bouts or around 1000 steps, aiming to achieve at least 30 minutes daily on most days.		
Health professionals should encourage and advise the following for modest weight-loss, prevention of weight-regain and greater health benefits:	CCR	
• a minimum of 250 min/week of moderate intensity activities or 150 min/week of vigorous intensity or an equivalent combination of both, and muscle strengthening activities involving major muscle groups on 2 non-consecutive days/week;		
• minimised sedentary, screen or sitting time.		
Physical activity includes leisure time physical activity, transportation such as walking or cycling, occupational work, household chores, games, sports or planned exercise, in the context of daily, family and community activities.	CPP	
Daily, 10000 steps is ideal, including activities of daily living and 30 minutes of structured physical activity or around 3000 steps.		
Structuring of recommended activities need to consider women's and family routines as well as cultural preferences.		

Table 6 (continued)

Recommendation(s) from current guidelines ^a	Category of recommendation ^b	Research gaps
Behavioural interventions		
Lifestyle interventions could include behavioural strategies such as goal-setting, self-monitoring, stimulus control, problem solving, assertiveness training, slower eating, reinforcing changes and relapse prevention, to optimise weight management healthy lifestyle and emotional wellbeing in women with PCOS.	CCR	<ul style="list-style-type: none"> To identify behavioural and cognitive strategies that should be targeted in women with PCOS, more observational research that characterises women's use of self-management strategies is needed. To aid replication and interpretation of findings, RCTs must clearly define the theoretical frameworks and behavioural components used in intervention design.
Comprehensive health behavioural or cognitive behavioural interventions could be considered to increase support, engagement, retention, adherence and maintenance of healthy lifestyle and improve health outcomes in women with PCOS.	CPP	
Assessment and treatment of infertility (as it relates to alcohol and smoking use)		
Cardiovascular disease risk (as it relates to alcohol and smoking use)	CPP	<ul style="list-style-type: none"> Determine whether women with PCOS are at a higher risk of alcohol and smoking-related infertility complications (with a focus on anovulatory infertility) when compared to women without PCOS. Determine whether women with PCOS are at a higher risk of smoking-related CVD complications when compared to women without PCOS.
Factors such as blood glucose, weight, blood pressure, smoking, alcohol, diet, exercise, sleep and mental, emotional and sexual health need to be optimised in women with PCOS, to improve reproductive and obstetric outcomes, aligned with recommendations in the general population.	CCR	
If screening reveals CVD risk factors including obesity, cigarette smoking, dyslipidaemia, hypertension, impaired glucose tolerance and lack of physical activity, women with PCOS should be considered at increased risk of CVD.	CCR	
Quality of life		
Health professionals and women should be aware of the adverse impact of PCOS on quality of life.	CCR	<ul style="list-style-type: none"> Validate QoL tools longitudinally to identify clinically meaningful differences in QoL scores.
Health professionals should capture and consider perceptions of symptoms, impact on quality of life and personal priorities for care to improve patient outcomes.	CCR	
The PCOS quality of life tool (PCOSQ), or the modified PCOSQ, may be useful clinically to highlight PCOS features causing greatest distress, and to evaluate treatment outcomes on women's subjective PCOS health concerns.	CPP	

Table 6 (continued)

Recommendation(s) from current guidelines ^a	Category of recommendation ^b	Research gaps
Depression and anxiety symptoms, screening and treatment		
Psychosexual function		
Body image		
Eating disorders and disordered eating		
Health professionals should be aware that in PCOS, there is a high prevalence of moderate to severe anxiety and depressive symptoms in adults; and a likely increased prevalence in adolescents.	CCR	<ul style="list-style-type: none"> To determine accurate prevalence of psychological conditions in PCOS, more adequately powered cross-sectional studies using structured diagnostic interviews administered by appropriately qualified professionals are required. Future research should consider the efficacy of different types of psychological interventions in PCOS, with a focus on how changes to mental health symptoms influence engagement with lifestyle change. In particular, the development of a PCOS specific CBT program, tailored to meet the specific mental health needs of women with PCOS is warrant.
Anxiety and depressive symptoms should be routinely screened in all adolescents and women with PCOS at diagnosis. If the screen for these symptoms and/or other aspects of emotional wellbeing is positive, further assessment and/or referral for assessment and treatment should be completed by suitably qualified health professionals, informed by regional guidelines.	CCR	
If treatment is warranted, psychological therapy and/or pharmacological treatment should be offered in PCOS, informed by regional clinical practice guidelines.	CCR	
Factors including obesity, infertility, hirsutism need consideration along with use of hormonal medications in PCOS, as they may independently exacerbate depressive and anxiety symptoms and other aspects of emotional wellbeing.	CPP	
All health professionals should be aware of the increased prevalence of psychosexual dysfunction and should consider exploring how features of psychohirsutism and body image, impact on sex life and relationships in PCOS.	CCR	
If psychosexual dysfunction is suspected, tools such as the Female Sexual Function Index can be considered.	CCR	
Health professionals and women should be aware that features of PCOS can impact on body image.	CCR	
All health professionals and women should be aware of the increased prevalence of eating disorders and disordered eating associated with PCOS.	CCR	
If eating disorders and disordered eating are suspected, further assessment, referral and treatment, including psychological therapy, could be offered by appropriately trained health professionals, informed by regional clinical practice guidelines.	CCR	

Table 6 (continued)
Recommendation(s) from current guidelines^a

Category of recommendation ^b	Research gaps
Obstructive sleep apnoea (OSA)	<ul style="list-style-type: none"> To determine accurate prevalence of subclinical sleep disturbances in PCOS, more adequately powdered cross-sectional studies using validated subjective and objective sleep measures are required. While emerging evidence suggests that disturbed sleep may exacerbate IR via decreasing energy expenditure and increasing adipose tissue deposition, more research in women with PCOS is needed to confirm this hypothesis. Investigate effects of CBT interventions in women with PCOS who have disturbed sleep (outcomes of interest include food intake, metabolic rate, appetite hormones, weight, adherence to lifestyle changes and PCOS features).
Inositol	<ul style="list-style-type: none"> To reduce heterogeneity across studies investigating supplements or herbal medicine, RCTs should focus on specific populations within PCOS (i.e. age, BMI or phenotype) and adopt more consistent approaches to formulation (i.e. limit co-supplementation), dosage, intervention duration and the type of comparator used. Mechanistic studies are needed to investigate herb- or nutrient-drug interactions (with common pharmacological treatments used in PCOS) and other possible interactions with the biological processes underpinning PCOS. Research that characterises the uptake of CIM approaches by women with PCOS, including where they are sourcing information on this topic, will aid health professionals understanding of how to safely navigate the use of adjunct therapies in PCOS management.

Abbreviations: BMI Body mass index, CBT Cognitive behavioural therapy, CI/D Cardiovascular disease, DS/H Dietary approaches to stop hypertension, GI Glycaemic index, GL Glycaemic load, IR Insulin resistance, NAC N-acetyl-cysteine, PCOS Polycystic ovary syndrome, RCT Randomised controlled trial, QoL Quality of life

^a Recommendations are taken directly from the 2018 International Evidence-Based Guideline for the Assessment and Management of PCOS [18]. Does not include all recommendations, only those relevant to the findings of this review are presented

^b EBR Evidence based recommendations: Evidence sufficient to inform a recommendation made by the guideline development group. CCR Clinical Consensus Recommendations: In the absence of evidence, a clinical consensus recommendation has been made by the guideline development group. CPP Clinical Practice Points: Evidence not sought. A practice point has been made by the guideline development group where important issues arose from discussion of evidence-based or clinical consensus recommendations

Traditional, complementary and integrative medicine

The 2018 PCOS guideline includes recommendations on inositol supplementation, though do not include evidence regarding the use of other supplements, herbal medicine or other TCIM approaches, including acupuncture and yoga [18].

Vitamins, vitamin-like supplements, minerals and other supplements

The 2018 guideline highlights that inositol (including myo-inositol (MI) and di-chiro inositol) is a nutritional supplement that may be involved in insulin signalling transduction [191]. MI in particular is a key endocrine regulator that displays impaired metabolism in PCOS [191]. MI supplementation has been explored in a meta-analysis of nine RCTs ($n=496$), which showed improved metabolic profiles and reduced hyperandrogenism [191]. These findings are supported by two earlier meta-analyses, reporting improved ovulation, menstrual cyclicity, and hormonal profiles following MI supplementation [192, 193]. The 2018 PCOS guideline recommends that inositol (in any form) should be considered as an experimental therapy in PCOS management. The guideline also recognises that women participating in any form of TCIM should be encouraged to advise their health professional. However, it does not consider emerging evidence for the use of other types of TCIM in PCOS treatment as this was outside of the scope of the 2018 guideline.

Vitamins

B-group vitamins (B₁, B₆ and B₁₂), folic acid (B₉) and vitamins D, E, and K are critical for several biological processes that can affect metabolic and reproductive features of PCOS. B-group vitamins work alongside folic acid (the synthetic form of folate) to regulate homocysteine (Hcy) via re-methylation of Hcy to methionine [194]. Hcy is an amino acid that confers an increased risk of CVD at high levels, and which is often deranged in women with PCOS [195], likely related to a higher prevalence of folate deficiency [196–198]. One RCT explored the use of B-group vitamins combined with folic acid in 60 women with PCOS, and reported a reduction in the Hcy increasing effect of metformin [198]. Folic acid alone has also been examined in two RCTs of women with PCOS ($n=69$ [199] and $n=81$ [200]), improving FINS, HOMA-IR, C-reactive protein, total antioxidant capacity (TAC) and glutathione with doses ≥ 5 mg/day when compared with placebo [199, 200]. Regarding vitamin D supplementation, three large-scale meta-analyses reported improvements in measures of IR (HOMA-IR [201, 202], FINS [201]), fasting glucose [201]), lipid profiles (LDL-C [201–203], TC [203] and TAG [203]) and androgens (T) [202], when compared

with placebo. While vitamin E (or tocopherol) has various reported benefits on fertility outcomes in other populations [204], and has improved androgen profiles when co-supplemented with coenzyme Q10 (CoQ10) in women with PCOS [205], to date no RCTs have examined the use of vitamin E supplements alone in PCOS. Vitamin K also has limited available literature in PCOS, with only one RCT ($n=84$) demonstrating improvements in anthropometry, insulin and androgen profiles following supplementation (90 µg/day Menaquinone-7 for eight weeks), compared with placebo [206].

Vitamin-like supplements

Vitamin-like supplements including bioflavonoids, carnitine and alpha-lipoic acid (α-LA) have well-recognised antioxidant properties and play a role in fatty acid and glucose metabolism, providing possible metabolic benefits in PCOS [207]. Bioflavonoids consist of plant-derived polyphenolic compounds, some of which have been inversely associated with METS in women with PCOS [207]. In a pilot prospective study of 12 women with PCOS, 36 mg/day of the soy isoflavone genistein for six months improved lipid profiles but not anthropometry, IR, hormonal profiles or menstrual cyclicity [208]. Carnitine, particularly the active form L-carnitine, is reported to be lower in women with PCOS and linked with hyperandrogenism, hyperinsulinaemia and reduced oocyte quality [209, 210]. One RCT explored L-carnitine use in PCOS and found beneficial effects on mental health parameters and markers of oxidative stress [211], although the integrity of these have come under scrutiny and hence should be interpreted with caution [122212]. Regarding α-LA, a small pre-post study ($n=6$) administered 1200 mg/day for 16 weeks, and reported improved IR, LDL-C and TAG, though no effects on TAC or plasma oxidation metabolites [213]. Another RCT reported improved anthropometric (BMI), metabolic (FINS and HDL-C) and reproductive (menstrual cyclicity) features in 46 women with PCOS receiving α-LA supplementation (600 mg/day for 180 days) compared with controls [214]. However, as these women were co-supplemented with 1000 mg/day D-chiro-inostiol, findings are not isolated to the effects of α-LA alone [214].

Minerals

Minerals such as calcium, zinc, selenium, magnesium and chromium picolinate (CrP) have been explored in PCOS due to their reported insulin sensitising, antioxidant and anti-inflammatory properties [215–217]. A small number of studies have also reported women with PCOS are at higher risk of being deficient in calcium [218], zinc [215, 217] and selenium [195]. A recent systematic

review (six RCTs) reported that vitamin D and calcium co-supplementation in women with PCOS improved lipid and androgen profiles, follicular health and menstrual cyclicity [219]. While these findings are promising, it is difficult to attribute benefits to calcium alone, given calcium is often co-supplemented with vitamin D due to their complementary mechanisms of action. One systematic review (five RCTs) in PCOS reported zinc (often co-supplemented with other nutrients such as calcium, vitamin D and magnesium), improved HOMA-IR, lipids, T, FSH and DHEAS [220] compared to placebo. Another systematic review (five RCTs) examining selenium supplementation reported reduced IR, oxidative stress and inflammation, while results for anthropometry, lipids, androgens and hirsutism were inconsistent [221]. Regarding magnesium (an intracellular cation involved in insulin metabolism), while supplementation in PCOS has been associated with reduced IR in observational research [222], these findings are not supported by data from RCTs, with considerable inconsistencies between studies [222]. Two meta-analyses examined CrP in women with PCOS [223, 224]. While one reported that CrP supplementation reduced BMI, FINS and free testosterone [223], the other reported decreased IR, but not BMI, and increased levels of T [224].

Other supplements

Other supplements purported to provide a range of antioxidant and anti-inflammatory benefits, including omega-3 fatty acids, N-acetyl-cysteine (NAC), CoQ10, probiotics, quercetin, resveratrol and melatonin have been explored in PCOS. A meta-analysis (nine RCTs) of women with PCOS ($n=591$) receiving omega-3 supplementation reported reductions in HOMA-IR, TC, TAG and LDL-C, though showed no effect on other metabolic parameters or T [225]. In a meta-analysis of eight RCTs ($n=910$) examining NAC supplementation (the acylated form of L-cysteine), researchers reported improved glucose regulation and a greater likelihood of conception and livebirths in women with PCOS compared with placebo [226]. In a single RCT ($n=60$) CoQ10 supplementation (100 mg/day for 12 weeks) improved fasting glucose and insulin, HOMA-IR, insulin sensitivity index and TC, compared with the placebo group [227]. Two meta-analyses reported probiotics improved FAI, SHBG, IR and blood lipids, with no differences in weight or hirsutism between intervention and placebo groups [228, 229]. These findings may be linked to lower microbial diversity and increased intestinal permeability in women with PCOS [230, 231]. In regards to quercetin and resveratrol, which are both food derived polyphenols with a strong antioxidant capacity, one systematic review (three experimental studies, $n=246$ women with PCOS) reported

quercetin supplementation improved measures of IR and testosterone levels, but not anthropometry compared with placebo [232]. Similarly, one RCT in women with PCOS ($n=61$) reported resveratrol (800–1500 mg/day for four days) improved androgen and metabolic profiles and oocyte and embryo quality compared with placebo [233]. Finally, a systematic review (two RCTs and one cell-culture study) investigating the effects of melatonin supplementation in women with PCOS using assisted reproductive technologies reported melatonin significantly increased clinical pregnancy rates but not live birth rates [172]. A more recent RCT ($n=56$) reported improved levels of T, hirsutism, inflammatory and oxidative stress profiles in women receiving 10 g melatonin/day for 12 weeks, compared with placebo [234].

Herbal medicine

To date the most recent and comprehensive review (Cochrane review including five RCTs and $n=414$ women with PCOS) investigating the effects of herbal medicine on reproductive outcomes, reported no difference between the use of Chinese herbal medicine (CHM) and clomiphene for pregnancy rates, and limited evidence of increased pregnancy rate for CHM with clomiphene compared with clomiphene alone [235]. This review concluded that there was inadequate evidence to promote the use of CHM for the treatment of subfertility in women with PCOS [235]. Similarly, a smaller systematic review (five studies) investigating the effects of four herbal medicines (green tea, cinnamon, spearmint and black cohosh) on menstrual regularity in PCOS, found limited high-quality evidence from RCTs to support their clinical use and concluded that evidence for safety was lacking [236].

More recently, a number of small RCTs investigating metabolic and reproductive effects of a range of herbal medicines have been published. Curcumin, an active compound in turmeric (*Curcuma longa*), may exert hypoglycemic effects via a number of mechanisms, including attenuation of circulating levels of tumor necrosis factor- α [237]. One RCT ($n=67$) reported decreased levels of fasting glucose following supplementation compared with placebo [238], while another ($n=51$) which used a lower dose (1000 mg/day versus 1500 mg/day) and shorter duration (six weeks versus 12 weeks), reported no between group differences for fasting glucose, HOMA-IR or lipids [239]. *Salvia officinalis* or sage contains multiple active compounds that display antioxidant effects and therefore effects on glucose metabolism and insulin sensitivity [240]. One RCT ($n=72$) reported consuming sage extract for eight weeks improved IR and reduced BMI, with no effects on WHR or blood pressure [241]. *Foeniculum vulgare*

or fennel may provide protective effects on hormonal abnormalities in PCOS via its actions as a phytoestrogen [242]. One RCT ($n=55$) reported that six months of fennel tea and dry cupping was as effective as metformin for reducing BMI and menstrual cycle length [243]. *Glycyrrhiza glabra* or licorice contains active phytochemicals including isoflavane and glabridin, which have been shown to have antiandrogenic effects [244]. Two experimental studies in healthy women ($n=9$) [245] and women with PCOS ($n=32$) [246] reported that 3.5 g/day of licorice extract decreased T [245] and reduced side effects of spironolactone [246]. *Mentha spicata* (spearmint), *Zingiber officinale Roscoe* (ginger), *Cinnamomum cassia* (cinnamon) and *Citrus sinensis* (citrus) have been shown to exert anti-inflammatory and hypoglycemic effects [247–250]. One RCT in infertile women with PCOS ($n=60$) comparing the effects of a herbal mixture (citrus, ginger, cinnamon and spearmint) with clomiphene citrate (CC), herbal mixture alone, or CC alone reported that the herbal mixture, with or without CC, improved circulating antioxidant levels, IR and fasting blood glucose, but not menstrual regularity when compared to CC alone [251]. While observations from emerging research are promising, to support the safe translation of findings into the clinical setting there is a clear need for larger clinical trials investigating the efficacy and safety of herbal medicine use in PCOS.

Other traditional, complimentary and integrative medicine approaches

Acupuncture may provide beneficial impacts on sympathetic function [252] and ovarian blood flow [253] in women with PCOS. A recent meta-analysis of 22 RCTs ($n=2315$ women with PCOS) reported recovery of the menstrual period in the acupuncture group when compared with placebo, but no evidence for differences between groups in terms of live birth, pregnancy and ovulation [254]. While an earlier meta-analysis reported a significant reduction in BMI following acupuncture use, this was mainly due to one RCT ($n=80$) which compared acupuncture and the oral contraceptive pill to the oral contraceptive pill alone [255]. When this study was removed, the pooled analysis was no longer significant [255].

Yoga gymnastics have been recommended as an example of moderate physical activity in the 2018 evidence-based PCOS guideline [18]. However, as yoga is considered a mind-body therapy that incorporates aspects of meditation, it may provide additional benefits beyond those gained through other forms of exercise [256]. While one systematic review (16 observational and experimental studies, $n=365$ women with

PCOS) reported yoga may provide a range of psychological, reproductive and metabolic benefits, no meta-analysis was performed and a limited summary of included studies made it difficult to confirm findings [257]. A more recent systematic review (11 experimental studies) included a meta-analysis of two RCTs and found that yoga significantly decreased clinical hyperandrogenism, menstrual irregularity and fasting glucose and insulin [258]. Lastly, findings from a recent RCT ($n=67$ women with PCOS) suggests that 90 minutes of yoga per day for six weeks can significantly reduce hirsutism, waist and hip circumference when compared to controls [259]. Please see Table 5 for a summary of available evidence from meta-analyses and experimental studies investigating the effects of TCIM on PCOS outcomes.

Summary of findings and research gaps

The 2018 International Evidence-Based Guideline for the Assessment and Management of PCOS highlights lifestyle (diet, physical activity and/or behavioural) management as the primary initial treatment strategy [18]. It is important to consider that the definition of lifestyle management may warrant expansion consistent with the whole person model of healthcare provision, which may include care addressing psychological and sleep interventions, as well as a range of TCIM approaches [20]. In line with patient interest [31–35], and to assist women and healthcare providers in understanding the evidence to aid safe implementation of adjunct therapies, rigorous assessment of the evidence for these alternative lifestyle strategies in PCOS management is warranted. Using a holistic definition of patient care, this review has summarised evidence to date on the traditional components of lifestyle change (diet, physical activity and behavioural change), psychological interventions and non-pharmacological strategies (sleep, supplements, herbal medicine and other TCIM approaches). Table 6 provides a overview of current guideline recommendations alongside the key findings from this review, summarising the identified research gaps that need to be addressed before evidence-based recommendations for clinical practice can be updated.

With regards to traditional lifestyle treatment, the majority of studies focussed on weight loss as a primary treatment goal. This indicates more research is warranted to understand the role of diet and exercise in lean women and/or in weight gain prevention. RCTs using lifestyle interventions under isocaloric conditions that investigate effects on IR, body composition and androgens independent of weight loss are needed. Given the high risk of failure with long-term weight management [9, 37, 40, 261] and high attrition in weight loss trials in

PCOS [13], exploring interventions that focus on weight neural messaging around dietary quality and physical activity may also aid in optimising engagement, adherence and sustainability of lifestyle interventions. Future research should also identify subgroups who respond more favourably to weight loss [45, 53], to aid provision of a more targeted and personalised treatment approach.

With regards to diet strategies, there is a need for more research understanding the impact of low GI/GL diets on androgen status, as well as the biological mechanisms by which low GI/GL diets may impact reproductive and cardiometabolic outcomes associated with PCOS. With regards to physical activity, additional longer-term studies are required to guide exercise prescription in PCOS, although promising evidence supports the provision of vigorous aerobic exercise performed under supervised conditions (i.e. through referral to an exercise physiologist). While behavioural interventions are essential for long term sustainability of dietary and physical activity change, research in PCOS is scarce and interventions are not well defined. Future research should incorporate appropriate theoretical frameworks and clearly outline behavioural components utilised. This will aid intervention duplication and tailoring of active elements to ensure relevance in women with PCOS.

There is currently a lack of research investigating whether women with PCOS are at a higher risk of alcohol and smoking-related complications. This is particularly relevant given the well-established relationship between higher alcohol and cigarette use and rates of depression and anxiety in the general population [262–265]. There is also a need to better understand the relationship between alcohol intake and reproductive outcomes (particularly anovulatory infertility) [139], as safe alcohol limits in PCOS is currently unknown [139].

With regards to psychological interventions, the current evidence base for prevalence of mental health concerns in PCOS relies heavily on symptom prevalence. More adequately powered, gold standard prevalence studies using structured diagnostic interviews administered by appropriately qualified professionals are needed. While QoL has recently been highlighted as a core outcome in PCOS research [266], the application of QoL tools in clinical care is still unclear, with research yet to validate QoL tools longitudinally or identify clinically meaningful differences in QoL scores. The emerging evidence showing support for the use of CBT in PCOS [152–154] highlights an opportunity for tailoring of this psychological intervention to meet the specific mental health needs of women with PCOS, with a focus on how management of mental health symptoms affect lifestyle modifications. CBT that incorporates elements of

mindfulness-based stress reduction also warrants further investigation.

Future research in PCOS and sleep disorders should include more high-quality research in subclinical disorders using objective sleep measures (polysomnography and actigraphy). Future work should also consider emerging evidence showing that disturbed sleep can detrimentally effect energy expenditure, which may increase adipose tissue deposition and exacerbate IR [164, 184, 186, 267–271], thereby worsening the presentation of PCOS. Further, a consideration of how sleep disturbance can reduce engagement with positive lifestyle changes, for example through the disruption of appetite regulation [272, 273] or via contributing to poor mental health outcomes [190, 274], is warranted. CBT interventions including elements of stimulus control and psychoeducation are effective non-pharmacological treatments for both clinical sleep disorders and sleep disturbances in the general population [275–277]. RCTs in women with PCOS that investigate effects of CBT on dietary intake, energy metabolism, appetite regulation, anthropometry, adherence to lifestyle changes and PCOS features are required.

With regards to TCIM, there is a vast array of literature suggesting some beneficial effects of vitamins (B-group vitamins, folate, vitamins D, E and K), vitamin-like nutrients (bioflavonoids, carnitine and α-LA), minerals (calcium, zinc, selenium, and CrP) and other formulations (such as melatonin, omega-3 fatty acids, probiotics, NAC and cinnamon) in PCOS [278]. However, the quality of evidence across studies ranges from meta-analyses of RCTs (vitamin D, omega-3 fatty acids and NAC) to single retrospective observational studies (vitamin K and carnitine). In addition, heterogeneity in results related to factors including variable PCOS presentation and study methodology make it difficult to draw definite conclusions. Future research should focus on specific populations within PCOS, for example age, BMI or phenotype (factors which substantially affect nutrient sufficiency), and outline more consistent approaches to supplement formulation, dosage, intervention duration and type of comparator used. Mechanistic studies are also needed to investigate herb- or nutrient-drug interactions (with common pharmacological treatments used in PCOS) and other possible interactions with the biological processes underpinning PCOS. In regards to acupuncture and yoga, more sufficiently powered RCTs are needed to determine clinical relevance and integration into PCOS management is not yet warranted.

While current research is not sufficiently robust to support integration of TCIM into routine clinical practice, healthcare providers should broaden their knowledge pertaining to how these therapies can be safely and

appropriately utilised as adjuncts to conventional medical management [279–281]. TCIM is frequently used by women, with uptake of TCIM approaches increasing steadily over the past 10 years [31–35]. In women with PCOS, one cross-sectional study ($n=493$) found that 70% reported use of TCIM, namely nutritional and herbal supplements [282]. The most common reasons for use were to treat PCOS symptoms, improve general wellbeing and reduce depression. Of the women using TCIM, 77% had consulted with a complementary practitioner (acupuncturists, chiropractors, naturopaths and massage therapists) [282]. While the study did not report participants engagement with medical physicians, research in the general population has shown that patients are resistant to discuss TCIM use with their consulting physician [283–288]. Qualified health-care providers should be involved in TCIM discussions to help ensure appropriate use, maximise possible benefits and minimize potential harm [289]. For example, to sustain patient engagement in women who express the desire to experiment with supplementation, health-care providers could consider inositol supplementation, using a nuanced and case-specific approach that encapsulates the variety of pathologies in PCOS.

When considering all of the research summarised here, across traditional lifestyle, psychological, sleep and TCIM interventions, there is a clear need for more real-world PCOS research. This involves the translation of findings from clinical trials (where highly selected populations, intensive treatment protocols and expert multidisciplinary teams provide an ideal research setting), into the heterogeneous situations that face clinicians [290–292]. Health professionals provide care to women from diverse social contexts, are often restrained by finite resources and are required to juggle many competing demands for their time [290–292]. While some barriers to implementation, including time, resource and access issues are considered in the current PCOS guideline, they were generated by the guideline development groups and research is needed to validate and clarify their proposed concerns. Real-world research is required to: a) fully understand whether lifestyle recommendations can be practically integrated into current healthcare settings; b) tailor interventions to meet the unique needs of women with PCOS; and c) generate evidence on clinical outcomes that are of great relevance to patients and clinicians, such as live birth, miscarriage and menstrual regularity, which can be collected through routine care.

It is also important to highlight that while lifestyle management is a first-line treatment for PCOS, the addition of pharmacological therapies to further improve clinical features of hyperandrogenism, menstrual irregularity and infertility are often indicated [293]. In these instances,

prescribing physicians should consider how medical management and lifestyle change can be used in adjunct to optimise treatment. For example, the use of combined oral contraceptive pills may have detrimental effects on weight gain [294] and mental health [295], which can be mitigated by appropriate lifestyle intervention. Further, the combination of lifestyle modification and metformin has been shown to lower BMI, subcutaneous adipose tissue and improve menstruation compared with lifestyle modification alone, and hence may have an additive effect on improving cardio-metabolic outcomes in high risk groups [296].

Conclusion

Using the whole person or holistic definition of health, this review has highlighted emerging areas of research that could be considered for integration into future classifications of lifestyle management in PCOS. When developing lifestyle recommendations for PCOS management, interpreting and communicating evidence not only for diet, physical activity and behavioural interventions, but also psychological, sleep and TCIM approaches, will aid clinicians to deliver patient-centred care by affording women more choice and therefore autonomy over their treatment options. This sentiment aligns with the core objectives underpinning the 2018 PCOS guideline, which sought to understand the unmet needs of women with PCOS through continuing to engage consumers in co-design of guideline development, implementation, translation and dissemination.

Abbreviations

α -LA	Alpha-lipoic acid
BMI	Body mass index
CVD	Cardiovascular disease
CHM	Chinese herbal medicine
CrP	Chromium picolinate
CoQ10	Coenzyme Q10
CBT	Cognitive behavioural therapy
DASH	Dietary Approaches to Stop Hypertension
FINS	Fasting insulin level
FSH	Follicle stimulating hormone
FAI	Free androgen index
GI	Glycaemic index
GL	Glycaemic load
HDL-C	High density lipoprotein cholesterol
Hcy	Homocysteine
IR	Insulin resistance
LDL-C	Low density lipoprotein cholesterol
LH	Luteinizing hormone
$VO_{2\max}$	Maximal rate of oxygen
METS	Metabolic syndrome
MUFA	Monounsaturated fatty acid
MI	Myo-inositol
NAC	N-acetyl-cysteine
OGTT	Oral glucose tolerance test
PCOS	Polycystic ovary syndrome
PUFA	Polyunsaturated fatty acid
RCT	Randomised controlled trial
SHBG	Sex hormone-binding globulin
TAC	Total antioxidant capacity

TC	Total cholesterol
T	Testosterone
TCIM	Traditional, complementary and integrative medicine
TAG	Triglycerides
T2DM	Type 2 diabetes
WC	Waist circumference
WHR	Waist-hip-ratio

Lifestyle management in polycystic ovary syndrome – beyond diet and physical activity

Stephanie Cowan^{1*} , Siew Lim², Chelsea Alycia¹, Stephanie Pirotta³, Rebecca Thomson⁴, Melanie Gibson-Helm^{1,5}, Rebecca Blackmore⁶, Negar Naderpoor¹, Christie Bennett⁷, Carolyn Ee⁸, Vibhuti Rao⁸, Aya Mousa¹, Simon Alesi¹ and Lisa Moran¹

Abstract

Polycystic ovary syndrome (PCOS) is a common condition affecting reproductive-aged women with reproductive, metabolic and psychological consequences. Weight and lifestyle (diet, physical activity and behavioural) management are first-line therapy in international evidence-based guidelines for PCOS. While these recommend following population-level diet and physical activity guidelines, there is ongoing interest and research in the potential benefit of including psychological and sleep interventions, as well as a range of traditional, complimentary and integrative medicine (TCIM) approaches, for optimal management of PCOS. There is limited evidence to recommend a specific diet composition for PCOS with approaches including modifying protein, carbohydrate or fat quality or quantity generally having similar effects on the presentations of PCOS. With regards to physical activity, promising evidence supports the provision of vigorous aerobic exercise, which has been shown to improve body composition, cardiorespiratory fitness and insulin resistance. Psychological and sleep interventions are also important considerations, with women displaying poor emotional wellbeing and higher rates of clinical and subclinical sleep disturbance, potentially limiting their ability to make positive lifestyle change. While optimising sleep and emotional wellbeing may aid symptom management in PCOS, research exploring the efficacy of clinical interventions is lacking. Uptake of TCIM approaches, in particular supplement and herbal medicine use, by women with PCOS is growing. However, there is currently insufficient evidence to support integration into routine clinical practice. Research investigating inositol supplementation have produced the most promising findings, showing improved metabolic profiles and reduced hyperandrogenism. Findings for other supplements, herbal medicines, acupuncture and yoga is so far inconsistent, and to reduce heterogeneity more research in specific PCOS populations, (e.g. defined age and BMI ranges) and consistent approaches to intervention delivery, duration and comparators are needed. While there are a range of lifestyle components in addition to population-recommendations for diet and physical activity of potential benefit in PCOS, robust clinical trials are warranted to expand the relatively limited evidence-base regarding holistic lifestyle management. With consumer interest in holistic healthcare rising, healthcare providers will be required to broaden their knowledge pertaining to how these therapies can be safely and appropriately utilised as adjuncts to conventional medical management.

Introduction

Polycystic ovary syndrome (PCOS) is a common condition affecting up to 13% of reproductive-aged women [1]. It is diagnosed through the European Society for Human Reproduction and Embryology/American Society for Reproductive Medicine (ESRHE/ASRM) criteria, requiring two of the following features: polycystic ovaries on ultrasound, oligoovulatory or anovulatory cycles and biochemical or clinical hyperandrogenism [2]. Women with PCOS experience a combination of reproductive (infertility, pregnancy complications) [3], metabolic (risk factors for and conditions of type 2 diabetes (T2DM) and cardiovascular disease (CVD)) [4, 5] and psychological (conditions including anxiety, depression, poor quality of life (QoL), disordered eating) comorbidities [6, 7].

Insulin resistance (IR) is defined as a key pathophysiological feature in PCOS, contributing to hyperandrogenism and worsening the clinical presentation of PCOS. While lean women present with IR in a form that is mechanistically different from IR caused by excess weight, overweight and obesity further exacerbate IR and consequent hyperinsulinaemia [8]. Women with PCOS also display a higher rate of weight gain over time [9] and a greater prevalence of overweight and obesity [10], which can further contribute to this worsening of IR and hence worsening of the presentation of PCOS [11]. The reason for this is unclear, but may be related to differences in intrinsic psychological and biological mechanisms [12–15], or extrinsic lifestyle factors such as diet and physical activity [16, 17]. Improving IR and excess adiposity are therefore key targets in PCOS management.

The International Evidence-Based Guideline for the Assessment and Management of PCOS [18], highlights lifestyle intervention as the primary early management strategy. Lifestyle interventions are traditionally defined as those designed to improve dietary intake or physical activity through appropriate behavioural support. In the 2018 PCOS guideline, lifestyle management is recommended for general health benefits [18]. Given that excess weight is associated with increased IR in PCOS [8], the guideline additionally promotes weight management, defined as: 1) weight gain prevention in all women with PCOS, and 2) achieving and maintaining modest weight loss in women with excess weight [18].

Lifestyle interventions in PCOS management can also be viewed as a broader construct beyond physical health. Since the emergence of the biopsychosocial model of healthcare in 1977, health disciplines have seen a gradual shift away from the classical biomedical model (where health is defined as the ‘absence of disease’) towards whole person or holistic care [19]. This is an approach that reflects many facets of the patient context, via integrating care that addresses biological, psychological, social, spiritual and ecological

aspects [20]. It therefore requires a range of different treatment strategies to improve health. Provision of whole person or holistic care has been identified as a core objective of healthcare reforms internationally [21–23]. In line with these reforms the PCOS guideline recognises the importance of emotional wellbeing to overall health and QoL in women living with PCOS [18]. It also highlights evidence which suggests that the psychological impact associated with PCOS is under-appreciated in clinical care [4, 5], and that few women are satisfied with the mental health support they receive [6, 7]. Recommendations for appropriate screening, assessment and treatment strategies for anxiety, depression, psychosexual dysfunction, eating disorders and poor body image are provided [18]. These specific areas of emotional wellbeing are of particular concern, with research showing a higher prevalence and severity of depression and anxiety [24, 25], lower scores for satisfaction with sex life and feeling sexually attractive [26] and a higher prevalence of disordered eating and eating disorders [7] in women with PCOS. Features of PCOS, in particular hirsutism and increased weight, have also been shown to negatively affect body image [27, 28], with poor body image being strongly related to depression in women with PCOS [29, 30].

While the current PCOS guideline is comprehensive, considering all available evidence at the time of development and providing best-practice recommendations for necessary screening, risk assessment and management, it could not possibly cover all aspects of PCOS care. An International Delphi process was used to prioritise clinical questions, with consensus reached through extensive consultation with both consumers and multidisciplinary clinicians with expertise in PCOS care. Therapies, such as traditional, complementary and integrative medicine (TCIM), supplement use, sleep and meditation interventions are either briefly considered or not at all included in the 2018 PCOS guideline. Many of these therapies are novel and there is a paucity of evidence to support intervention efficacy on PCOS outcomes. However, as patient interest in these types of non-pharmacological interventions are growing [31–35], it is prudent to provide more guidance to healthcare providers in this area on their potential efficacy in PCOS. Whole person or holistic care recognises that the doctor-patient relationship should be one of open dialogue, where healthcare providers involve the patient in negotiating their care and recognises patient’s autonomy to guide treatment (Figure 1) [36].

This review provides an extensive overview of evidence to date on lifestyle strategies used to optimise management of PCOS. Using a holistic definition of patient care, this review considers the traditional components of lifestyle change (diet, physical activity and behavioural change), psychological and sleep interventions, as well as TCIM approaches (supplements, herbal medicine,

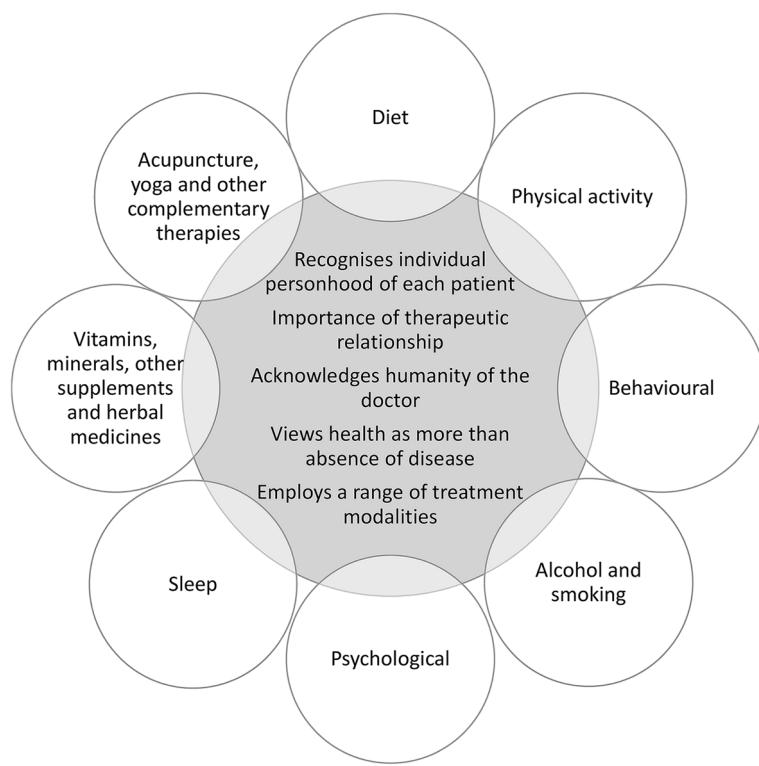

Fig. 1 Viewing lifestyle modifications through a whole person or holistic care lens. The key features of whole person or holistic care listed in the centre of the figure have been adapted from Thomas et al. [20]. ‘Recognises individual personhood’ relates to focusing on the unique needs of the person rather than the disease. ‘Importance of therapeutic relationship’ emphasises patient autonomy and responsibility. ‘Acknowledges humanity of the doctor’ considers the doctors’ ability to self-reflect on how they engage in the care of the patient. ‘Health as more than absence of disease’ incorporates the mental, emotional, physical, environmental and social needs of the patient. ‘Employs a range of treatment modalities’ promotes continuity of care across health disciplines, and while it may include traditional, complementary and integrative medicine (TCIM), TCIM is not holistic if used in isolation and without adequate integration into conventional healthcare

acupuncture and yoga). To improve translation of findings, evidence summaries are accompanied by an overview of relevant recommendations from the existing PCOS guideline. This highlights where emerging evidence supports current recommendations or provides new insights for research. As this is a narrative review, while evidence summaries include peer-reviewed journal articles identified from databases including Medline OVID, this is supplemented by expert opinion of the authors.

Traditional lifestyle and weight management

The PCOS guideline recommends the promotion of healthy lifestyle behaviours in all women with PCOS, to achieve and/or maintain a healthy weight and to optimise general health [18]. In women with excess weight, a weight loss of 5–10% is advised, aiming for an energy deficit of 30% or 500–750 kcal/day (1200–1500 kcal/day). While weight management is seen as a core component of lifestyle interventions, the guideline recognises that a healthy lifestyle provides benefits that occur independent of weight change.

A recent Cochrane review of 15 randomised controlled trials (RCT) and 498 participants, reported that lifestyle interventions compared with minimal intervention or usual care, significantly reduces weight (kg) and body mass index (BMI) and improves secondary reproductive outcomes such as free androgen index (FAI), testosterone (T), sex hormone-binding globulin (SHBG) and hirsutism (Ferriman-Gallwey score) [37]. In terms of metabolic outcomes, lifestyle intervention resulted in significant reductions in total cholesterol (TC), low density lipoprotein cholesterol (LDL-C) and fasting insulin (FINS). These findings are largely similar to that of other systematic reviews [38–41]. While no studies in the Cochrane review assessed clinical reproductive outcomes [37], individual trials that were not included in the review have reported that lifestyle interventions resulting in modest weight loss (2–5% total body weight) improve ovulation and menstrual regularity [42–45]. Losing >5% of weight is additionally associated with being able to conceive, having live births, reduction of ovarian volume and reduction in the number of follicles [46–52].

Table 1 Reviews and experimental studies investigating the effects of diet on polycystic ovary syndrome outcomes

Dietary intervention	N study design	N studies; N participants	Main findings ^a	References
Low CHO	2 SR/MA (27 RCT total - 18 RCT using low CHO diet) [56, 85] 1 SR (5 RCT total - 1 RCT using low CHO diet) [16]	14; 901	Low CHO compared with control diets [56]: ↓ BMI, HOMA-IR, TC, LDL-C ↑ SHBG ↔ LH, T, HDL-C Dietary intervention ↓ HOMA-IR, FINS, FGL, BMI, BW, WC compared with minimal intervention, and subgroup analysis showed no additional benefits for low CHO diets [85] Weight loss improved the presentation of PCOS regardless of dietary composition, with no subtle differences observed for low CHO diets [16]	Shang et al. 2020 [85] Zhang et al. 2019 [56] Moran et al. 2013 [16]
Low GI	1 SR/MA (10 RCT total - 8 RCT using low GI diet) [55] 1 SR (5 RCT total - 1 RCT using low GI diet) [16] 4 Pre-post prospective [61, 76, 77, 118] 1 RCT [78]	16 ^b ; 582	High GI compared with low GI diets [55]: ↓ HOMA-IR, FINS, TC, LDL-C, TAG, WC, T ↔ FGL, HDL-C, BW, FAI Low GI diets had greater improvements in IR, TC, HDL-C, fibrinogen, menstrual regularity and QoL [16] Low GI diets followed for ≥ 12 weeks: ↓ BW [76, 77], BMI [76, 77], BFM [77], WC [77], WHR [77], FINS [76, 77], FGL [77], TC [77], LDL-C [77], TAG [77], T [77], LH [77], androstenedione [77], prolactin [77] ↑ insulin sensitivity (HOMA2-IS) [61], synthesis of predominantly anti-inflammatory eicosanoid mediators (e.g. 16(R)/16(S)-HETE, 13(S)-HODE, 9(S)-HODE, 15(S)-HETE, 12(S)-HETE, 5(S)-oxoETE, 5(S)-HETE) [118], fasting glucagon (higher glucagon levels associated with lower levels of self-reported hunger) [78]	Kazemi et al. 2020 [55] Moran et al. 2013 [16] Shishrehgar et al. 2019 [76] Barr et al. 2016 [61] Szczuko et al. 2018 [77] Szczuko et al. 2017 [118] Hoover et al. 2021 [78]
High protein	1 SR (5 RCT total - 3 RCT using high protein diet) [16] 2 Pre-post prospective [73, 74] 6 RCT [92, 94–97]	11; 308	High protein diets improve depression and self-esteem [16] ↓ BFM [74, 97], BW [73, 74, 97], BMI [73, 74], WC [73, 74, 97], WHR [73], FINS [74, 98], FGL [97], HOMA-IR [73, 98], TAG [73], VLDL-C [73], T [73, 98], Ferriman-Gallwey scores [73] High protein and standard/low protein diet ↓ BW [92, 94, 95], BMI [92, 94, 95], BFM [95], WC [92, 94], WHR [94], FINS [95, 96], HOMA-IR [95], TAG [96], LDL-C [98] CRP [96], MPA [96], leptin [95], T [98], DHEAS [98], FAI [98] and there was ↔ between high and standard/low protein diets	Moran et al. 2013 [16] Moran et al. 2010 [96] Moran et al. 2004 [95] Sorensen et al. 2012 [97] Toscani et al. 2011 [92] Nadjarzadeh et al. 2021 [94] Phy et al. 2015 [73] Pohlmeier et al. 2014 [74] Mehrabani et al. 2012 [98]
Low fat	1 SR/MA (19 RCT total - 1 RCT using low fat diet) [85] 1 SR (5 RCT total - 1 RCT using low fat diet) [16] 1 RCT [107]	3; 137	Dietary intervention ↓ HOMA-IR, FINS, FGL, BMI, BW, WC compared with minimal intervention, and subgroup analysis showed no additional benefits for low fat diets [85] Weight loss improved the presentation of PCOS regardless of dietary composition, with no subtle differences observed for low fat diets [16] Low fat (25% E fat) ↓ BW, BFM, BMI though there was ↔ between low fat and standard fat (35% E fat) diets [107]	Shang et al. 2020 [85] Moran et al. 2013 [16] Wong et al. 2016 [107]

Table 1 (continued)

Dietary intervention	N study design	N studies; N participants	Main findings ^a	References
Fatty acids	1 SR (5 RCT total - 1 RCT using MUFA enriched diet) [16] 3 RCT [86, 102, 105] 1 controlled trial (not randomised) [103] ^c	5; 146	MUFA enriched diets may produce greater weight loss when compared to other dietary patterns [16] MUFA enriched compared with PUFA enriched diets ↓ FGL [103], glucose response to OGTT [103], HgBA1 [102] Diets with a higher alpha-linolenic acid, lower omega-6/omega-3 ratio and saturated fat content ↓ TAG, TC/HDL-C, LDL-C-/HDL-C, TAG/HDL-C, and HOMA-IR [105] High total and saturated fat meals compared with high fibre low fat meals produce prolonged ↓ in T [86]	Moran et al. 2013 [16] Yahay et al. 2021 [105] Kalgaonkar et al. 2011 [102] Kasim-Karakas et al. 2004 [103] Katcher et al. 2009 [86]
DASH	1 SR/MA (19 RCT total - 4 RCT using DASH diet) [85]	4; 228	Dietary intervention ↓ HOMA-IR, FINS, FGL, BMI, BW, WC compared with minimal intervention, and subgroup analysis showed DASH diet was more effective at improving insulin sensitivity [85]	Shang et al. 2020 [85]
Plant-based	3 RCT	3; 108	Plant-based (35% animal protein, 35% textured soy protein, 30% vegetable protein) compared to control (70% animal protein, 30% vegetable protein) ↓ BMI, FGL, FINS, TAG, HOMA-IR, T, MDA and ↑ QUICKI [67] Plant-based and control diets (calorie restriction [68] and general dietary recommendations [72]) ↓ BW [68], HOMA-IR [72], T [72], LH/FSH [72] and there was ↔ between plant-based and control diets	Turner-McGrievy et al. 2014 [68] Kazemi et al. 2020 [72] Karamali et al. 2018 [67]
Meal pattern	1 RCT	1; 40	6 meals/day compared with 3 meals/day: ↓ FINS ↑ post-OGTT insulin sensitivity	Papakonstantinou et al. 2016 [111]
Meal timing	1 RCT	1; 60	Consuming a high kilojoule breakfast compared with a high kilojoule dinner: ↓ FGL, FINS, HOMA-IR, T ↑ SHBG	Jakubowicz et al. 2013 [66]

^a Summarises commonly used measures in PCOS research and does not report on all measured outcomes. For prospective pre-post studies significant changes from baseline are reported. For RCTs significant changes between intervention(s) and control are reported. Only experimental studies not already summarised in included systematic reviews/meta-analysis are presented

^b Shishregar et al. 2019 total study population included 62 women though only findings for the women with PCOS ($n=28$) are included

^c While habitual diet (control) was not enriched with MUFA, nutritional analysis showed that it was rich in oleic acid

Although weight loss has shown clear benefits to PCOS outcomes, including not only on reproductive function, but also glucoregulatory status, androgen status and lipid profiles [42–52], there are varying degrees of responsiveness to weight loss in terms of improvement of PCOS symptoms. One study by Pasquali et al. [53] found that when women achieved similar levels of weight loss (>5% weight) only one-third displayed a full recovery from PCOS, with the remainder showing

only partial or no recovery. Higher waist circumference (WC), waist-hip-ratio (WHR) and androstenedione at baseline were associated with a poorer chance of successful outcomes [53], suggesting that central adiposity and more severe hyperandrogenism may predict responsiveness to weight loss interventions in PCOS. Huber-Buchholz et al. [45] also reported women who achieve greater reductions in central fat and insulin sensitivity show greater symptom improvement with

weight loss. This suggests that lifestyle interventions which simultaneously reduce IR and improve body composition (namely fat distribution), may help to optimise outcomes in PCOS management independent of changes in weight status.

Diet

The 2018 PCOS guideline recognises there is insufficient evidence to suggest that any specific dietary approaches provide greater benefits on health outcomes [18]. Dietary recommendations may take on a variety of balanced dietary strategies according to the individual's lifestyle needs and preferences, as per general population recommendations [18]. This advice is based on a systematic review comparing different dietary compositions (e.g. low carbohydrate, low glycaemic index (GI) and glycaemic load (GL), high protein, monounsaturated fatty acid (MUFA) enriched and fat counting diets) to best manage PCOS, identifying minimal differences between diets on anthropometric outcomes, concluding weight loss improves the presentation of PCOS regardless of dietary composition [16, 54]. There is now an emerging body of evidence that suggests a range of dietary strategies may produce favourable effects on PCOS features that occur independent of weight loss. It is important that the emerging findings from these studies are thoroughly considered to support consumer and health professional interests. To summarise current evidence this review has grouped diets in terms of those that modify carbohydrates, protein and fat, as well as specific dietary patterns.

Carbohydrates

The use of altered carbohydrate composition remains the most researched dietary approach for PCOS management. Two systematic reviews published after guideline inception support altered carbohydrate intake to improve intermediate markers of PCOS [55, 56], finding that altering carbohydrate type, as opposed to content, is preferable to better manage PCOS [55]. RCTs [57–72] and pre-post intervention studies [73–80] demonstrate that following a low GI/GL diet for at least eight weeks significantly reduces WC [55, 73, 74] and BMI when compared to high GI/GL [56] or a regular diet [73–76], although levels of weight loss are generally comparable to other dietary compositions [59, 60, 72, 74]. These reductions are proposed to be a result of decreased hunger, which may reduce energy intake and make it easier to follow dietary recommendations in the long-term [78, 81–84]. Low GI/GL diets also improve insulin sensitivity and reproductive hormones (T, SHBG, FAI) compared to high carbohydrate [16, 55, 57, 79, 85] or control diets [56, 59, 73–76], contributing to improvements in reproductive function, specifically menstrual regularly [60, 79]. Lastly, low GI/GL diets can improve risk factors for T2DM and CVD, including glucose

[86, 87], TC [55, 56, 59, 75, 77], LDL-C [55, 59, 75, 85], TAG [55, 59, 73] and HDL-C [75], when compared to a regular or high GI/GL diet. It must be noted that beneficial effects of low GI/GL diets may also be attributed to proportional increases in protein and/or fat loads.

Protein

In women with PCOS higher protein intakes may be superior at suppressing androgen levels when compared to high carbohydrate diets. Postprandial research has shown that high protein meals can reduce insulin and dehydroepiandrosterone stimulation compared to meals rich in glucose [88]. Research in the general population has also shown that reduced appetite and energy intakes from low GI/GL diets are related to increased protein intakes [89, 90]. RCTs and pre-post intervention studies found that high protein diets (defined here as protein constituting $\geq 25\%$ energy [91]) consumed for at least four weeks reduce weight [12, 73, 74, 92–96], BMI [73, 74, 92, 95], WC [73, 74, 92, 97], WHR [73] and fat mass [74, 92, 97]. These reductions in anthropometric measures are accompanied by improved FINS [12, 74, 95, 98] and HOMA-IR [12, 73, 95, 98], blood lipids [12, 96], T [73, 92, 94] and hirsutism (Ferriman-Gallwey score) [73]. However, only three of these studies were able to show significant improvements in anthropometric measures [97], insulin sensitivity [98] and blood lipids [12] when compared to low/standard protein [12, 97] or control diets [98]. Only one study investigated effects on mental health outcomes and found that a high protein diet reduced depression and improved self-esteem [99].

Fats

Fatty acid composition is also an important consideration as metabolic disorders associated with PCOS can benefit from increased MUFA and polyunsaturated fatty acid (PUFA) intakes [63–65]. Postprandial research in PCOS reported prolonged reductions in T for high fat compared to low fat meals, which likely results from delayed nutrient absorption [86]. Two acute meal studies in lean and obese women with and without PCOS reported that proatherogenic inflammatory markers [100] and oxidative stress [101] were elevated, independent of but augmented by obesity, following saturated fat ingestion with this associated with worsened IR and androgens. Two experimental studies in PCOS investigated the effects of habitual walnut (PUFA rich diet) [102, 103] and almond (MUFA rich diet) [102] intake for at least six weeks and reported no differences in glucoregulatory status, lipids or androgens with the exception of HbA1c significantly decreasing in the walnut relative to the almond group. Kasim-Karakas et al. [103] reported increased fasting and postprandial glucose

(oral glucose tolerance test (OGTT)) for increased walnut intake compared to habitual (control), which they postulated may be related to the control diet being rich in oleic acid. Together these findings suggest minimal benefit for improving dietary PUFA compared to MUFA content. Two RCTs in women with PCOS investigated the effects of diets rich in olive [104, 105], canola [105] and sunflower [105] oil. Yahay et al. [105] reported 25g/day canola oil caused reductions in TAG, TC/HDL-C, LDL-C/HDL-C, TAG/HDL-C and HOMA, but not androgens, compared to 25 g/day olive and sunflower oils [105]. This may be related to the more favourable fatty acid composition of canola oil, with comparable MUFA content to olive oil, higher alpha-linolenic acid, lower omega-6/omega-3 ratio and saturated fat than both olive and sunflower oils. Douglas et al. [104] reported weight and the acute insulin response (OGTT) were lower following a eucaloric low carbohydrate compared to a eucaloric MUFA-enriched olive oil diet, suggesting that reduced carbohydrate intake may have greater glucoregulatory benefits than increased MUFA intake [104]. Lastly, two RCTs compared hypocaloric low-fat diets to a low carbohydrate [106] or low GI [107] diets, with reductions in weight [106], WC [106], body fat [106, 107], FINS [106] and FAI [106] in both groups but no difference between groups.

Dietary and eating patterns

In addition to diets that focus on specific macronutrient manipulations, there are a range of dietary patterns which have been explored in PCOS management. A systematic review (including 19 studies and 1,193 participants) published after guideline development (2020) found that the Dietary Approaches to Stop Hypertension (DASH) diet (rich in fruit, vegetables, wholegrains, nuts, legumes and low-fat dairy and with a predominantly low-GI carbohydrate profile) was the optimal choice for reducing IR [85]. RCTs in PCOS also report beneficial effects on weight [63, 64], BMI [62, 63], IR [62] and hormonal profile, including SHBG [64], androstenedione [64] and FAI [62] for a DASH compared to a control diet after 8–12 weeks. A vegetarian diet also reduced inflammatory markers (CRP, resistin and adiponectin) compared to a meat inclusive diet [80]. A vegan diet improved weight loss at three, but not six months [68], and a pulse-based diet led to similar reductions in weight, insulin sensitivity and reproductive hormones compared to a healthy control diet [72]. All of these dietary patterns are high in fibre and plant proteins, producing favourable effects on microbial diversity and encouraging production of short-chain fatty acids that possess potential anti-inflammatory actions [108, 109]. With mechanistic animal studies suggesting a possible pathophysiological role of gut microbiota in IR and

ovarian dysfunction, it is possible that metabolic and hormonal benefits associated with plant-based dietary patterns in PCOS are related to increased intakes of dietary prebiotics [110]. However, further mechanistic studies exploring the role of gut microbiota in PCOS and RCTs investigating effects of dietary prebiotics on PCOS outcomes are required.

Lastly, particular eating patterns, such as eating smaller more frequent meals across the day [111] and eating a larger breakfast and smaller dinner [66], have also been found to be beneficial for insulin sensitivity [66, 111] and androgen reductions [66]. This is an important finding, as women with PCOS are more likely to either skip breakfast or consume their breakfast and lunch later in the day [112].

Studies examining specific food items in relation to PCOS outcomes, including raw onions [65], concentrated pomegranate juice [69, 113–115] and flaxseed powder [70, 116] have yielded largely inconsistent results. A core limitation of these single food studies is that foods are never consumed alone within the diet, omitting the influence of the dietary matrix and the interactions that occur amongst dietary constituents within meals. These studies provide limited applicability in the context of formulating practical dietary recommendations [117]. Please see Table 1 for a summary of available evidence from reviews and experimental studies investigating the effects of different types of diets on PCOS outcomes.

Physical activity

The 2018 PCOS guideline recommends ≥150 minutes per week of moderate or ≥75 minutes per week of vigorous intensity exercise for weight gain prevention, and ≥250 minutes per week of moderate or ≥150 minutes per week of vigorous intensity exercise for weight loss and weight regain prevention [18]. Minimising sedentary time and the inclusion of strength training exercise for two days per week is also recommended [18].

To date the most comprehensive review in PCOS (including 27 papers from 18 trials up until June 2017) reported that exercise improved FINS, HOMA-IR, TC, LDL-C, TAG, body composition (body fat percentage and WC) and aerobic fitness ($\text{VO}_{2\text{max}}$) [119] compared with usual care or control groups. In regards to exercise type, subgroup analysis reported aerobic exercise improved BMI, WC, body fat percentage, FINS, HOMA-IR, TC, TAG and $\text{VO}_{2\text{max}}$. In contrast, while resistance training produced unfavourable effects on HDL-C (decrease) and BMI (increase), it improved other measures of anthropometry, including WC. Combined interventions (using both aerobic and resistance training) had no effect on any of the measured markers. Subgroup analysis also found that more outcomes improved when

^a Significant findings from meta-analyses when comparing exercise groups to control

^b Subgroup analyses compared different types of exercise; only 1 study included for combined exercise

interventions were supervised, of a shorter duration (≤ 12 weeks) and were conducted in women who were above a healthy weight [119].

Three more recent systematic reviews have looked at the effects of specific types of exercise on PCOS outcomes [120–122]. These reviews found that vigorous aerobic exercise can improve measures of insulin responsiveness and resistance, including HOMA-IR [121] and the insulin sensitivity index [120]; body composition, including WC [121] and BMI [122]; and cardiorespiratory fitness (VO_{2max}) [121]. High intensity interval training (HIIT) alone may be effective for improving IR and BMI [123], however this has not been consistently shown [124]. Interventions involving a combination of aerobic and resistance exercise [122] or resistance training only [120] did not result in improvements in BMI [122] or weight status [120]. Exercise involving resistance training did result in other beneficial improvements to body composition (reduced body fat, WC and increased lean mass) and strength. This is important, as the degree of

central adiposity predicts responsiveness to weight loss interventions in PCOS [53], and women who achieve greater reductions in central fat show greater symptom improvement with weight loss [45]. Resistance training may also improve androgen levels, though findings are inconsistent and more research is needed to draw definite conclusions [120]. There was insufficient evidence from available data to assess the effects of exercise type on reproductive function [122]. Please see Table 2 for a summary of available evidence from meta-analyses investigating the effects of different types of exercise on PCOS outcomes.

When comparing the effects of exercise and diet combined with diet alone, a systematic review and meta-analysis (three studies) found no differences for any measured outcomes (glucose, insulin HOMA-IR, weight, BMI, WC, body fat, fat free mass, T, SHBG and FAI) [119]. In regards to exercise and diet combined compared to exercise alone, subgroup analysis (including 17 studies) from a large systematic review found that the addition of diet to exercise,

^a Qualitative analysis only

^b Statistical analysis compares order of intervention arms (e.g. counselling followed by exercise versus exercise followed by counselling) and doesn't compare effects of counselling versus exercise

particularly vigorous intensity aerobic exercise, resulted in greater reduction to BMI, WC, FAI and HOMA-IR than exercise only [121]. In regards to exercise (aerobic) alone versus diet alone, one intervention study found that exercise induced weight loss produced greater improvements

in menstrual frequency and ovulation rates [125], with no differences in pregnancy rates [125]. However, this study was not randomised and treatments were self-selected, which may have biased the results and precludes firm conclusions [125].

Table 4 Key observational studies that report non-clinical sleep disruption in polycystic ovary syndrome

Reference	Sample size	Sleep methodology used	Main findings
Moran et al. 2015 [182]	PCOS: n=87 Non-PCOS: n=637	Modified version of the Jenkins Sleep Questionnaire	Women with PCOS were twice as likely to experience sleep disturbance PCOS was associated with difficulty falling asleep and maintaining sleep
Mo et al 2019 [140] ^a	PCOS: n=484 Non-PCOS: n=6094	Sleep duration was self-reported on a work day and non-work day Sleep quality was self-reported through frequency questions about difficulty falling asleep, restless sleep, difficulty sleeping and severe tiredness	Women with/without PCOS had similar sleep duration Women with PCOS had higher prevalence of sleep disturbance, and this relationship maintained even after controlling for BMI, depression, income, marital status, occupation, education status and COB
Bennett et al. 2021 [183] ^a	PCOS: n=464 Non-PCOS: n=5603	Sleep duration was self-reported on a work day and non-work day Sleep quality was self-reported through frequency questions about difficulty falling asleep, restless sleep, difficulty sleeping and severe tiredness	Overall women with PCOS had greater adverse sleep symptoms and higher DGI However, subgroup analysis revealed PCOS was only associated with a higher DGI in women with adequate sleep There was no association between PCOS and DGI in women with poor sleep The higher DGI observed in women with PCOS may only be maintained in women who achieve adequate amounts of good quality sleep
Shreeve et al. 2013 [167]	PCOS: n=15 Non-PCOS: n=18	Actigraphy, PSQI and ESS	Women with PCOS had higher night time melatonin levels Women with PCOS had reduced sleep when compared to controls
Kutanaee et al. 2019 [181]	PCOS: n=201 Non-PCOS: n=199	PSQI	Women with PCOS had lower sleep quality and daytime function Women with PCOS were more likely to utilise medication to assist with sleep

^a Mo et al. [140] and Bennett et al. [183] share the same cohort

Behavioural

The 2018 PCOS guideline promotes the use of behavioural interventions that foster self-efficacy [18]. These include the use of SMART (specific, measurement, achievable, realistic and timely) goals, self-monitoring, stimulus control, problem solving and relapse prevention [18].

Behavioural and cognitive interventions are required to improve sustainability of lifestyle changes, through considering not only the specific behaviour, but also their antecedents, consequences and cognition [126, 127]. Given that women with PCOS show higher rates of weight gain over time [9] and high attrition rates in clinical weight management research [37], there is a clear need to improve adherence to diet and physical activity interventions. However, the majority of research investigating lifestyle change in PCOS involve short-term dietary interventions with/without an exercise element, and there is a paucity of research on behavioural change strategies. As such, guideline development relied heavily on evidence taken from the general population. Only three RCTs in women with PCOS included a ‘behavioural intervention’ [128–130]. While

these studies showed enhanced weight loss [128, 130] and improved androgen and lipid profiles [129] when compared with placebo, the interventions were not well defined, with negligible context provided regarding the theoretic framework or behavioural strategies utilised.

More recently, a cross-sectional study in 501 women with PCOS [131] and two RCTs [44, 132] explored the use of self-management strategies [131] and behavioural modification interventions [44, 132] in PCOS. In the cross-sectional study, implementation of physical activity self-management strategies improved the likelihood of meeting physical activity recommendations, but had no association with BMI. Dietary self-management strategies were associated with reductions in BMI, though were not related to weight or nutritional intake [131]. In the RCTs, only the behavioural modification programme and not the control (general healthy lifestyle recommendations) produced significant weight loss after four months. A significantly greater proportion of women in the intervention group also improved menstrual regularity [44] and psychological well-being (lower anxiety and depressive

symptoms) [132] when compared to the control group. The women who achieved greater weight loss reported higher social desirability and lower embitterment scores on a personality trait assessment measure [132]. These findings are particularly novel, as they provide insight into the influence of personality traits and their contribution to success in following behavioural modifications [132].

Alcohol and smoking

In the clinical setting, smoking and alcohol consumption are often addressed alongside dietary and physical activity changes, employing the same behavioural and cognitive interventions to promote adherence. Hence, alcohol and cigarette use are considered here under traditional lifestyle strategies. The PCOS international guideline highlights the importance of assessing alcohol consumption and cigarette smoking when improving fertility and reproductive outcomes in women with PCOS [18]. Assessment of cigarette use is also recommended when evaluating CVD risk factors and thromboembolism risk associated with oral contraceptive pills [18]. These recommendations are based on existing practice guidelines used for the general population.

There is a paucity of observational research characterising alcohol consumption in women with PCOS. One Swedish study comparing women with PCOS ($n=72$) to healthy controls ($n=30$), demonstrated a lower alcohol intake in the PCOS group [133]. A larger study in Australia comparing women with ($n=409$) and without ($n=7,057$) PCOS, reported no significant difference in alcohol intake [134]. Similarly, a Spanish study ($n=22$ PCOS and $n=59$ controls) and a Chinese study ($n=2,217$ PCOS and $n=279$ controls), found no significant difference in alcohol intake between PCOS and non-PCOS groups [135, 136].

Current evidence on the impact of alcohol intake on anovulatory infertility (a common feature of PCOS) is controversial, with some studies showing adverse effects and others reporting no significant correlation [136, 137]. One prospective study including 18,555 married women from The Nurses' Health Study II, who had no history of infertility, found no clinically significant impact of alcohol intake on anovulatory infertility, after adjusting for parity and other factors [138]. Similarly, a Danish study ($n=6,120$ women aged 21 to 45 years) found no fertility effect with alcohol consumption of less than 14 standard drinks per week [137]. In contrast, a study on 3,833 women who recently gave birth and 1,050 women with infertility, reported an increased risk of anovulatory infertility and endometriosis with increasing alcohol intake [139].

Current observational evidence does not reveal any significant difference in smoking between women with and without PCOS [135, 136, 140], with the exception of one

study in pregnant women which showed a lower smoking rate in women with PCOS ($n=354$) compared to women without PCOS at 15 weeks gestation [3]. However, a significantly higher rate of smoking (including passive and active) is reported in women with PCOS and oligo-anovulation and/or reduced fertility compared to women with PCOS and normal menstruations or healthy controls [141, 142]. Smoking is also associated with PCOS risk independent of BMI and age [142]. A Mendelian randomisation study supports these findings, demonstrating a 38% higher risk of PCOS development in genetically predicted smokers (based on single-nucleotide polymorphisms associated with smoking initiation) compared with those who never smoked [143]. In PCOS, smoking is associated with increased levels of T, DHEAS, TC, LDL-C and FINS [141, 144, 145]. However, the underlying mechanisms are not fully understood and there are inconsistencies in findings from different studies. Furthermore, smoking is associated with lower conception and live birth rates and less favourable ART outcomes in women with PCOS [141, 146].

Psychological

The current guideline highlights the need for awareness, and appropriate assessment (such as stepwise screening) and management, of QoL, depression and anxiety, psychosexual dysfunction, negative body image and disordered eating [18]. The guideline emphasises the importance of clinicians and women working in partnership to address women's individual priorities; understanding that the impact of PCOS on an individual's QoL is key to delivering meaningful outcomes [147, 148]. To assist women to communicate with clinicians about what is important to them, the PCOS Question Prompt List [149] was developed and is consistent with the 2018 guideline. The 2018 guideline recommends screening for risk factors and symptoms of depression and anxiety at time of diagnosis. Women with positive screening results should be supported with further assessment and treatment by appropriately qualified clinicians. To screen for psychosexual dysfunction tools such as the Female Sexual Function Index [150] should be utilised. If negative body image, disordered eating or eating disorders are suspected, the PCOS guideline outlines a stepped approach for screening, and where appropriate promotes the use of psychological therapy offered by trained health professionals, which should be guided by regional clinical practice guidelines [18].

While the PCOS guideline provides justification and summarises evidence for mental health screening and diagnostic assessment, there is also a need for consideration of additional aspects, such as the efficacy of different types of psychological interventions and how

Table 5 Reviews and experimental studies investigating the effects of traditional, complimentary and integrative medicine on polycystic ovary syndrome outcomes

^a Summarises commonly used measures in PCOS research and does not report on all measured outcomes. For prospective pre-post studies significant changes from baseline are reported. For RCTs significant changes between intervention(s) and control are reported

^b Not all participants are included in the findings reported here (e.g. where findings from subgroup analysis are reported)

psychological interventions influence engagement with lifestyle change. This is important, as poorer mental health outcomes at baseline are positively associated with higher rates of attrition in lifestyle interventions [13]. Cognitive behavioural interventions could be considered to improve engagement and adherence to healthy lifestyle in women with PCOS. Research has shown support for a range of different psychological interventions, such as counselling [151], cognitive behavioural therapy (CBT) [152–154] and mindfulness meditation [155, 156], helping to change the way clinicians' approach and deliver optimal PCOS management.

CBT is one of the most widely-researched psychological interventions, and is well-recognised as the most effective psychological treatment for depression and anxiety [157]. One RCT showed that eight weekly group CBT sessions were effective in improving QoL ratings and reducing psychological fatigue in women with PCOS [152]. Another more recent RCT investigated the outcome of a 1 year three-component intervention focusing on CBT, diet and exercise [154] and reported improvements in self-esteem and depressive symptoms as compared to usual care [154]. Similarly, an RCT by Cooney et al. [153], comparing the effects of CBT and lifestyle modification versus lifestyle modification alone, reported the CBT/lifestyle modification group lost more than twice as much weight per week

and had greater improvements in QoL compared to lifestyle only. Depression scores decreased in the overall group and there was no difference between the two groups [153]. Lastly, a pilot intervention study of adolescents with PCOS has shown promising results for the use of CBT in the reduction of weight and improvement in depressive symptoms [158].

Mindfulness meditation programs have gained increasing popularity over the past few decades, and are being included as part of clinical trials to reduce stress and improve psychological wellbeing across a range of medical conditions [159]. Mindfulness meditation can be used to reduce the production of adrenal androgens, activated via the adrenal glands as a direct result of psychological distress [156]. Despite the proposed benefits, there are very few studies investigating the use of mindfulness meditation as a treatment for psychological symptoms associated with PCOS. One RCT ($n=86$) compared the provision of an eight week mindfulness-based stress reduction (MBSR) program, and found that when compared to the control group (health education), the MBSR group produced greater reductions in perceived stress, depressive symptoms and fasting blood glucose [160]. Similarly, another RCT investigating the impact of mindfulness meditation for eight weeks in PCOS showed reduced stress, depression and anxiety symptoms, and increased life satisfaction and QoL in the intervention

group compared to no treatment [156]. In adolescents with PCOS ($n=37$), a pilot RCT reported higher levels of nutrition and physical activity self-efficacy following a mindfulness and self-management program [161]. Mindfulness-based cognitive therapy (MBCT) combines both elements of MBSR and CBT, but as yet there are no trials investigating this intervention in PCOS.

In addition to CBT and mindfulness meditation, there is some evidence to support group counselling sessions as beneficial in conjunction with exercise programs to increase and support weight loss [151]. In one RCT ($n=17$) participants followed a high-intensity aerobic exercise program for eight weeks, followed by eight weeks of group counselling [151]. Qualitative analysis of data taken from the group counselling and physical exercise sessions revealed that development of supportive relationships was important for successful behavioural change. By fostering the exchange of narratives relating to their illness (e.g. effects of PCOS on aspects of everyday life), and generating feedback between group members, counselling sessions helped to reduce social isolation and improve adherence to the exercise intervention [151]. Please see Table 3 for a summary of experimental studies investigating effects of psychological interventions on PCOS outcomes.

Sleep

Women with PCOS have an increased risk of both clinical sleep disorders and non-clinical sleep disturbance, which is mediated by hormone derangement, in particular reduced oestrogen, progesterone and melatonin levels [164]. Oestrogen is required for the metabolism of neurotransmitters (norepinephrine and serotonin) involved in regulating sleep patterns, and plays an important role in maintaining a low body temperature at night [165]. Progesterone has sedative and anxiolytic actions that can support sleep quality, and acts as a respiratory stimulant that lessens airway resistance in obstructive sleep apnoea (OSA) [166]. Melatonin is a neuroendocrine hormone that is widely recognised as crucial in maintaining circadian rhythm regulation. However, melatonin is also involved in ovarian function, with actions including delaying ovarian senescence, promoting follicle formation and improving oocyte quality [167–173].

The current PCOS guideline recognises that OSA is 6.5–8.3 times more likely in women with PCOS [164, 174–177], and promotes routine screening to identify and treat associated symptoms, such as snoring, excessive sleepiness and the potential for fatigue to worsen mood disorders [18]. Screening should include a simple questionnaire, such as the Berlin tool [178], and where appropriate women should be referred onto a specialist for further assessment and

treatment [18]. The guidelines also highlight that treatment of OSA in PCOS should not be used to improve metabolic features. Since guideline inception evidence has emerged reporting weight, PCOS and sleep are interrelated factors that can each contribute to the worsening presentation of one another, whereby sleep disorders and disturbance may worsen the presentation of PCOS related metabolic outcomes and vice versa [179].

Hypersomnia and insomnia are also common clinical sleep disorders in PCOS [164, 177, 180], with prevalence estimated at 11% versus 1% in women with versus those without PCOS [180]. Even in the absence of clinically diagnosed sleep disorders, women with PCOS have a higher prevalence of sleep disturbances, including poor sleep quality [181], issues with sleep initiation [182], severe fatigue [140], restless sleep [140] and difficulty sleeping overnight [140]. The prevalence of sleep disturbances may be up to 20% higher in women with PCOS compared to women without PCOS [183]. Emerging research also suggests that social restrictions arising from the COVID-19 pandemic have worsened sleep disturbances in women with PCOS [177]. Findings from key studies of non-clinical sleep disturbance can be found in Table 4.

In the general population short and disturbed sleep is consistently associated with excess weight [184], IR [185], T2DM [185] and CVD [186]. Similar relationships are observed in PCOS, where OSA and sleep disordered breathing exacerbates risk of IR and metabolic consequences of abnormal glucose tolerance [187, 188]. A cross-sectional study in adolescents with PCOS ($n=103$) reported those with sleep disordered breathing had significantly higher BMI Z-scores, and a higher prevalence of metabolic syndrome (METS) [188]. Similar metabolic consequences are seen in women with PCOS who suffer from non-clinical sleep disturbance [164]. Underlying mechanisms linking sleep disorders and disturbance with worsened metabolic outcomes include amplified sympathetic tone and oxidative stress [164], reduced adipose tissue lipolysis, and an increase in energy intake stemming from heightened hedonic and endocrine appetite signals [189].

Unfavourable effects on energy metabolism and appetite regulation, may explain why women with PCOS who display sleep disturbance have a reduced capacity to maintain dietary interventions [183]. Moreover, depression and anxiety share a bidirectional relationship with disrupted and reduced sleep [190], and as stated previously, interventions that improve mental health can help to increase engagement with dietary and physical activity recommendations [131]. Optimising sleep may therefore be an important consideration when promoting healthy lifestyle change in women with PCOS [183].

Table 6 Current recommendations for clinical practice and research gaps identified by this review

Recommendation(s) from current guidelines ^a	Category of recommendation ^b	Research gaps
Effectiveness of lifestyle interventions		
Healthy lifestyle behaviours encompassing healthy eating and regular physical activity should be recommended in all those with PCOS to achieve and/or maintain healthy weight and to optimise hormonal outcomes, general health, and QoL across the life course.	CCR	<ul style="list-style-type: none"> • Improves sustainability of weight loss interventions. • Identifies subgroups who respond to weight loss with clinically relevant metabolic and reproductive improvements (this requires the inclusion of more clinical reproductive outcomes in RCTs). • Defines weight loss thresholds for improvements in different PCOS features (metabolic, reproductive and psychological). • Characterises the degree of metabolic and reproductive improvements related to different lifestyle factors (diet, physical activity and behavioural) independent of weight changes. • Considers effects of weight gain prevention on limiting the progression/worsening of PCOS features. • Investigates how different dietary, physical activity and behavioural interventions affect engagement, adherence and sustainability of lifestyle change. • Investigates efficacy and effectiveness of healthy lifestyle changes independent of weight change.

Table 6 (continued)

Recommendation(s) from current guidelines ^a	Category of recommendation ^b	Research gaps
Dietary interventions		
A variety of balanced dietary approaches could be recommended to reduce dietary energy intake and induce weight loss in women with PCOS and overweight and obesity, as per general population recommendations.	CCR	<ul style="list-style-type: none"> Low GI/GL diets may provide benefits in reducing weight and IR in women with PCOS. Further research needs to assess additional risk factors including reproductive function and CVD risk. Identify and define the optimal diet for PCOS management by comparing a range of different dietary approaches (e.g. DASH, Mediterranean or low GI/GL).
General healthy eating principles should be followed for all women with PCOS across the life course, as per general population recommendations.	CCR	
To achieve weight loss in those with excess weight, an energy deficit of 30% or 500 - 750 kcal/day (1,200 to 1,500 kcal/day) could be prescribed for women, also considering individual energy requirements, body weight and physical activity levels.	CPP	
In women with PCOS, there is no or limited evidence that any specific energy equivalent diet type is better than another, or that there is any differential response to weight management intervention, compared to women without PCOS.	CPP	
Tailoring of dietary changes to food preferences, allowing for a flexible and individual approach to reducing energy intake and avoiding unduly restrictive and nutritionally unbalanced diets, are important, as per general population recommendations.	CPP	
Physical activity interventions		
Health professionals should encourage and advise the following for prevention of weight gain and maintenance of health:	CCR	While evidence supports the provision of supervised vigorous aerobic exercise, which may provide greater benefits on PCOS symptoms than other types of exercise (e.g. resistance training), additional larger and longer-term studies are required to: <ul style="list-style-type: none"> Characterise optimal exercise prescription for PCOS management. Identify factors that improve adherence to exercise interventions. Identify subgroups who respond to exercise with clinical improvements.
• in adults from 18 – 64 years; a minimum of 150 min/week of moderate intensity physical activity or 75 min/week of vigorous intensities or an equivalent combination of both, including muscle strengthening activities on 2 non-consecutive days/week;		
• in adolescents, at least 60 minutes of moderate to vigorous intensity physical activity/day, including those that strengthen muscle and bone at least 3 times weekly;		
• activity be performed in at least 10-minute bouts or around 1000 steps, aiming to achieve at least 30 minutes daily on most days.		
Health professionals should encourage and advise the following for modest weight-loss, prevention of weight-regain and greater health benefits:	CCR	
• a minimum of 250 min/week of moderate intensity activities or 150 min/week of vigorous intensity or an equivalent combination of both, and muscle strengthening activities involving major muscle groups on 2 non-consecutive days/week;		
• minimised sedentary, screen or sitting time.		
Physical activity includes leisure time physical activity, transportation such as walking or cycling, occupational work, household chores, games, sports or planned exercise, in the context of daily, family and community activities.	CPP	
Daily, 10000 steps is ideal, including activities of daily living and 30 minutes of structured physical activity or around 3000 steps.		
Structuring of recommended activities need to consider women's and family routines as well as cultural preferences.		

Table 6 (continued)

Recommendation(s) from current guidelines ^a	Category of recommendation ^b	Research gaps
Behavioural interventions		
Lifestyle interventions could include behavioural strategies such as goal-setting, self-monitoring, stimulus control, problem solving, assertiveness training, slower eating, reinforcing changes and relapse prevention, to optimise weight management healthy lifestyle and emotional wellbeing in women with PCOS.	CCR	<ul style="list-style-type: none"> To identify behavioural and cognitive strategies that should be targeted in women with PCOS, more observational research that characterises women's use of self-management strategies is needed. To aid replication and interpretation of findings, RCTs must clearly define the theoretical frameworks and behavioural components used in intervention design.
Comprehensive health behavioural or cognitive behavioural interventions could be considered to increase support, engagement, retention, adherence and maintenance of healthy lifestyle and improve health outcomes in women with PCOS.	CPP	
Assessment and treatment of infertility (as it relates to alcohol and smoking use)		
Cardiovascular disease risk (as it relates to alcohol and smoking use)	CPP	<ul style="list-style-type: none"> Determine whether women with PCOS are at a higher risk of alcohol and smoking-related infertility complications (with a focus on anovulatory infertility) when compared to women without PCOS. Determine whether women with PCOS are at a higher risk of smoking-related CVD complications when compared to women without PCOS.
Factors such as blood glucose, weight, blood pressure, smoking, alcohol, diet, exercise, sleep and mental, emotional and sexual health need to be optimised in women with PCOS, to improve reproductive and obstetric outcomes, aligned with recommendations in the general population.	CCR	
If screening reveals CVD risk factors including obesity, cigarette smoking, dyslipidaemia, hypertension, impaired glucose tolerance and lack of physical activity, women with PCOS should be considered at increased risk of CVD.	CCR	
Quality of life		
Health professionals and women should be aware of the adverse impact of PCOS on quality of life.	CCR	<ul style="list-style-type: none"> Validate QoL tools longitudinally to identify clinically meaningful differences in QoL scores.
Health professionals should capture and consider perceptions of symptoms, impact on quality of life and personal priorities for care to improve patient outcomes.	CCR	
The PCOS quality of life tool (PCOSQ), or the modified PCOSQ, may be useful clinically to highlight PCOS features causing greatest distress, and to evaluate treatment outcomes on women's subjective PCOS health concerns.	CPP	

Table 6 (continued)

Recommendation(s) from current guidelines ^a	Category of recommendation ^b	Research gaps
Depression and anxiety symptoms, screening and treatment		
Psychosexual function		
Body image		
Eating disorders and disordered eating		
Health professionals should be aware that in PCOS, there is a high prevalence of moderate to severe anxiety and depressive symptoms in adults; and a likely increased prevalence in adolescents.	CCR	<ul style="list-style-type: none"> To determine accurate prevalence of psychological conditions in PCOS, more adequately powered cross-sectional studies using structured diagnostic interviews administered by appropriately qualified professionals are required. Future research should consider the efficacy of different types of psychological interventions in PCOS, with a focus on how changes to mental health symptoms influence engagement with lifestyle change. In particular, the development of a PCOS specific CBT program, tailored to meet the specific mental health needs of women with PCOS is warrant.
Anxiety and depressive symptoms should be routinely screened in all adolescents and women with PCOS at diagnosis. If the screen for these symptoms and/or other aspects of emotional wellbeing is positive, further assessment and/or referral for assessment and treatment should be completed by suitably qualified health professionals, informed by regional guidelines.	CCR	
If treatment is warranted, psychological therapy and/or pharmacological treatment should be offered in PCOS, informed by regional clinical practice guidelines.	CCR	
Factors including obesity, infertility, hirsutism need consideration along with use of hormonal medications in PCOS, as they may independently exacerbate depressive and anxiety symptoms and other aspects of emotional wellbeing.	CPP	
All health professionals should be aware of the increased prevalence of psychosexual dysfunction and should consider exploring how features of psychohirsutism and body image, impact on sex life and relationships in PCOS.	CCR	
If psychosexual dysfunction is suspected, tools such as the Female Sexual Function Index can be considered.	CCR	
Health professionals and women should be aware that features of PCOS can impact on body image.	CCR	
All health professionals and women should be aware of the increased prevalence of eating disorders and disordered eating associated with PCOS.	CCR	
If eating disorders and disordered eating are suspected, further assessment, referral and treatment, including psychological therapy, could be offered by appropriately trained health professionals, informed by regional clinical practice guidelines.	CCR	

Table 6 (continued)

Recommendation(s) from current guidelines^a

Category of recommendation ^b	Research gaps
Obstructive sleep apnoea (OSA)	<ul style="list-style-type: none"> To determine accurate prevalence of subclinical sleep disturbances in PCOS, more adequately powdered cross-sectional studies using validated subjective and objective sleep measures are required. While emerging evidence suggests that disturbed sleep may exacerbate IR via decreasing energy expenditure and increasing adipose tissue deposition, more research in women with PCOS is needed to confirm this hypothesis. Investigate effects of CBT interventions in women with PCOS who have disturbed sleep (outcomes of interest include food intake, metabolic rate, appetite hormones, weight, adherence to lifestyle changes and PCOS features).
Screening should only be considered for OSA in PCOS to identify and alleviate related symptoms, such as snoring, waking unrefreshed from sleep, daytime sleepiness, and the potential for fatigue to contribute to mood disorders. Screening should not be considered with the intention of improving cardiometabolic risk, with inadequate evidence for metabolic benefits of OSA treatment in PCOS and in general populations.	CCR
A simple screening questionnaire, preferably the Berlin tool [178], could be applied and if positive, referral to a specialist is considered.	CPP
A positive screen raises the likelihood of OSA, however it does not quantify symptom burden and alone does not justify treatment. If women with PCOS have OSA symptoms and a positive screen, consideration can be given to be referral to a specialist centre for further evaluation.	
Inositol	<ul style="list-style-type: none"> EBR Women taking inositol and other complementary therapies are encouraged to advise their health professional.
Inositol (in any form) should currently be considered an experimental therapy in PCOS, with emerging evidence on efficacy highlighting the need for further research.	CPP

Abbreviations: BMI Body mass index, CBT Cognitive behavioural therapy, CV/D Cardiovascular disease, DASH Dietary approaches to stop hypertension, GI Glycaemic index, GL Glycaemic load, IR Insulin resistance, NAC N-acetyl-cysteine, PCOS Polycystic ovary syndrome, RCT Randomised controlled trial, QoL Quality of life

^a Recommendations are taken directly from the 2018 International Evidence-Based Guideline for the Assessment and Management of PCOS [18]. Does not include all recommendations, only those relevant to the findings of this review are presented

^b EBR Evidence based recommendations: Evidence sufficient to inform a recommendation made by the guideline development group. CCR Clinical Consensus Recommendations: In the absence of evidence, a clinical consensus recommendation has been made by the guideline development group. CPP Clinical Practice Points: Evidence not sought. A practice point has been made by the guideline development group where important issues arose from discussion of evidence-based or clinical consensus recommendations

Traditional, complementary and integrative medicine

The 2018 PCOS guideline includes recommendations on inositol supplementation, though do not include evidence regarding the use of other supplements, herbal medicine or other TCIM approaches, including acupuncture and yoga [18].

Vitamins, vitamin-like supplements, minerals and other supplements

The 2018 guideline highlights that inositol (including myo-inositol (MI) and di-chiro inositol) is a nutritional supplement that may be involved in insulin signalling transduction [191]. MI in particular is a key endocrine regulator that displays impaired metabolism in PCOS [191]. MI supplementation has been explored in a meta-analysis of nine RCTs ($n=496$), which showed improved metabolic profiles and reduced hyperandrogenism [191]. These findings are supported by two earlier meta-analyses, reporting improved ovulation, menstrual cyclicity, and hormonal profiles following MI supplementation [192, 193]. The 2018 PCOS guideline recommends that inositol (in any form) should be considered as an experimental therapy in PCOS management. The guideline also recognises that women participating in any form of TCIM should be encouraged to advise their health professional. However, it does not consider emerging evidence for the use of other types of TCIM in PCOS treatment as this was outside of the scope of the 2018 guideline.

Vitamins

B-group vitamins (B₁, B₆ and B₁₂), folic acid (B₉) and vitamins D, E, and K are critical for several biological processes that can affect metabolic and reproductive features of PCOS. B-group vitamins work alongside folic acid (the synthetic form of folate) to regulate homocysteine (Hcy) via re-methylation of Hcy to methionine [194]. Hcy is an amino acid that confers an increased risk of CVD at high levels, and which is often deranged in women with PCOS [195], likely related to a higher prevalence of folate deficiency [196–198]. One RCT explored the use of B-group vitamins combined with folic acid in 60 women with PCOS, and reported a reduction in the Hcy increasing effect of metformin [198]. Folic acid alone has also been examined in two RCTs of women with PCOS ($n=69$ [199] and $n=81$ [200]), improving FINS, HOMA-IR, C-reactive protein, total antioxidant capacity (TAC) and glutathione with doses ≥ 5 mg/day when compared with placebo [199, 200]. Regarding vitamin D supplementation, three large-scale meta-analyses reported improvements in measures of IR (HOMA-IR [201, 202], FINS [201]), fasting glucose [201]), lipid profiles (LDL-C [201–203], TC [203] and TAG [203]) and androgens (T) [202], when compared

with placebo. While vitamin E (or tocopherol) has various reported benefits on fertility outcomes in other populations [204], and has improved androgen profiles when co-supplemented with coenzyme Q10 (CoQ10) in women with PCOS [205], to date no RCTs have examined the use of vitamin E supplements alone in PCOS. Vitamin K also has limited available literature in PCOS, with only one RCT ($n=84$) demonstrating improvements in anthropometry, insulin and androgen profiles following supplementation (90 µg/day Menaquinone-7 for eight weeks), compared with placebo [206].

Vitamin-like supplements

Vitamin-like supplements including bioflavonoids, carnitine and alpha-lipoic acid (α-LA) have well-recognised antioxidant properties and play a role in fatty acid and glucose metabolism, providing possible metabolic benefits in PCOS [207]. Bioflavonoids consist of plant-derived polyphenolic compounds, some of which have been inversely associated with METS in women with PCOS [207]. In a pilot prospective study of 12 women with PCOS, 36 mg/day of the soy isoflavone genistein for six months improved lipid profiles but not anthropometry, IR, hormonal profiles or menstrual cyclicity [208]. Carnitine, particularly the active form L-carnitine, is reported to be lower in women with PCOS and linked with hyperandrogenism, hyperinsulinaemia and reduced oocyte quality [209, 210]. One RCT explored L-carnitine use in PCOS and found beneficial effects on mental health parameters and markers of oxidative stress [211], although the integrity of these have come under scrutiny and hence should be interpreted with caution [122212]. Regarding α-LA, a small pre-post study ($n=6$) administered 1200 mg/day for 16 weeks, and reported improved IR, LDL-C and TAG, though no effects on TAC or plasma oxidation metabolites [213]. Another RCT reported improved anthropometric (BMI), metabolic (FINS and HDL-C) and reproductive (menstrual cyclicity) features in 46 women with PCOS receiving α-LA supplementation (600 mg/day for 180 days) compared with controls [214]. However, as these women were co-supplemented with 1000 mg/day D-chiro-inostiol, findings are not isolated to the effects of α-LA alone [214].

Minerals

Minerals such as calcium, zinc, selenium, magnesium and chromium picolinate (CrP) have been explored in PCOS due to their reported insulin sensitising, antioxidant and anti-inflammatory properties [215–217]. A small number of studies have also reported women with PCOS are at higher risk of being deficient in calcium [218], zinc [215, 217] and selenium [195]. A recent systematic

review (six RCTs) reported that vitamin D and calcium co-supplementation in women with PCOS improved lipid and androgen profiles, follicular health and menstrual cyclicity [219]. While these findings are promising, it is difficult to attribute benefits to calcium alone, given calcium is often co-supplemented with vitamin D due to their complementary mechanisms of action. One systematic review (five RCTs) in PCOS reported zinc (often co-supplemented with other nutrients such as calcium, vitamin D and magnesium), improved HOMA-IR, lipids, T, FSH and DHEAS [220] compared to placebo. Another systematic review (five RCTs) examining selenium supplementation reported reduced IR, oxidative stress and inflammation, while results for anthropometry, lipids, androgens and hirsutism were inconsistent [221]. Regarding magnesium (an intracellular cation involved in insulin metabolism), while supplementation in PCOS has been associated with reduced IR in observational research [222], these findings are not supported by data from RCTs, with considerable inconsistencies between studies [222]. Two meta-analyses examined CrP in women with PCOS [223, 224]. While one reported that CrP supplementation reduced BMI, FINS and free testosterone [223], the other reported decreased IR, but not BMI, and increased levels of T [224].

Other supplements

Other supplements purported to provide a range of antioxidant and anti-inflammatory benefits, including omega-3 fatty acids, N-acetyl-cysteine (NAC), CoQ10, probiotics, quercetin, resveratrol and melatonin have been explored in PCOS. A meta-analysis (nine RCTs) of women with PCOS ($n=591$) receiving omega-3 supplementation reported reductions in HOMA-IR, TC, TAG and LDL-C, though showed no effect on other metabolic parameters or T [225]. In a meta-analysis of eight RCTs ($n=910$) examining NAC supplementation (the acylated form of L-cysteine), researchers reported improved glucose regulation and a greater likelihood of conception and livebirths in women with PCOS compared with placebo [226]. In a single RCT ($n=60$) CoQ10 supplementation (100 mg/day for 12 weeks) improved fasting glucose and insulin, HOMA-IR, insulin sensitivity index and TC, compared with the placebo group [227]. Two meta-analyses reported probiotics improved FAI, SHBG, IR and blood lipids, with no differences in weight or hirsutism between intervention and placebo groups [228, 229]. These findings may be linked to lower microbial diversity and increased intestinal permeability in women with PCOS [230, 231]. In regards to quercetin and resveratrol, which are both food derived polyphenols with a strong antioxidant capacity, one systematic review (three experimental studies, $n=246$ women with PCOS) reported

quercetin supplementation improved measures of IR and testosterone levels, but not anthropometry compared with placebo [232]. Similarly, one RCT in women with PCOS ($n=61$) reported resveratrol (800–1500 mg/day for four days) improved androgen and metabolic profiles and oocyte and embryo quality compared with placebo [233]. Finally, a systematic review (two RCTs and one cell-culture study) investigating the effects of melatonin supplementation in women with PCOS using assisted reproductive technologies reported melatonin significantly increased clinical pregnancy rates but not live birth rates [172]. A more recent RCT ($n=56$) reported improved levels of T, hirsutism, inflammatory and oxidative stress profiles in women receiving 10 g melatonin/day for 12 weeks, compared with placebo [234].

Herbal medicine

To date the most recent and comprehensive review (Cochrane review including five RCTs and $n=414$ women with PCOS) investigating the effects of herbal medicine on reproductive outcomes, reported no difference between the use of Chinese herbal medicine (CHM) and clomiphene for pregnancy rates, and limited evidence of increased pregnancy rate for CHM with clomiphene compared with clomiphene alone [235]. This review concluded that there was inadequate evidence to promote the use of CHM for the treatment of subfertility in women with PCOS [235]. Similarly, a smaller systematic review (five studies) investigating the effects of four herbal medicines (green tea, cinnamon, spearmint and black cohosh) on menstrual regularity in PCOS, found limited high-quality evidence from RCTs to support their clinical use and concluded that evidence for safety was lacking [236].

More recently, a number of small RCTs investigating metabolic and reproductive effects of a range of herbal medicines have been published. Curcumin, an active compound in turmeric (*Curcuma longa*), may exert hypoglycemic effects via a number of mechanisms, including attenuation of circulating levels of tumor necrosis factor- α [237]. One RCT ($n=67$) reported decreased levels of fasting glucose following supplementation compared with placebo [238], while another ($n=51$) which used a lower dose (1000 mg/day versus 1500 mg/day) and shorter duration (six weeks versus 12 weeks), reported no between group differences for fasting glucose, HOMA-IR or lipids [239]. *Salvia officinalis* or sage contains multiple active compounds that display antioxidant effects and therefore effects on glucose metabolism and insulin sensitivity [240]. One RCT ($n=72$) reported consuming sage extract for eight weeks improved IR and reduced BMI, with no effects on WHR or blood pressure [241]. *Foeniculum vulgare*

or fennel may provide protective effects on hormonal abnormalities in PCOS via its actions as a phytoestrogen [242]. One RCT ($n=55$) reported that six months of fennel tea and dry cupping was as effective as metformin for reducing BMI and menstrual cycle length [243]. *Glycyrrhiza glabra* or licorice contains active phytochemicals including isoflavane and glabridin, which have been shown to have antiandrogenic effects [244]. Two experimental studies in healthy women ($n=9$) [245] and women with PCOS ($n=32$) [246] reported that 3.5 g/day of licorice extract decreased T [245] and reduced side effects of spironolactone [246]. *Mentha spicata* (spearmint), *Zingiber officinale Roscoe* (ginger), *Cinnamomum cassia* (cinnamon) and *Citrus sinensis* (citrus) have been shown to exert anti-inflammatory and hypoglycemic effects [247–250]. One RCT in infertile women with PCOS ($n=60$) comparing the effects of a herbal mixture (citrus, ginger, cinnamon and spearmint) with clomiphene citrate (CC), herbal mixture alone, or CC alone reported that the herbal mixture, with or without CC, improved circulating antioxidant levels, IR and fasting blood glucose, but not menstrual regularity when compared to CC alone [251]. While observations from emerging research are promising, to support the safe translation of findings into the clinical setting there is a clear need for larger clinical trials investigating the efficacy and safety of herbal medicine use in PCOS.

Other traditional, complimentary and integrative medicine approaches

Acupuncture may provide beneficial impacts on sympathetic function [252] and ovarian blood flow [253] in women with PCOS. A recent meta-analysis of 22 RCTs ($n=2315$ women with PCOS) reported recovery of the menstrual period in the acupuncture group when compared with placebo, but no evidence for differences between groups in terms of live birth, pregnancy and ovulation [254]. While an earlier meta-analysis reported a significant reduction in BMI following acupuncture use, this was mainly due to one RCT ($n=80$) which compared acupuncture and the oral contraceptive pill to the oral contraceptive pill alone [255]. When this study was removed, the pooled analysis was no longer significant [255].

Yoga gymnastics have been recommended as an example of moderate physical activity in the 2018 evidence-based PCOS guideline [18]. However, as yoga is considered a mind-body therapy that incorporates aspects of meditation, it may provide additional benefits beyond those gained through other forms of exercise [256]. While one systematic review (16 observational and experimental studies, $n=365$ women with

PCOS) reported yoga may provide a range of psychological, reproductive and metabolic benefits, no meta-analysis was performed and a limited summary of included studies made it difficult to confirm findings [257]. A more recent systematic review (11 experimental studies) included a meta-analysis of two RCTs and found that yoga significantly decreased clinical hyperandrogenism, menstrual irregularity and fasting glucose and insulin [258]. Lastly, findings from a recent RCT ($n=67$ women with PCOS) suggests that 90 minutes of yoga per day for six weeks can significantly reduce hirsutism, waist and hip circumference when compared to controls [259]. Please see Table 5 for a summary of available evidence from meta-analyses and experimental studies investigating the effects of TCIM on PCOS outcomes.

Summary of findings and research gaps

The 2018 International Evidence-Based Guideline for the Assessment and Management of PCOS highlights lifestyle (diet, physical activity and/or behavioural) management as the primary initial treatment strategy [18]. It is important to consider that the definition of lifestyle management may warrant expansion consistent with the whole person model of healthcare provision, which may include care addressing psychological and sleep interventions, as well as a range of TCIM approaches [20]. In line with patient interest [31–35], and to assist women and healthcare providers in understanding the evidence to aid safe implementation of adjunct therapies, rigorous assessment of the evidence for these alternative lifestyle strategies in PCOS management is warranted. Using a holistic definition of patient care, this review has summarised evidence to date on the traditional components of lifestyle change (diet, physical activity and behavioural change), psychological interventions and non-pharmacological strategies (sleep, supplements, herbal medicine and other TCIM approaches). Table 6 provides a overview of current guideline recommendations alongside the key findings from this review, summarising the identified research gaps that need to be addressed before evidence-based recommendations for clinical practice can be updated.

With regards to traditional lifestyle treatment, the majority of studies focussed on weight loss as a primary treatment goal. This indicates more research is warranted to understand the role of diet and exercise in lean women and/or in weight gain prevention. RCTs using lifestyle interventions under isocaloric conditions that investigate effects on IR, body composition and androgens independent of weight loss are needed. Given the high risk of failure with long-term weight management [9, 37, 40, 261] and high attrition in weight loss trials in

PCOS [13], exploring interventions that focus on weight neural messaging around dietary quality and physical activity may also aid in optimising engagement, adherence and sustainability of lifestyle interventions. Future research should also identify subgroups who respond more favourably to weight loss [45, 53], to aid provision of a more targeted and personalised treatment approach.

With regards to diet strategies, there is a need for more research understanding the impact of low GI/GL diets on androgen status, as well as the biological mechanisms by which low GI/GL diets may impact reproductive and cardiometabolic outcomes associated with PCOS. With regards to physical activity, additional longer-term studies are required to guide exercise prescription in PCOS, although promising evidence supports the provision of vigorous aerobic exercise performed under supervised conditions (i.e. through referral to an exercise physiologist). While behavioural interventions are essential for long term sustainability of dietary and physical activity change, research in PCOS is scarce and interventions are not well defined. Future research should incorporate appropriate theoretical frameworks and clearly outline behavioural components utilised. This will aid intervention duplication and tailoring of active elements to ensure relevance in women with PCOS.

There is currently a lack of research investigating whether women with PCOS are at a higher risk of alcohol and smoking-related complications. This is particularly relevant given the well-established relationship between higher alcohol and cigarette use and rates of depression and anxiety in the general population [262–265]. There is also a need to better understand the relationship between alcohol intake and reproductive outcomes (particularly anovulatory infertility) [139], as safe alcohol limits in PCOS is currently unknown [139].

With regards to psychological interventions, the current evidence base for prevalence of mental health concerns in PCOS relies heavily on symptom prevalence. More adequately powered, gold standard prevalence studies using structured diagnostic interviews administered by appropriately qualified professionals are needed. While QoL has recently been highlighted as a core outcome in PCOS research [266], the application of QoL tools in clinical care is still unclear, with research yet to validate QoL tools longitudinally or identify clinically meaningful differences in QoL scores. The emerging evidence showing support for the use of CBT in PCOS [152–154] highlights an opportunity for tailoring of this psychological intervention to meet the specific mental health needs of women with PCOS, with a focus on how management of mental health symptoms affect lifestyle modifications. CBT that incorporates elements of

mindfulness-based stress reduction also warrants further investigation.

Future research in PCOS and sleep disorders should include more high-quality research in subclinical disorders using objective sleep measures (polysomnography and actigraphy). Future work should also consider emerging evidence showing that disturbed sleep can detrimentally effect energy expenditure, which may increase adipose tissue deposition and exacerbate IR [164, 184, 186, 267–271], thereby worsening the presentation of PCOS. Further, a consideration of how sleep disturbance can reduce engagement with positive lifestyle changes, for example through the disruption of appetite regulation [272, 273] or via contributing to poor mental health outcomes [190, 274], is warranted. CBT interventions including elements of stimulus control and psychoeducation are effective non-pharmacological treatments for both clinical sleep disorders and sleep disturbances in the general population [275–277]. RCTs in women with PCOS that investigate effects of CBT on dietary intake, energy metabolism, appetite regulation, anthropometry, adherence to lifestyle changes and PCOS features are required.

With regards to TCIM, there is a vast array of literature suggesting some beneficial effects of vitamins (B-group vitamins, folate, vitamins D, E and K), vitamin-like nutrients (bioflavonoids, carnitine and α-LA), minerals (calcium, zinc, selenium, and CrP) and other formulations (such as melatonin, omega-3 fatty acids, probiotics, NAC and cinnamon) in PCOS [278]. However, the quality of evidence across studies ranges from meta-analyses of RCTs (vitamin D, omega-3 fatty acids and NAC) to single retrospective observational studies (vitamin K and carnitine). In addition, heterogeneity in results related to factors including variable PCOS presentation and study methodology make it difficult to draw definite conclusions. Future research should focus on specific populations within PCOS, for example age, BMI or phenotype (factors which substantially affect nutrient sufficiency), and outline more consistent approaches to supplement formulation, dosage, intervention duration and type of comparator used. Mechanistic studies are also needed to investigate herb- or nutrient-drug interactions (with common pharmacological treatments used in PCOS) and other possible interactions with the biological processes underpinning PCOS. In regards to acupuncture and yoga, more sufficiently powered RCTs are needed to determine clinical relevance and integration into PCOS management is not yet warranted.

While current research is not sufficiently robust to support integration of TCIM into routine clinical practice, healthcare providers should broaden their knowledge pertaining to how these therapies can be safely and

appropriately utilised as adjuncts to conventional medical management [279–281]. TCIM is frequently used by women, with uptake of TCIM approaches increasing steadily over the past 10 years [31–35]. In women with PCOS, one cross-sectional study ($n=493$) found that 70% reported use of TCIM, namely nutritional and herbal supplements [282]. The most common reasons for use were to treat PCOS symptoms, improve general wellbeing and reduce depression. Of the women using TCIM, 77% had consulted with a complementary practitioner (acupuncturists, chiropractors, naturopaths and massage therapists) [282]. While the study did not report participants engagement with medical physicians, research in the general population has shown that patients are resistant to discuss TCIM use with their consulting physician [283–288]. Qualified health-care providers should be involved in TCIM discussions to help ensure appropriate use, maximise possible benefits and minimize potential harm [289]. For example, to sustain patient engagement in women who express the desire to experiment with supplementation, health-care providers could consider inositol supplementation, using a nuanced and case-specific approach that encapsulates the variety of pathologies in PCOS.

When considering all of the research summarised here, across traditional lifestyle, psychological, sleep and TCIM interventions, there is a clear need for more real-world PCOS research. This involves the translation of findings from clinical trials (where highly selected populations, intensive treatment protocols and expert multidisciplinary teams provide an ideal research setting), into the heterogeneous situations that face clinicians [290–292]. Health professionals provide care to women from diverse social contexts, are often restrained by finite resources and are required to juggle many competing demands for their time [290–292]. While some barriers to implementation, including time, resource and access issues are considered in the current PCOS guideline, they were generated by the guideline development groups and research is needed to validate and clarify their proposed concerns. Real-world research is required to: a) fully understand whether lifestyle recommendations can be practically integrated into current healthcare settings; b) tailor interventions to meet the unique needs of women with PCOS; and c) generate evidence on clinical outcomes that are of great relevance to patients and clinicians, such as live birth, miscarriage and menstrual regularity, which can be collected through routine care.

It is also important to highlight that while lifestyle management is a first-line treatment for PCOS, the addition of pharmacological therapies to further improve clinical features of hyperandrogenism, menstrual irregularity and infertility are often indicated [293]. In these instances,

prescribing physicians should consider how medical management and lifestyle change can be used in adjunct to optimise treatment. For example, the use of combined oral contraceptive pills may have detrimental effects on weight gain [294] and mental health [295], which can be mitigated by appropriate lifestyle intervention. Further, the combination of lifestyle modification and metformin has been shown to lower BMI, subcutaneous adipose tissue and improve menstruation compared with lifestyle modification alone, and hence may have an additive effect on improving cardio-metabolic outcomes in high risk groups [296].

Conclusion

Using the whole person or holistic definition of health, this review has highlighted emerging areas of research that could be considered for integration into future classifications of lifestyle management in PCOS. When developing lifestyle recommendations for PCOS management, interpreting and communicating evidence not only for diet, physical activity and behavioural interventions, but also psychological, sleep and TCIM approaches, will aid clinicians to deliver patient-centred care by affording women more choice and therefore autonomy over their treatment options. This sentiment aligns with the core objectives underpinning the 2018 PCOS guideline, which sought to understand the unmet needs of women with PCOS through continuing to engage consumers in co-design of guideline development, implementation, translation and dissemination.

Abbreviations

α -LA	Alpha-lipoic acid
BMI	Body mass index
CVD	Cardiovascular disease
CHM	Chinese herbal medicine
CrP	Chromium picolinate
CoQ10	Coenzyme Q10
CBT	Cognitive behavioural therapy
DASH	Dietary Approaches to Stop Hypertension
FINS	Fasting insulin level
FSH	Follicle stimulating hormone
FAI	Free androgen index
GI	Glycaemic index
GL	Glycaemic load
HDL-C	High density lipoprotein cholesterol
Hcy	Homocysteine
IR	Insulin resistance
LDL-C	Low density lipoprotein cholesterol
LH	Luteinizing hormone
$VO_{2\max}$	Maximal rate of oxygen
METS	Metabolic syndrome
MUFA	Monounsaturated fatty acid
MI	Myo-inositol
NAC	N-acetyl-cysteine
OGTT	Oral glucose tolerance test
PCOS	Polycystic ovary syndrome
PUFA	Polyunsaturated fatty acid
RCT	Randomised controlled trial
SHBG	Sex hormone-binding globulin
TAC	Total antioxidant capacity

TC	Total cholesterol
T	Testosterone
TCIM	Traditional, complementary and integrative medicine
TAG	Triglycerides
T2DM	Type 2 diabetes
WC	Waist circumference
WHR	Waist-hip-ratio

INTRODUCTION

Polycystic Ovary Syndrome (PCOS) is one of the most common endocrinopathy affecting women.^[1] It has an unknown etiology and is recognized as a heterogeneous disorder that results in overproduction of androgens, primarily from the ovary, and is associated with insulin resistance (IR).^[1] The Rotterdam 2003 criteria defines PCOS as incidence of any two of the three key criteria, namely, oligoovulation and/or anovulation, excess androgen activity and polycystic ovaries(PCO).^[1,2] However, the terminology used in the context of PCOS needs to be revisited to reflect the actual clinical nature of PCOS.

Studies of PCOS in India carried out in convenience samples reported a prevalence of 3.7% to 22.5%,^[3,4] with 9.13% to 36% prevalence in adolescents only.^[5,6] The wide variation in prevalence might be due to heterogeneous presentation of symptoms, diagnostic criteria practiced, limitations in diagnosis, age groups, and ethnic populations studied. Therefore, it is essential to consider these factors before diagnosis and/or management is initiated. Further studies are needed to understand the dynamics in prevalence rates of PCOS across India. Although there is a paucity of data from large scale surveillance studies, the higher incidence of PCOS risk factors (high body mass index

(BMI), IR) in India, suggests that the real extent of the problem might be currently underestimated.^[7]

The most common symptoms of PCOS can range from menstrual disorders, infertility, hyperandrogenemia to metabolic syndrome (MS).^[8] Elevated insulin levels due to IR may lead to development of PCOS by contributing to the underlying abnormalities seen in the hypothalamic-pituitary-ovarian axis. The resulting complex of physiological dysfunction produced by interrelated metabolic and hormonal factors, predisposes patients with PCOS to different complications like endometrial hyperplasia and cancer, cardiovascular disease (CVD), miscarriage, and acanthosis nigricans (AN).^[8] The complications add to the burden faced by patients, besides effecting social and emotional wellbeing, especially in adolescents, who are under the impression of being afflicted by a 'disease'.

Efficient management of PCOS provides a prospective window of opportunity to avoid the risk of associated complications. Treatment is broadly aimed at tackling (IR), effects of hyperandrogenism, irregular menstruation, and infertility. However, given the complex nature of PCOS, tailoring treatment options to the needs of individual patients can be a difficult clinical exercise. Long-term risks of PCOS must be balanced against current acute needs of the patients like the desire for continued fertility and the need to ameliorate the cosmetic challenges associated with PCOS. Due to its heterogeneous nature, effective management of PCOS needs a sustained, multi-pronged strategy with inter-disciplinary expertise, based on strong evidentiary framework to guide the standardization of care. However, in contemporary clinical practice in India, successful interdisciplinary cross-linking of efforts is stymied by the lack of awareness about PCOS and guidelines addressing its management. Further, in view of the higher risk of PCOS in Indian women, and the relative lack of medical infrastructure to deal with the chronic outcomes of PCOS, effective, evidence-based treatment guidelines for India are an immediate necessity. The current good clinical practice recommendations (GCPs) are an effort to provide a comprehensive framework for addressing

issues relating to the management of PCOS in India. It is aimed at providing scientific evidence and well-balanced information on multi-disciplinary approach for the management of PCOS to health care providers in India.

METHODOLOGY

Systematic review of literature was conducted to provide the best possible evidence base for the GCPR. Existing guidelines, meta-analyses, systematic reviews, key cited articles relating to PCOS were reviewed by a group of doctors and recommendations relevant to Indian scenario were framed. The recommendations were discussed by an expert panel of gynecologists, physicians, ultrasonologists, endocrinologists, dermatologists, and pediatricians in a series of meetings. GCPR for each section of the guidelines were discussed and where there was little or no evidence, the panel relied on experience, judgment and consensus to make their recommendations. The current consensus GCPR are developed in accordance to the American Association of Clinical Endocrinologists (AACE) protocol for standardized production of clinical practice guidelines. Recommendations are based on clinical importance (graded as A: strongly recommended, B: suggested, and C: unresolved) coupled by four intuitive levels of evidence (1 = 'at least one randomized controlled trial (RCT) or meta-analysis of RCTs', 2 = 'at least one non-randomized or non-controlled, prospective epidemiological study', 3 = 'cross-sectional or observational or surveillance or pilot study' and 4 = 'existing guideline or consensus expert opinion on extensive patient experience or review').^[9]

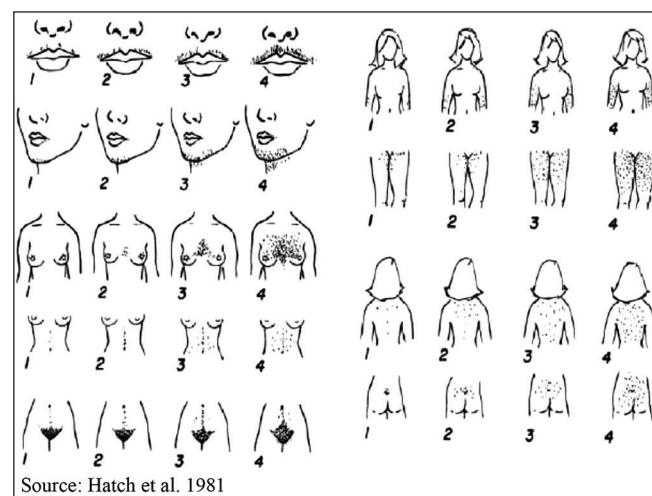

RISK FACTORS FOR THE ASSESSMENT OF PCOS

Current Evidence:

Several risk factors are associated with the incidence of PCOS, but not all are causative or predisposing factors for PCOS. However, their presentation is indicative of the incidence of PCOS. Thus the risk factors included in the current section indicate the risk for PCOS diagnosis but not the etiological likelihood of disease development. A preliminary understanding of the clinical characteristics and medical history of the patients is an invaluable resource for assessing the risk of PCOS incidence.

Biochemical risk factors

BMI is a key risk factor associated with the incidence of PCOS (mean BMI: 29.3 ± 7.5 vs. $25.6 \pm 5.8 \text{ kg/m}^2$, $p < 0.001$ in women with and without PCOS);^[10,11] higher BMI has been implicated as an important indicative marker of PCOS status. In women with PCOS, changes in BMI during adolescence are positively associated with changes in waist circumference ($p < 0.0001$), low density lipoprotein-cholesterol (LDL-C) ($p = 0.01$), triglycerides (TG) ($p = 0.008$), and systolic blood pressure (SBP) ($p = 0.002$).^[12] In adults, a BMI $\geq 23 \text{ kg/m}^2$ is considered overweight /obese,^[13] whereas in adolescents BMI $> 97.5^{\text{th}}$ percentile for age and gender are regarded as overweight/obese.^[14,15] In addition, development of clinical features of PCOS is often preceded by a history of weight gain,^[16,17] and factors independently associated with BMI: higher energy intake and glycaemic index, low physical activity, smoking, alcohol intake.^[18,19]

Source: Hatch et al. 1981

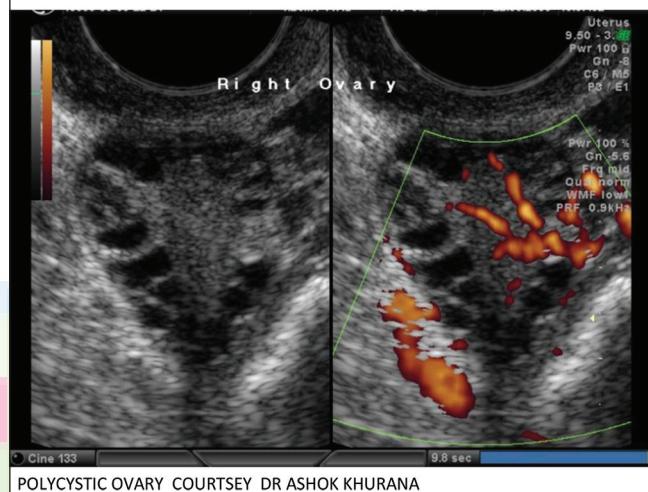

Figure 1: Modified Ferriman-Gallwey hirsutism scoring system

Development of IR and dysregulation of lipid metabolism are seen even in the early stages of PCOS.^[19] Significantly higher IR (fasting serum insulin) is observed in patients with PCOS with apparently normal oral glucose tolerance test (OGTT).^[20] Similarly, early signs of lipid metabolic dysregulation (elevated serum total cholesterol, TG and LDL-C levels and carotid intima-media thickness) were observed in age-matched patients with PCOS between 18-35 years.^[19] Presence of family history of PCOS or diabetes or an inadequate lifestyle have also been shown to be important risk factors for incidence of PCOS [Figure 1].^[21,22]

Clinical risk factors

Patients with normal menstrual cycle compared to patients with oligo/amenorrhea show significantly better metabolic parameters (BMI, fasting insulin, and Homeostasis Model Assessment-insulin resistance (HOMA-IR)).^[23] Due consideration to the patient's demographic profile is important in determining the PCOS status of a patient, since the risk and presentation varies in different patient groups. In adolescent patients, the diagnostic criteria of PCOS based on the signs and symptoms often overlap with the characteristics of normal puberty. In adolescents and younger women with PCOS, primary risk factors include disturbances in periodicity/timing of menstrual cycle and chronic anovulation while, in older women obesity, IR, and metabolic disturbances are

predominant.^[24] An association between younger age at menarche and development of PCOS was observed in adolescents (odds ratio: 0.63 [95% CI: 0.47; 0.85] p = 0.003).^[25] Thus, careful consideration must be given to the age of puberty and presentation of PCOS; deviations in terms of early or late puberty may be a risk factor for development of PCOS. Cutaneous manifestations like early acne or hirsutism, persistent acne and hirsutism for > two years, persistent severe acne; frequent relapse in acne; acne in facial V area are also known to be associated with PCOS [Figure 1].^[26,27]

Compared to women with PCOS of Caucasian ethnicity, Indian women with PCOS have a higher degree of hirsutism, infertility, and acne; and experience lower live birth rates following in vitro fertilization.^[28] Similarly, South Asians with PCOS have a higher prevalence of IR and MS compared to BMI matched PCOS patients from other ethnic groups (Definition: Appendix I).^[28] A rapid increase in the prevalence of PCOS associated morbid conditions such as IR, excess body fat, adverse body fat patterning, hypertriglyceridemia, and obesity-related disease (diabetes and CVD) in Asian Indians has been noted in a recent review of literature on PCOS.^[7] Thus, in patients of South Asian and specifically Indian ethnicity, regular PCOS surveillance is warranted.

Existing Guidelines:

Currently, no strategy for stratifying the risk of PCOS in the general population has been suggested by any major guidelines. The clinical practice guidelines from Endocrine society, USA,^[29] PCOS Australian alliance, Australia,^[30] The Royal College of Obstetricians and Gynecologists (RCOG), UK,^[31] and Society of Obstetricians and Gynecologists of Canada (SOGC), Canada^[32] have not proposed a system of risk classification in general population. However, in Indian clinical practice a preliminary assessment of risk in general population is likely to help in further referrals to higher medical centers for appropriate diagnosis and management. Such a risk classification is only to help in a preliminary assessment and not to posit an alternative scheme of diagnosis; in primary care settings such a risk classification is likely to help in proper channeling of patients to specialized centers for systematic diagnosis.

Recommendations on risk factors for assessment of PCOS

- It is recommended that Indian women showing at least one biochemical characteristic in conjunction with one clinical

symptom should be considered for further evaluation for the likelihood of PCOS (Grade A, EL 3).

- Biochemical characteristics: high BMI for overweight/obesity > 23 kg/m² for adults and > 97.5th percentile for age in adolescents, insulin resistance (acanthosis nigricans as clinical marker of insulin resistance), family history of diabetes or PCOS, obesity and inadequate lifestyle, any marker of lipid metabolic dysregulation (elevated serum total cholesterol, triglyceride and LDL-C levels),
- Clinical symptoms: pubertal deviations (early or late), disturbances in periodicity/timing of menstrual cycle, presence of PCO and clinical signs of hyperandrogenism such as early acne or hirsutism, persistent severe acne, frequent relapse in acne, acne in facial 'V' area, persistent acne and hirsutism for more than two years
- In women suspected to have PCOS, it is recommended to screen and appropriately document all clinical and biochemical risk factors in the case history (Grade A, EL 4).
- It is recommended that patients who currently show either a clinical symptom or fit into a biochemical characteristic may be referred for further diagnosis when feasible or should be regularly monitored for appearance of other presentations of PCOS (Grade A, EL 4)
- It is recommended that individual patients with two or more clinical risk factors be subjectively assessed by the gynecologist and referred to an appropriate healthcare provider for further diagnosis of PCOS (Grade B, EL 4).

DIAGNOSTIC CRITERIA FOR ADULTS AND ADOLESCENTS WITH PCOS

The three main criteria for diagnosis of PCOS are androgen excess (AE), chronic anovulation, and presence of (PCO) [Table 1].^[2,29,33,34] Initially, hyperandrogenism (clinical or biochemical) and anovulation along with recommendations for exclusion of other mimicking etiologies were common diagnostic criteria.^[2,33,34] The European Society of Human Reproduction and Embryology/American Society for Reproductive Medicine (ESHRE/ASRM) sponsored Rotterdam group on PCOS introduced an extension to incorporate ovarian morphology (based on an ultrasoundogram).^[2] The Rotterdam criteria proposed that a positive observation of two of the three criteria (AE, ovulatory dysfunction, or PCO) constituted a diagnosis for PCOS. A recent National Institute of Health (NIH)-sponsored workshop on PCOS endorsed the Rotterdam criteria for diagnosis of PCOS.^[35]

Table 1. Diagnostic criteria for PCOS

Category	Specific abnormality	Recommended diagnosis	NIH	Rotterdam	AE-PCOS
Androgen status	Clinical hyperandrogenism Biochemical hyperandrogenism	Hirsutism, acne, and central alopecia Increased total, bioavailable, or free serum testosterone levels	XX XX	X X	XX XX
Menstrual history	Oligo- or anovulation	Anovulation: frequent (< 21 d) or infrequent (> 35 d) bleeding intervals			
Mid-luteal progesterone test: for anovulatory bleeding in women with regular ovulation	XX	X		XX	
Ovarian appearance	Ovarian size/morphology on ultrasound	PCO morphology: presence of ^a 12 follicles of 2-9 mm diameter and/or ovarian volume > 10 mL without a cyst or dominant follicle > 10mm		X	X

PCOS: polycystic ovary syndrome; NIH: National Institute of Health; AE-PCOS: Androgen excess-polycystic ovary syndrome; PCO: Polycystic ovary, Source: Adapted from Legro *et al.* 2013

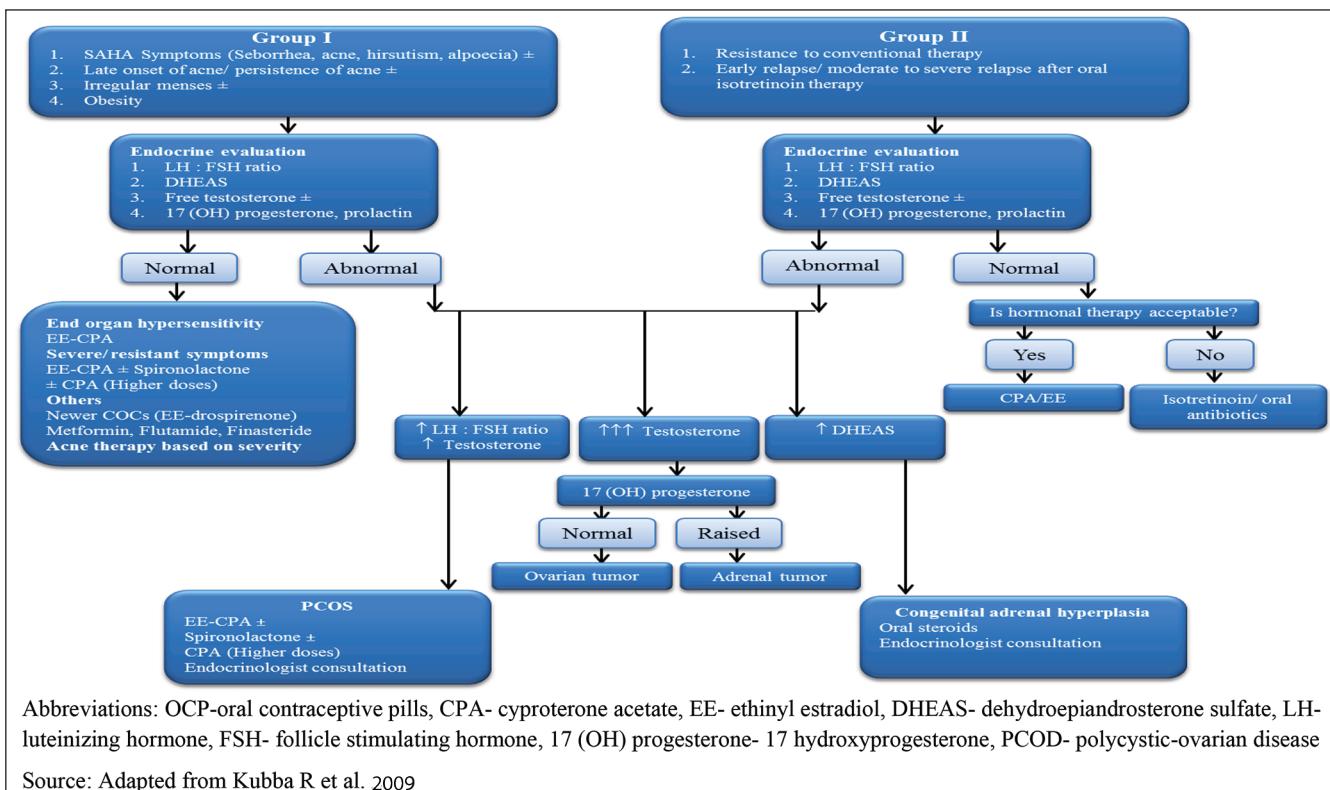

Figure 2: Treatment algorithm for acne, based on endocrine evaluation-Recommendation of Indian Acne Association

The diagnostic criteria proposed for diagnosis of PCOS are established in adults, and requires objective evaluation for diagnosis in adolescents.

Current evidence

Androgen excess

It is established using either clinical or biochemical determination of hyperandrogenism.^[2]

Biochemical hyperandrogenism

Biochemical hyperandrogenism is a measure of androgen levels, determined by total, bioavailable, or free serum testosterone (T) levels.^[36] In addition, the free androgen index (FAI = 100 x [total testosterone/ Sex hormone-binding globulin]) is also widely used.^[30] However, total serum T levels are considered more reliable and suitable for diagnosing androgens status.^[3,37] Given the methodological challenges, variability in T levels during pubertal development,^[38] and uncertainty in clinical practice^[39] defining absolute values using local assays that are diagnostic of PCOS and/or to exclude other causes of hyperandrogenism is preferable. Further, since the physiological T levels alter with pharmacological agents used for induction of periods, diagnosis of AE should not be carried in these subjects.

Clinical hyperandrogenism

Clinical hyperandrogenism includes hirsutism, acne, and androgenic/ central alopecia.^[30]

A. Hirsutism: Hirsutism is the excessive growth of thick, dark terminal hair in women where hair growth is normally absent.

^[40] The modified Ferriman-Gallwey (mFG) score is used to grade hirsutism,^[41] which is also used in India.^[37,42-44] A score of 0

Appendix Table 1: Grading of acne severity: Recommendation of Indian Acne Association

Mild acne (Grade I)	Comedones < 30
Predominance of comedones	Papules < 10 No scarring
Moderate acne (Grade II)	Comedones any number Predominance of papules
Severe acne (Grade III)	Papules > 10 Nodules < 3 With or without scarring
Many nodules	Comedones any number Papules any number Nodules/cysts > 3 With scarring

Source: Kubba R et al. 2009

Appendix Table 2: Acne distribution by age groups: Recommendation of Indian Acne Association

Age group	Location of lesions	Type of lesions	Sex
Neonates	Cheeks, chin, eyelids, forehead	Papules and pustules, no comedones	Both
Infants	Full face	Comedones, papules, nodules, scars	Male
Preadolescent	Forehead, upper cheeks, nose	Predominantly comedonal, occasional papule	Both
Adolescent	Full face, seborrheic areas of torso	All types of lesions	Both
Adults	Chin, upper lip, jaws	Papules, excoriated papules	Female

Source: Kubba R et al. 2009 (Consensus recommendations of Indian Acne Association)

(none) to 4 (severe) in nine areas of the body is assigned with a maximum possible score of 36. Scores < 4 indicate mild hirsutism, 4–7 indicate moderate hirsutism, ≥ 8 indicate severe hirsutism.^[40,41] In addition, presentation of AN with or without obesity is suggested an additional diagnostic criteria in adults and adolescents [Figure 2].

B. Acne: Acne can be graded as mild, moderate, and severe forms of acne, based on the number and types of inflammatory lesions [Appendix Table 1]. The prevalence of acne varies in relation to age and ethnicity. In girls, acne starts between 12–14 years of age, and in boys between 14–16 years of age.^[45] A description of the location and type of acne lesions according to the age group, as described by the Indian Acne Association (IAA) is presented in Appendix Table 2.

Among the different variants of acne, the SAHA syndrome (seborrhea, acne, hirsutism, alopecia) denotes acne specific to endocrine abnormality of a subject. When diagnosing PCOS in adolescents, acne, a common and transient feature^[46] should not be interpreted in isolation, as is the case with androgenic alopecia.^[47]

C. Alopecia: Androgenic/central alopecia may also be presented as female pattern hair loss in some patients with PCOS. Ludwig score is used to grade androgenic alopecia.^[48]

Ovulatory dysfunction

Ovulatory dysfunction is assessed by menstrual history of oligo/anovulation with bleeding intervals outside the normal interval (25–35 days), happening frequently at ≤ 21 days and/or infrequently at ≥ 35 days. In adults with regular cycles and anovulation, the Rotterdam criteria suggest determining anovulation with mid-luteal progesterone test to help diagnose PCOS.^[11] The presence of oligomenorrhea during normal reproductive maturation in adolescents must not be confused with PCOS.

In adolescents, anovulatory cycles comprise 85%, 59% and 25% during the first, third and sixth years, respectively of normal puberty after menarche. Therefore, determining anovulation with mid-luteal progesterone test might help diagnose PCOS in adolescents, and is a matter of clinical debate. The high serum androgen and leutinizing hormone (LH) levels, occurring naturally during anovulatory cycles of adolescence, might not be sufficient to diagnose PCOS in them.^[49] A persistent observation of oligo-/amenorrhea beyond two years of menarche in children/adolescents can be evaluated as an early clinical sign of PCOS.^[50,51]

Table 2: Diagnostic tests for exclusion of PCOS

Test	Disorder	Abnormal values
Serum thyroid stimulating hormone	Thyroid disease	Hypothyroidism: If TSH > upper limit (0.5 mU/L) Hyperthyroidism: If TSH < lower limit (< 0.1 mIU/L)
Serum prolactin	Prolactin excess	> Upper limit of normal (2–29 ng/mL)
Serum 17-hydroxyprogesterone*	Non-classical congenital adrenal hyperplasia	Early follicular phase of normal cycle: 200–400 ng/dL

PCOS: Polycystic ovary syndrome, TSH: Thyroid stimulating hormone,

*To be done before 8 a.m.

Polycystic ovary

Polycystic ovary morphology as defined by ESHRE/ASRM consensus criteria is as at least one ovary with ≥ 12 follicles of 2–9 mm (between day 2–5 of cycle) or ovarian volume > 10 mL in the absence of a cyst or dominant follicle > 10 mm,^[52] established with ultrasound examination of ovaries. It is also endorsed by the Rotterdam criteria^[2] and NIH.^[35] It is important to distinguish PCO from multi-follicular ovaries to make an appropriate diagnosis of PCO morphology.^[2,29] Multi-follicular ovaries contain larger (up to 10 mm diameter) and fewer (up to 6 each ovary) cysts, without hypertrophic echogenic stroma.^[53] A study comparing sonographic ovarian morphology in Indian women with and without PCOS found that a combination of two-three sonographic criteria is required to improve the sensitivity of PCO diagnosis.^[54]

In normal adolescent physiology, presence of multi-follicular/PCO is a common feature that decreases with cycle regularity^[55] and requires strict interpretation of ultrasonography findings of PCO morphology.^[56] Since no well-defined cut-off values for determining the levels of anti-mullerian hormone (non-invasive test) exist, ultrasound examination of ovaries is recommended for the diagnosis of PCO morphology in adolescents also.^[51] In adolescent girls with PCOS, obesity is common; magnetic resonance imaging (MRI) scanning is a more accurate modality^[57] to evaluate PCO in these adolescents.^[58]

On the other hand, ovarian volume and follicle number decrease from peak reproductive years to age > 40 years in normal as well as PCOS women.^[59] Therefore, diagnostic criteria with a combination of age, log ovarian volume, follicle number, and testosterone can be used to distinguish PCO morphology in women at menopausal stage.^[58]

Exclusion criteria for diagnosis of PCOS

PCOS is considered a diagnosis of exclusion. During the diagnosis of PCOS, it is important to screen all women to exclude other disorders like thyroid disease, prolactin excess and non-classical congenital adrenal hyperplasia, which mimic the symptoms of PCOS [Table 2].^[60–62] Mild prolactinemia and subclinical hyperthyroidism are common features in patients with PCOS. Therefore a referral to specialist is required if excess values are reported for prolactin and thyroid stimulating hormone (TSH) T4 levels.

Minimal diagnosis of PCOS in adolescents

Since the three diagnostic criteria for PCOS defined by the guidelines were derived for adults, to establish the diagnosis of PCOS in adolescents, other biochemical and clinical estimations can be ordered by the consulting physician or gynecologist. However, it is essential to order use minimal tests possible to diagnose PCOS in adolescent subjects to avoid burden of tests [Figure 2].

Existing guidelines

The clinical practice guidelines from Endocrine society, USA,^[29] PCOS Australian alliance, Australia,^[30] The RCOG, UK,^[31] and SOGC, Canada^[32] endorse the Rotterdam criteria for the diagnosis of PCOS. However, all guidelines advocate that specific phenotypes leading to diagnosis of PCOS be documented in all research studies and clinical care.

Recommendations for the diagnosis of PCOS in adults and adolescents

- In women with PCOS, for the objective assessment of cutaneous manifestations such as hirsutism, acne and androgenic alopecia, Indian specific grading should be performed with appropriate scales and possibility of other etiologies should be excluded (Grade B, EL 3)

Adults

- In adult women, it is recommended that diagnosis of PCOS be made using the Rotterdam criteria, meeting two of the following three conditions: (Grade A, EL 4)
 - Androgen excess
 - biochemical: serum total testosterone
 - clinical: persistent acne, hirsutism, female pattern hair loss
 - Ovulatory dysfunction
 - Polycystic ovary
- Presentation of acanthosis nigricans with or without obesity is an additional diagnostic criterion for PCOS in adults and adolescents* (Grade B, EL 4).
- Mild prolactinemia and subclinical hypothyroidism are common in PCOS; referral to specialist should be made when indicated by prolactin or TSH, T4 levels (Grade B, EL 4).
- Determination of anti-mullerian hormone levels for diagnosis of PCO is not recommended in adult and adolescent women (Grade A, EL 4).
- In peri-menopausal and menopausal women with a clinical history of prolonged periods of androgen excess and oligomenorrhea during the reproductive years, additional evidence of PCO morphology, low ovarian volume, follicle number, and testosterone should be considered as a diagnosis of PCOS (Grade B, EL 3).

Adolescents

- In adolescents, presence of oligomenorrhea or amenorrhea beyond two years of menarche should be considered an early clinical sign of PCOS, followed by Rotterdam criteria (of adults) for diagnosis of PCOS (Grade B, EL 4).
 - Androgen excess
 - biochemical: serum total testosterone
 - clinical: acne, hirsutism, female pattern hair loss
 - Ovulatory dysfunction
 - PCO with strict interpretation of ultrasonography findings
- Minimal diagnosis of PCOS in adolescents should include 5 tests (Grade A, EL 4):
 - Serum total testosterone (cut off 60 ng/dL)
 - OGTT (at zero and two hours after 75 g glucose load)
 - Serum 17-hydroxy progesterone (assessed at 8 am)
 - Serum TSH
 - Serum prolactin levels
- For the diagnosis of PCOS in adolescents, serum LH, follicle stimulating hormone (FSH) and cortisol should be assessed as indicated (Grade B, EL 4).

*Healthcare provider should assess other signs of IR and MS

MANAGEMENT OF PATIENTS WITH PCOS

Management of PCOS stretches beyond the realm of symptomatic treatment and encompasses management of long-term consequences that have clinical and psychological effects on women with PCOS. Both non-pharmacological and pharmacological management

strategies are crucial in overall management of PCOS. Because the three main characteristics of PCOS (hyperandrogenism, oligoovulation and IR) drive most of its long-term consequences, management approaches targeted at them may potentially provide improvement in all aspects of the syndrome.

Non-pharmacological interventions for management of obesity and body weight in patients with PCOS

Management of IR and obesity should be considered the first-line of treatment of PCOS. A meta-analysis reported improved levels of FSH, sex-hormone binding globulin, total T, androstenedione, FAI, and mFG score in women with PCOS as a result of lifestyle interventions (diet and physical activity); similar improvements in metabolic indicators were also reported.^[63-65]

Exercise

Current Evidence

Studies on PCOS from India reported a prevalence rate of 37.5%^[66] to 62.5%^[37] for obesity in patients with PCOS. A family history of obesity is also associated with PCOS phenotype.^[67] Obese women with PCOS have a higher incidence of characteristics of MS (hypertension, impaired glucose tolerance (IGT) and type 2 diabetes Mellitus (T2DM) as well as higher odds of irregular menstrual cycles and clinical hyperandrogenism than lean women with PCOS.^[66] Despite lack of large RCTs, the benefits of physical activity (at least 150 minutes of per week) in improving metabolic status and reducing the incidence of diabetes in high risk groups of general population have been demonstrated in small controlled studies.^[68,69]

In Indian adolescents with PCOS, compared to controlled (C) treatment with physical exercise, holistic yoga (Y) was found to significantly reduce the T levels ($Y = -6.01$, $C = +2.61$, $p = 0.014$), mFG score for hirsutism ($Y = -1.14$, $C = +0.06$, $p = 0.002$), and improved menstrual frequency ($Y = 0.89$, $C = 0.49$, $p = 0.049$).^[70] Another RCT on adolescents with PCOS from India found significantly improved fasting insulin and glucose levels, HOMA-IR, and lipid values, independent of their anthropometric changes, with yoga practice compared to conventional physical exercise.^[71]

Existing guidelines

Clinical practice guidelines from Endocrine society^[29] and RCOG^[31] suggest exercise therapy in the management of weight and obesity in PCOS.

Recommendations on non-pharmacological management of PCOS- physical activity

- In adults and adolescents with PCOS, daily strict physical activity sessions for at least 30min/day or 150min/ week are recommended (Grade A, EL 4).

Diet

Current evidence

While the benefits of diet control on obesity and IR in PCOS have been widely reported, data from RCTs, especially in Indian women is limited. Women with PCOS have been reported to have higher prevalence of central obesity.^[72] In women with PCOS and obesity, weight loss through diet control has been shown to improve pregnancy rates, normalize hyperandrogenemia,^[64,73,74] improve

insulin sensitivity, menstrual functions, and hirsutism.^[73,75]

However, no PCOS-specific diet has been reported. Therefore, it is essential to consult dietician for optimal weight management in women with PCOS. In patients with weight loss response after lifestyle modification + calorie-restricted diet as first-line therapy, weight neutral, insulin sensitizer drugs such as metformin can be used as second-line therapy.

Existing guidelines

The clinical practice guidelines from Endocrine society,^[29] RCOG^[31] and PCOS Australia alliance,^[30] suggest using low calorie diet as first-line therapy for the management of obesity in PCOS.

Recommendations on non-pharmacological management of PCOS- dietary

- For the management of obesity in adults (BMI > 23 kg/m²) and adolescents (BMI > 97.5th percentile for age) with PCOS, it is recommended to follow lifestyle modifications in combination with healthy, balanced diet consisting of regular, calorie-restricted meals (Grade B, EL 4).
- In adult and adolescent women with PCOS, it is recommended to routinely screen for BMI and waist circumference as an index for increasing adiposity and development of hyperandrogenism (Grade A, EL 3).
- It is recommended to follow calorie restricted diet (low carbohydrate and fat, high protein) in consultation with dietician and lifestyle modification as first-line therapy for at least 6 months, then add metformin as second-line therapy (Grade B, EL 4).

PHARMACOLOGICAL INTERVENTIONS FOR MANAGEMENT OF PATIENTS WITH PCOS

As discussed above, the choice of treatment in women with PCOS can be broadly categorized to treat the symptoms of menstrual irregularities (MI) and hyperandrogenism.

Menstrual irregularity

Current evidence

In women with (MI), proliferation of endometrium can be inhibited using either cyclic progestin or combined oral contraceptives (COCs: estrogen + progestin). Low-dose COCs (< 50 mcg of estrogen in combination with a progestin) have been the mainstay of treatment for MI in patients with PCOS not willing to conceive. In order to reduce the risk of endometrial proliferative disorders, progesterone withdrawal bleeds are generally accepted as first-line therapy to ameliorate cycle regularity in women with PCOS. Three issues have to be considered while choosing a COC: type of progestin compound used, type of estrogen compound used (usually 30 mcg ethinyl estradiol [EE]), and dosage of progestin and estrogen compounds in combination.^[76]

Current evidences from India in the management of MI in women with PCOS are available on COCs with two progestin components- drospirenone and desogestrel. The effects of two COCs 3 mg drospirenone vs. 0.15 mg desogestrel (in combination with 30 mcg EE) on MI in women with PCOS were compared for 6 month treatment period and 6 months

post-treatment.^[42] Although patients from both groups achieved menstrual regularity during the treatment, higher proportion of patients from drospirenone group continued to have regular cycles (44.8%) than desogestrel group (17.2%) at 6 months post-treatment ($p < 0.01$). In another study, drospirenone group was effective in reducing the hirsutism score in patients with both MI and.^[42] Overall, drospirenone containing COCs are more efficient compared to desogestrel containing COCs because of its anti-androgenic effects on menstrual cycle regularity, lipid profile, Blood Pressure(BP), and hormonal profile.^[42] Besides drospirenone and desogestrel, other progestins commonly used in India for clinical practice, either as cyclic progestin or COCs, for the management of MI in women with PCOS include natural micronized progesterone, dienogest, nor-ethisterone and the levonorgestrel- intrauterine system (LNG-IUS).

Since there is limited evidence of use of COCs in adolescents with MI, physician discretion is needed to judge the long-term effects of estrogen component during normal pubertal development. With clinical experience on patients with PCOS pan-India, the expert panel has suggested use of only low-dose COCs for short-periods (up to 7 days) to attain MI in 12-16 year old patients. In this age group, MI was defined as achievement of at least 4 cycles/ year. Similarly, in adolescents above 16 years of age, use of low-dose COCs is permissible for the management of MI.

The AE in women with PCOS is also linked to IR and consequent hyperinsulinemia,^[77] driving the use of insulin sensitizers such as metformin^[78] and thiazolidinediones^[79] in the management of PCOS. The effects of metformin on glucose homeostasis and improved cycle pattern are mainly attributed to increased insulin sensitivity.^[80] Metformin in combination with a low-dose anti-androgen (spironolactone) was more beneficial than either drug alone in improving MI in adult women with PCOS, presenting with oligo-/amenorrhea, hyperandrogenism and PCO morphology.^[81,82]

However, metformin monotherapy for six months resulted in regular menses within 4 months of treatment, but a consistent reversal towards pre-treatment conditions was observed within 3 months of metformin withdrawal.^[83] Adverse events such as vomiting, nausea, diarrhea, and hyperadrenergic symptoms were reported in patients taking metformin including drug withdrawal in subjects.^[81] Therefore the expert panel recommends against the use of metformin as first-line therapy for MI, but as second-line therapy with or without low-dose COCs, if COCs are not successful or tolerated.

The duration of metformin treatment for treatment of ovulatory dysfunctions in adolescents is not established due to very limited evidence from long-term studies and conflicting evidences from short-term studies. Therefore an extrapolation of evidence from studies conducted in adults may be required to recommend the use of metformin in adolescents. Use of spironolactone alone for the management of MI seems clinically inappropriate, since MI have been reported in 18% patients with low-dose spironolactone (50-100 mg daily) and in 70% patients with high-dose (200 mg daily).^[84,85] In an Indian study, polyuria (> 5%), abdominal pain, MI (> 10%), and dryness of mouth were reported in patients with PCOS taking spironolactone, and caused drug withdrawal in four subjects.^[81]

Existing guidelines

The ACOG recommends low-dose COCs as primary treatment option for improved MI and other menstrual disorders in women with PCOS.^[86] The clinical practice guidelines from Endocrine society,^[29] RCOG^[31] and PCOS Australia alliance,^[30] also recommend use of hormonal contraceptives as first-line therapy for menstrual abnormalities of PCOS. The guidelines from Endocrine society^[29] further recommend screening contraindications to COC use via established criteria set by 'Centers for disease control and prevention (CDC)- US medical eligibility criteria for contraceptive use'.

Recommendations on management of menstrual irregularity in PCOS [Figure 2]

Adults

- In adults with PCOS showing menstrual irregularity, it is recommended to include progesterone withdrawal bleeds as first-line therapy till menopause to avoid the risk of endometrial proliferative disorders (Grade A, EL 4)
- In adults with PCOS who do not intend to conceive, it is recommended to use COCs (drospirenone and desogestrel as progestin component) for the management of menstrual irregularity (Grade A, EL 1). Drospirenone has been shown to be more beneficial than desogestrel in Indian conditions.
- In women with PCOS, metformin is not recommended as first-line therapy for the management of menstrual irregularity (Grade A, EL 4).
- In women with PCOS, spironolactone is not recommended for menstrual irregularity (Grade B, EL 4)
- In adults and adolescents with PCOS, if there is no improvement of menstrual irregularity with COCs or COCs are not tolerated, it is recommended to use insulin sensitizers such as metformin (with or without progestins), but not thiazolidinediones for the management of menstrual irregularity (Grade A, EL 2).

Adolescents

- In adolescents with PCOS, it is suggested to use low-dose COCs (with or without anti-androgenic progestins- drospirenone and desogestrel) for the management of MI (Grade A, EL 4).
- Between 12-16 years of age, low-dose COCs only to be used, for short period (up to 7 days)
- After 16 years, low-dose COCs to be used
- Menstrual regularity: 4 cycles/year in adolescents of 12-16 years
- In adults and adolescents with PCOS with menstrual irregularity and hirsutism, low-dose COCs are suggested (Grade A, EL 2).

Hyperandrogenism

Current evidence

Hirsutism, acne and androgenic alopecia are the clinical symptoms of hyperandrogenism observed in women with PCOS. The AE in women with PCOS is manifested as excessive terminal hair growth and acne.^[87] A prevalence of 44.16% for hirsutism and AN and 20% for acne were observed in PCOS women from India.^[37] Features of clinical hyperandrogenism-hirsutism (33.6% vs. 28%) as well as acne and oily skin (40.6% vs. 22.6%) were found to be significantly higher in obese women with PCOS than lean PCOS women.^[66]

Management of hirsutism

Management of hyperandrogenism requires long-term and multi-dimensional treatment. This involves a combination of lifestyle modification, mechanical hair removal methods and pharmacological therapy for androgenic suppression.

Lifestyle modifications

A recent review comparing minimal or no treatment with lifestyle modifications (diet, exercise, behavioral or combined treatments) in patients with PCOS, reported improved body composition, hyperandrogenism and IR in women with PCOS.^[18] Further, metformin + weight reduction therapy are reported to reduce IR and T levels in women with PCOS.^[88]

Pharmacological therapy

As with menstrual cycles, COCs are first-line agents for pharmacologic treatment of hirsutism in women not willing to conceive.^[76] COCs with anti-androgenic progestins such as cyproterone acetate (CPA), drospirenone, desogestrel are generally used for the management of hirsutism in women with PCOS. Parallel administration of direct (mechanical) hair removal methods ameliorates the condition and reduces the time required.

Treatment with two mg CPA was shown to significantly reduce mean FG scores from (14.3 to 5.7) after 12 weeks of therapy in women with PCOS.^[89] In another study, two mg CPA + 35 mcg EE (for 48 consecutive cycles) demonstrated significant reduction of mFG score (mean FG score 10.4) in 73% subjects.^[90] No significant side effects or patient withdrawal were reported during 48 cycles of therapy, probably due to considerable effects on hirsutism, complete remission of acne, excellent cycle regularity and endometrial control observed with EE/CPA.^[90] Evidence from India comparing COCs: CPA, desogestrel (deso), and drospirenone (dros) in women with PCOS reporting MI + hirsutism, found that CPA showed the strongest anti-androgen activities with significant decrease in mFG score (treatment difference: CPA -5.29, dros -2.12, deso -1.69) after 12 months of treatment.^[91] In this study, very few patients reported adverse events: desogestrel group- bloatedness and sensation of weight gain, nausea and headache, rise of BP; CPA group- breast tenderness and absence of withdrawal bleeding in the pill-free week; drospirenone group- one patient with nausea, vomiting, and vertigo, another with altered liver function test. Studies on drospirenone (3 mg + 30 mcg EE)^[92] and desogestrel (150 mcg + 30 mcg EE)^[91] also demonstrated significant improvement in mFG score (4.6 vs. 6.4) compared to baseline.

In another evidence from India, compared to metformin, spironolactone demonstrated better improvement in hirsutism score (12.5 ± 4.9 and 12.9 ± 3.2 at baseline to 10.0 ± 3.3 and 8.7 ± 1.9 , respectively) after 6 months therapy in women with PCOS reporting MI, hirsutism.^[93] Whereas finasteride (5 mg/day), a 5 α -reductase inhibitor, in comparison with CPA (25 mg/day on days 5-14) + EE (20 mcg/day on days 5-25) was equally effective in reducing mFG scores after 9 months of treatment.^[94] However, due to the risk of teratogenicity (feminization of male infant) with their use,^[95,96] the expert panel has recommended to cease the use at least 6 months before planned pregnancy. Therefore, spironolactone and finasteride can be used as second-line treatment for the management of hirsutism in patients with PCOS.

Insulin sensitizers

In addition to hormonal therapy, administration of insulin sensitizers can improve the hyperinsulinemic as well as hyperandrogenic state in women with PCOS. However, due to limited evidence on use of metformin in adolescents without established glucose intolerance, the expert panel recommends against its use in adolescents with PCOS. Further, lifestyle modification is better than metformin in improving hyperandrogenism, obesity and signs of IR. Therefore the expert panel recommends lifestyle modification as first-line therapy followed by metformin in adolescents and children. Metformin should be initiated in children only after a wait-period of two years post-menarche.

By virtue of the nature of hyperandrogenism, the source of androgen cannot be eliminated permanently, and evidence suggests that hyperandrogenism requires long-term therapy. Therefore, ideal time to stop the hormonal therapy for hyperandrogenism cannot be established.

Risk of venous thromboembolism

Use of different COCs with varying risks of venous thromboembolism (VTE) is reported in general population.^[97] However evidence in women with PCOS is inconsistent. A recent meta-analysis of trials using either COCs with anti-androgens, or metformin in women with PCOS found that thromboembolic episodes were not reported in any study.^[98] A cross-sectional analysis on a database (2003-2008, US women) observed that PCOS women were more likely to have thromboembolism than those without and reported a protective association (OR 0.8; 95% CI: 0.73-0.98) with use of COCs.^[99] Since there is lack of consistent data on diagnosis and management of VTE specific to PCOS, the expert panel has suggested ways to minimize the risks and maximize the benefits of COC use. It is essential to regularly monitor the risk and provide three months of pause after one year of COC regimen. Investigations used to monitor VTE risk in general population (such as using duplex ultrasonography for deep vein thrombosis and chest X-ray/ventilation-perfusion scan/CT pulmonary angiography for pulmonary embolism) can also be adopted in women with PCOS.^[100]

Mechanical hair removal methods

Apart from the pharmacological approaches to deal with hirsutism, temporary and permanent methods of hair removal/reduction should also be used as first-line therapy for management of hirsutism in women with PCOS. Permanent methods of hair reduction therapy include electrolysis and photo epilation devices such as laser and intense pulsed light. In patients seeking permanent hair reduction therapy, it is essential to initiate pharmacologic therapy to minimize hair regrowth. Temporary hair removal methods such as depilation, epilation, and bleaching are effective in reducing facial hair growth in women with PCOS. In addition, topical treatment with eflornithine, an ornithine decarboxylase inhibitor approved by United States of food and drug administration (US-FDA), is also effective.^[76,86,101]

Management of acne

Management of acne needs careful selection of anti-acne agents according to clinical presentation and individual patient needs. Adjunctive therapies of topical applications along with hormone

therapy should be used as first-line therapy for synergistic effects. Physical treatment methods (lesion removal, phototherapy) are also suggested for acne management.^[102]

Topical applications

Based on the clinical presentation of acne in individual patient, specific topical medication for mild and moderate acne, and maintenance therapy should be prescribed in consultation with dermatologist. Benzoyl peroxide, topical retinoids, and topical antibiotics are used as first-line treatment for acne management.

Hormone therapy

Hormone therapy is suggested as first-line therapy for androgenic acne in women with PCOS, SAHA syndrome, HAIRAN syndrome (hyperandrogenism, IR, AN), or cutaneous hyperandrogenism. The IAA consensus guideline further justifies hormonal therapy in refractory/difficult acne and in nodulocystic acne where isotretinoin is either contraindicated or inadequate.^[45] However, due to the multiple causes of acne vulgaris, evaluation of hormonal status is a prerequisite before initiating hormone therapy.^[45]

Treatment with two mg CPA (+ 35 mcg EE) for 12 cycles significantly reduced acne score in all 41% cases (at baseline), with improved facial acne by the end of third cycle and improved thorax and back acne by end of 6th cycle.^[89] Treatment with CPA/EE combination for 48 cycles demonstrated a complete recovery of various types of acne lesions (moderate 67%, severe 33% cases at baseline) in all subjects (100%) within 24 cycles of treatment.^[90] In a study conducted in Indian women with PCOS, CPA demonstrated numerically higher reduction in acne score (CPA -1.52, drospirenone -1.42, desogestrel -1.41) compared to other pills.^[91] CPA has been well studied as an androgen receptor blocking agent, effective in acne management in females.^[103,104] Higher doses of CPA have been reported to be more effective than lower dose to treat acne.^[102]

In another study, drospirenone (3 mg + 30 mcg EE) containing COC showed significant improvement in acne at six cycles (54.9% vs. 31.4%, p < 0.05) compared to baseline.^[43] Although EE/drospirenone^[43] was administered only for 6 months, the beneficial effects in reducing hyperandrogenic features of hirsutism and acne were maintained up to 12 months after treatment. No adverse effects were reported. Similarly, desogestrel (150 mcg) + EE 30 mcg also showed significant improvement in the incidence of acne (54.1% vs. 23.4%) in women with PCOS from India after 6 cycles of treatment.^[44] No adverse effects were reported up to one year with EE/desogestrel also.^[44]

The guidelines issued by IAA recommend hormonal therapy in patients presenting acne with symptoms of SAHA syndrome (with or without irregular cycles) or resistance to conventional therapy/ relapse after isotretinoin therapy along with altered endocrine function. Based on the consensus developed by IAA, hormone therapy with low-dose EE/CPA or high-dose CPA or spironolactone are specifically suggested.^[45]

In adolescents with PCOS, improvement in acne was observed with the use of oral contraceptives with anti-androgen activity. In a latest randomized cross-over trial, therapy with

medroxyprogesterone acetate and CPA for four months each,^[105] CPA significantly improved acne score and LH/FSH ratio.^[105] Due to the limited evidence on long-term use of COCs for hyperandrogenic features in adolescents, the expert panel suggested using COCs in adolescents based on the clinical presentation of acne, in consultation with a dermatologist.

A summary of studies conducted in India with COCs containing anti-androgen in progestins (cyproterone acetate, drospirenone, and desogestrel) for the management of hyperandrogenism features is presented in Appendix Table 3.

Management of alopecia

Although there is limited evidence on the management of alopecia, COCs and androgen blockers can be used to reduce alopecia. It is essential to determine and exclude etiologies that mimic alopecia. In a study on alopecia in general population, CPA+EE demonstrated a marked improvement in alopecia (success rate: 55%).^[106] In another study, CPA (for 6–9 months) demonstrated a marked reduction in hair loss, hair thinning, and seborrhea in androgenic feminine alopecia.^[107]

Existing guidelines

The clinical practice guidelines from Endocrine society,^[29] recommend use of hormonal contraceptives as first-line therapy for management of clinical features of hyperandrogenism such as hirsutism/acne in women with PCOS. The consensus guideline from IAA recommends the use of hormone therapy with low-dose EE/CPA or higher doses of CPA or spironolactone.^[45]

Recommendations for management of Hyperandrogenism in PCOS

Hirsutism

- Following options can be used alone or in combination to suit individual patient needs and clinical requirements for the management of hirsutism:
 - In adult women with PCOS who do not intend to conceive, it is recommended to use low-dose COCs with anti-androgen progestin (cyproterone acetate, drospirenone, or desogestrel) for the management of hirsutism (Grade A, EL 1). Cyproterone acetate has been shown to be more beneficial than other progestins in Indian conditions.
 - Use of direct hair removal methods are recommended along with COCs as fist-line therapy (Grade A, EL 1).
 - If there is no improvement with COCs or COCs are not tolerated, it is recommended to use spironolactone or finasteride (Grade A, EL 2); spironolactone or finasteride are suggested but recommended to stop 6 months before planned pregnancy.
- In women with PCOS, if menstrual irregularity and hirsutism are diagnosed, low-dose COCs with anti-androgenic activity (CPA, drospirenone, desogestrel) are suggested (Grade A, EL 2). The ideal time to stop hormonal therapy for hyperandrogenism cannot be established with existing evidence (Grade A, EL 4).
- Risk of thromboembolism with use of COCs can be managed by identifying susceptible patients and/or pausing treatment for 3 months after one year of treatment (Grade A, EL 4).
- In adolescents/children with hyperandrogenism, obesity and signs of insulin resistance, lifestyle modification is first-line

therapy; metformin is second-line therapy with a wait period of 2 years post-menarche in children (Grade A, EL 4).

- In adolescents with hyperandrogenism, if glucose intolerance is not established by OGTT, metformin should not be started (Grade B, EL 4).
- Due to insufficient evidence, alternative (acupuncture) and complementary therapeutic options (e.g. myoinositol, omega-3 fatty acids) are not recommended for the management of hyperandrogenism (Grade B, EL 4).

Acne

- In adults and adolescents with PCOS and acne, it is suggested to use topical medication along with pharmacological interventions based on the clinical presentation of acne as early as possible, in consultation with dermatologist (Grade A, EL 4).
- In adults with PCOS, it is suggested to use oral contraceptives (cyproterone acetate, drospirenone, or desogestrel as progestin component) as first-line therapy for management of all types of acne lesions (Grade A, EL 1). Cyproterone acetate has been shown to be more beneficial than other progestins in Indian conditions.
- In adolescents with PCOS and acne, it is suggested to use oral contraceptives (cyproterone acetate, drospirenone, or desogestrel as progestin component) based on the clinical presentation of acne, in consultation with dermatologist (Grade A, EL 2).

Alopecia

- In women with PCOS presenting with alopecia, COCs and androgen blockers are recommended as first line therapy (Grade B, EL 3).

EVALUATION AND MANAGEMENT OF ASSOCIATED MORBID CONDITIONS

A number of short- and long-term health problems are associated with PCOS. These include short-term psychosocial problems and long-term problems such as T2DM,^[108] obesity, CVD, sleep-disordered breathing^[109] and increased risk of endometrial cancer (EC) as well as short-term problems such as impaired fertility, complications during pregnancy.^[110]

PSYCHOSOCIAL MANAGEMENT

PCOS is strongly associated with reproductive and metabolic

implications affecting patients' psychological functioning and satisfaction with life.^[8] Psychological implications entail challenges in depression, physical appearance/feminine identity, eating habits and psychosexual dysfunction with significant impact on quality of life (QoL).^[111]

Depression

Current evidence

Increased rate of depressive symptoms compared to non-BMI matched controls^[112,113] with prevalence ranging from 28 to 64% (for depression) and 34 to 57% (for anxiety) have been reported in women with PCOS.^[114,115] Also, a lower health related QoL^[116] and increased risk of mental depression are reported in women with PCOS.^[113] In Indian women a 54% prevalence of depression (GHQ28 score ≥ 8) was reported, of whom 72% were obese, 70% had hirsutism, 61% had acne and 56% were infertile indicating a considerable effect on QoL of these women.^[117] The Patient Health Questionnaire 9 (PHQ-9) can be used to measure the severity of depression [Appendix Table 4],^[118] whereas the generic Short Form-36 (SF-36)^[119] and disease-specific polycystic ovary syndrome questionnaire (PCOSQ)^[120] are used to assess the health related QoL in women with PCOS [Appendix Table 5].

Existing guidelines

The clinical practice guidelines from Endocrine society^[29] and PCOS Australian alliance, Australia^[30] suggest screening all women with PCOS for depression and anxiety by history and, if identified, provide appropriate referral and/or treatment.

Recommendations on management of depression in PCOS

- In adults and adolescents with PCOS, it is recommended to routinely screen for depression and anxiety with appropriate psychological instruments (Grade B, EL 3).
- In patients with PCOS evaluated with depression and/or anxiety, psychological counseling by an appropriate professional is suggested, based on severity of disease (Grade B, EL 4).

Other psychosocial dysfunctions

Current evidence

In patients with PCOS, negative self-image coupled with lower self-esteem owing to their physical appearance that significantly

Appendix Table 6. Risk factors for cardiovascular disease and lipid target values^a in women with polycystic ovary syndrome

PCOS	At risk	At high risk
Risk factors	Obesity, cigarette smoking, hypertension, dyslipidemia, subclinical vascular disease, IGT, family history of premature CVD (55 years of age in male relative, 65 years of age in female relative)	Metabolic syndrome, T2DM, overt vascular or renal disease, cardiovascular diseases
Waist circumference, cm	88 *; ≥80 **	
BMI, kg/m ²	>30 ***	
BP, mmHg	Systolic=120; Diastolic=80	
Triglycerides, mg/dL	<150	
LDL target, mg/dL	≤130	70-100
Non-HDL target, mg/dL	≤160	100-130

^a Values are based on at least 12-h fasting lipid determinations. Predictive utility for CVD events based on non-fasting lipoprotein lipid values has not yet been clearly validated. *For Caucasian/African-American women, **For Hispanic, Native American, Asian (East and South), and European women, ***A 2-h post 75-g oral glucose challenge be performed in PCOS women, or alternatively in lean PCOS women with advanced age (>40 year), personal history of gestational diabetes, or family history of T2DM. PCOS: Polycystic ovary syndrome, IGT: Impaired glucose tolerance, CVD: Cardiovascular disease, T2DM: Type 2 diabetes mellitus, BMI: Body mass index, BP: Blood pressure, LDL: Low-density lipoprotein, HDL: High-density lipoprotein, Source: Adapted from Wild *et al.* 2010

impacts the mood and QoL^[121] are observed. Similarly, significantly more patients with PCOS compared to community controls reported eating disorders (12% vs. 4%) and/or social phobia (27% vs. 2%)^[122], which may cause medical, psychological, social and occupational difficulties.^[123,124] Physical manifestations of PCOS such as hirsutism, obesity, MI and infertility can have a negative effect on the patients' sexual life.^[125]

Existing guidelines

The clinical practice guidelines from PCOS Australian alliance,

Australia^[30] suggest the screening and assessment of patient's psychosocial dysfunctions and if identified, offer appropriate treatment.

6.1.2 Recommendations on management of other psychosocial dysfunctions in PCOS

- If a woman with PCOS is positive on screening for any psychosocial dysfunction, the practitioner should perform a more detailed clinical interview (Grade B EL 4).

- In those evaluated with any psychosocial dysfunction, appropriate treatment for improvement of quality of life is suggested (Grade B, EL 4).

Type 2 diabetes mellitus

Current evidence

Diagnosis of PCOS confers a 5- to 10-fold increased risk of developing T2DM.^[126-128] IR, resulting in hyperinsulinemia also plays a role in the pathogenesis of reproductive disorders in women with PCOS.^[126,129] The prevalence of glucose intolerance in Indian women with PCOS^[93] was reported as 16.3% (adults 19.1%, adolescents 9.7%).^[67]

Due to the risk of IGT, T2DM, and IR in PCOS, evaluation of abnormalities in glucose intolerance at periodic intervals is essential.^[9,31,82] (A 75-gm (OGTT with 75 g- oral glucose load) has been recommended over measuring glycated hemoglobin (HbA1c) for the detection of T2DM^[130] and fasting glucose^[67] for assessment of IGT.^[2] An observational study from India reported '2-hour post-glucose insulin levels' as a better indicator of IR in women with PCOS than other techniques.^[131]

Lifestyle modification with exercise and diet are the first-line treatment for weight management and impaired IGT in women with PCOS. Due to the inherent IR in this condition, oral anti-diabetics (OADs) particularly insulin sensitizers such as metformin are the most promising pharmacological option.^[132] However, an early referral to specialist diabetological care is recommended for timely management of diabetes and its complications. Metformin alone or in combination with low-dose spironolactone/clomiphene has demonstrated significant alleviation of not only the MI but also glucose tolerance and insulin sensitivity in patients with PCOS.^[81,133]

Hyperthyroidism

Evidence from India reported high prevalence of thyroid disorders (higher mean TSH level 4.547 ± 2.66 vs. 2.67 ± 3.11 , $p < 0.05$) in women with PCOS than those without.^[134] Metformin can lower TSH levels in women with PCOS and hypothyroidism. Metformin (1500 mg/day) was shown to significantly decrease (mean \pm SD) TSH levels (7.78 ± 1.74 at baseline to 6.14 ± 2.47 , $p < 0.001$) over placebo in overweight women with PCOS and hypothyroidism after 6 months of treatment, with no significant change in free T3 and free T4 levels throughout the study.^[135]

Existing guidelines

The clinical practice guidelines from Endocrine society, USA recommend screening women with PCOS for IGT test and T2DM using OGTT or HbA1c and suggest rescreening based on development of clinical factors and/or symptoms of diabetes.^[29] The RCOG suggests fasting blood glucose test or an OGTT for screening of diabetes in women with PCOS. The clinical practice guidelines from Endocrine society recommend use of metformin in women with PCOS with T2DM or IGT and fail lifestyle modification and suggest the same in adolescent stage if the goal is to treat IGT/MS.^[29]

Recommendations for the management of diabetes in PCOS

- In women with PCOS who develop symptoms and/or a risk

factor of diabetes, screening at a clinically feasible periodicity is suggested (Grade B, EL 4).

- It is recommended to screen adult and adolescent women with PCOS for impaired glucose tolerance and T2DM using a 75 gm oral glucose tolerance test; an HbA1c test should be used only when an OGTT is not feasible (Grade A, EL 2).
- In women with PCOS who have impaired glucose tolerance or T2DM, it is recommended to use metformin alone, or in combination with oral contraceptives (Grade A, EL 1).
- Early referral to specialist diabetological care is recommended for timely management of diabetes and its complications (Grade A, EL 4)

Cardiovascular risk

Women with PCOS often have cardiovascular disease risk factors. The AE-PCOS society recommends all women with PCOS to be assessed for CVD risk; to test for BMI, waist circumference and blood pressure at each clinical visit.^[136,137] In women diagnosed with PCOS, a complete fasting lipid profile as well as OGTT (if $BMI > 30 \text{ kg/m}^2$, age > 40 years, personal history of GDM, or family history of T2DM) are recommended.^[136] A stratification of risk factors for CVD in women with PCOS given by AE-PCOS society is presented in Appendix Table 6.

In India a 37.5% prevalence of obesity ($BMI > 27.5 \text{ kg/m}^2$),^[66] high levels of BP ($SBP/DBP > 120/80 \text{ mm of Hg}$) inform prospective^[138] and cross sectional^[139] studies were reported in women with PCOS. Further, increased LDL-C, CVD risk factors, markers of dyslipidemia were noted^[131,139,140] markers of and atherosclerosis, flow-mediated dilatation of brachial artery ($12.18 \pm 2.3\%$ in PCOS vs. $8.3 \pm 2.23\%$ in control) and carotid intima media thickness (0.68 ± 0.11 in PCOS vs 0.52 ± 0.02 in control, $p = 0.01$) were reported in women with PCOS compared to control subjects.^[139] Epidemiological data from USA reported a relative risk of 1.53 (95% CI: 1.24; 1.90) for CVD (after adjustment for BMI and potential confounders) in women with very irregular cycles.^[141] Therefore, in women with PCOS showing CV risk factors, specialist CV monitoring and care is recommended, irrespective of the severity of their symptoms.

Existing guidelines

The clinical practice guidelines from Endocrine society, USA,^[29] PCOS Australia alliance, Australia,^[30] RCOG,^[31] and AE-PCOS society^[136] recommend screening women with PCOS for CV risk factors. The clinical practice guidelines from Endocrine society^[29] suggest lifestyle modifications as first-line therapy for CVD and metformin as second line therapy in patients failing to achieve weight reduction with lifestyle modification.^[29] The RCOG guidelines^[31] suggest hypertension should be treated, but recommended against the use of routine lipid-lowering treatment in women with PCOS and risk of CVD. Consultation with specialists has been recommended by other guidelines for prescribing lipid lowering agents.

Recommendations for the management of cardiovascular risk in PCOS

- It is recommended to screen for CV disease in adult women with PCOS by assessing risk factors: obesity (especially abdominal obesity), smoking, hypertension, dyslipidemia

- (increased LDL-C), vascular disease, IGT, high-sensitivity C-reactive protein, homocysteine, and family history of premature CVD (Grade A, EL 1).
- It is recommended to screen for CV disease in adult women with PCOS by assessing high risk factors: metabolic syndrome, T2DM, overt vascular or renal disease (Grade A, EL 1).
 - It is suggested to assess obesity (by BMI and WC), lipid profile, oral glucose tolerance test, and BP in adult women at baseline, and repeat lipid profile and OGTT at 6 months for borderline risk and one year for normal profiles (Grade B, EL 4).
 - Specialist CV monitoring and care is recommended in all patients showing CV risk factors, irrespective of the severity of their symptoms (Grade A, EL 4).

Pregnancy complications

Current evidence

A population based cohort study among women with PCOS from Sweden observed that PCOS was strongly associated with pre-eclampsia (adjusted OR 1.45, 95% CI: 1.24-1.69), preterm birth (2.21, 1.69 to 2.90), more than double risk of GDM (2.32, 1.88 to 2.88), and birth of large for gestational age infants (1.39, 1.19 to 1.62).^[142] The results are further confirmed in an independent meta-analysis by Kjerulff.^[143] Recurrent pregnancy loss (RPL) in women with PCOS is commonly associated with IR,^[144] hyperhomocystinemia (HHcy)^[145] and obesity.^[146] In a retrospective study on RPL, a significantly higher incidence of HHcy (70.63% vs. 57.26%, p < 0.04) and IR (56.34% vs. 6.83%, p < 0.0001) was observed in women with PCOS compared to controls. Further analysis revealed HHcy as a strong plausible factor for diagnosis of RPL than IR (probability percentage: HHcy = 43.32%, IR = 37.29%). Findings on association of PCOS and GDM are conflicting with respect to BMI. Recent systematic review and meta-analysis in women with PCOS observed a significantly higher risk for development of GDM in PCOS women than those without (OR: 2.89, 95% CI: 1.68-4.98), albeit with significant statistical heterogeneity due to sensitivity analysis (I² = 59.3%).^[147] An RCT in women with PCOS treated with metformin found no difference in the prevalence of pre-eclampsia (p = 0.18), preterm delivery (p = 0.12), or prevalence of GDM (p = 0.87) compared to controls during pregnancy.^[148]

A latest meta-analysis of RCTs (n=5) comparing the effects of metformin with insulin on glycaemic control, maternal and neonatal outcomes in GDM concluded that metformin is comparable with insulin and might be more suitable for women with mild GDM.^[149] An observational study from India reported significantly higher benefits of using metformin over insulin in the management of GDM and T2DM.^[150] Although metformin is reported to be comparable with or superior to insulin in terms of glycaemic control and neonatal outcomes, lack of strong evidence on use of metformin in Indian subjects restricts its clinical use.

Existing guidelines

The clinical practice guidelines from Endocrine society, USA^[29] recommend pre-conceptual assessment of BMI, BP and OGTT whereas RCOG guidelines recommend screening for GDM before 20 weeks of gestation, in PCOS women requiring ovulation.^[31] The clinical practice guidelines from Endocrine society^[29] and

RCOG guidelines^[31] suggest against the use of metformin as first-line treatment for pregnancy complications in women with PCOS.

Recommendations for the management of pregnancy complications in PCOS

- In women with PCOS planning to have children, it is recommended to screen for markers of obesity, hypertension and IR to reduce the risk of pregnancy related complications (Grade A, EL 3).
- In women with PCOS who have experienced a miscarriage, it is suggested to assess serum homocysteine levels for identification and treatment of hyperhomocystenemia mediated repeated pregnancy losses (Grade B, EL 3).
- In women with PCOS, it is recommended not to use metformin therapy only during pregnancy until specific evidence on beneficial effects is demonstrated (Grade B, EL 3).

Endometrial cancer

Current evidence

Long-term studies and meta-analyses have observed an increased risk of development of EC in women with PCOS.^[151-153] The symptoms, oligo-/amenorrhea, hirsutism, and infertility, as well as risk factors of PCOS, obesity and T2DM, are common to EC.^[154,155] Evidence for the applicability of transvaginal sonography (TVS) for predicting endometrial hyperplasia has been inconsistent in literature.^[156-158]

Indian studies on the measurement of endometrial thickness in women with PCOS have routinely used TVS at a cut-off of 4 mm.^[159-161] In the context of increased risk of EC in PCOS patients with prolonged amenorrhea, abnormal uterine bleeding, obesity and/or diabetes, it is essential to assess endometrial thickness and raise awareness about EC in these women. It has been established that inducing a withdrawal bleed every 3 to 4 months with progestogens can reduce the risk of EC in women with PCOS.^[156] However, since hyperinsulinemia is the primary cause of endometrial hyperplasia, use of insulin sensitizers can reduce the hyperplasia in these women. Overall, for timely detection and management of EC, it is appropriate to screen for development of cancer at regular intervals with reference to oncological specialist.

Existing guidelines

The clinical practice guidelines from Endocrine society^[29] suggest against routine screening for endometrial thickness in women with PCOS. The RCOG guidelines suggest investigating oligomenorrheic women and absence of normal withdrawal bleeds using local protocols such as ultrasound scan, endometrial sampling and/or hysteroscopy^[31] and recommend treatment with progestogens to induce a withdrawal bleed at least every 3-4 months.

Recommendations for assessment and management of endometrial cancer in PCOS

- In women with PCOS without abnormal bleeding, routine screening using TVS is not recommended (Grade B, EL 1)
- In women with PCOS with unexpected bleeding and spotting, it is suggested to assess endometrial thickness using TVS and report the same to the physicians (Grade B, EL 4).

- In women with PCOS and risk of endometrial carcinoma, it is suggested to use progestogens every 3-4 months (Grade B, EL 3).
- Regular oncological referrals, for screening at a clinically feasible periodicity, are recommended for timely detection of endometrial cancer (Grade A, EL 4).

Obstructive sleep apnea

Current evidence

Studies have identified a higher incidence of obstructive sleep apnea (OSA) in women with PCOS compared to controls, even after controlling for BMI.^[162,163] Fasting plasma insulin levels and glucose-to-insulin ratios were strongest predictors for OSA. Therefore factors other than obesity may be involved in the high prevalence of OSA in women with PCOS. Interestingly, a decreased likelihood of OSA was reported in adult and post-menopausal women taking hormonal contraceptives.^[163,164] There is a lack of quality evidence on OSA in women with PCOS from India.

Existing guidelines

The clinical practice guidelines from Endocrine society^[29] suggest screening all overweight/ obese women with PCOS for symptoms suggestive of OSA and, if identified, diagnosed using polysomnography and referred for appropriate therapy. The RCOG guidelines suggest an enquiry of snoring and daytime fatigue/somnolence in all women with PCOS, and educate about the possible risks of OSA, and, if identified, offer diagnosis and appropriate therapy.^[31]

6.6 Recommendations for of obstructive sleep apnea in PCOS

In adult and adolescent women with PCOS, it is suggested to routinely screen for OSA and insomnolence, if symptoms are suggestive of OSA, investigate using polysomnography and refer to appropriate institution for further therapy (Grade B, EL 4).

Non-alcoholic fatty liver disease, non-alcoholic steatohepatitis

Current evidence

Ethnicity, increasing age and characteristics of MS (obesity, hypertension, dyslipidemia and diabetes) are risk factors of non-alcoholic fatty liver disease/ non-alcoholic steatohepatitis (NAFLD/NASH).^[165] A 15-60% prevalence of NAFLD is reported in women with PCOS.^[166-168] A cross-sectional, hospital-based study of women with PCOS from India reported a 67%, 31% and 35% prevalence of NASH, NAFLD and MS, respectively.^[169]

In the absence of other specific factors, serum markers for liver dysfunction (such as alanine amino transferase) may be used to screen PCOS women with co-existent IR and metabolic risk factors. However, because of low specificity and sensitivity of elevated levels of serum alanine amino transferase, diagnosing NAFLD in these women (PCOS with IR and/or MS) may require non-invasive quantification of fibrosis (ultrasound) and liver biopsy.^[170] In view of the potential complications of NAFLD and NASH in women with PCOS having IR and/or MS, early identification and management of NAFLD and MS is essential for overall reduction of effects of MS in PCOS women.

In non-diabetic non-cirrhotic NASH patients^[171] and pediatric

NASH patients,^[172] treatment with vitamin E (800IU/day) for 96 weeks demonstrated significant improvement in serum aminotransferase levels, hepatic steatosis, and lobular inflammation (early stage features) but not portal inflammation and hepatic fibrosis (more advanced histologic features). However, based on a meta-analysis^[173] that showed that RCTs with vitamin E and other antioxidants were heterogeneous (with respect to type and dose of drug, treatment duration and follow-up, population [pediatric versus adult], and implementation of lifestyle intervention) a recent review noted a firm conclusion on the effect of vitamin E on NAFLD cannot be made.^[174]

Existing guidelines

The clinical practice guidelines from Endocrine society^[29] suggest against routine screening of NAFLD and NASH but provide awareness of their possibility in women with PCOS.

Recommendations for NAFLD and NASH in PCOS

- In adult and adolescent women with PCOS, it is suggested to provide sufficient awareness on symptoms and complications of NAFLD and NASH and carry out appropriate screening in those diagnosed with insulin resistance and/or metabolic syndrome (Grade B, EL 4).
- In patients with PCOS and NASH, treatment with vitamin E is preferred and metformin is not suggested for reduction of metabolic syndrome with specialist inputs from a multidisciplinary team (Grade B, EL 1).

SUMMARY

PCOS is an important emergent public health problem in India that represents a unique trans-generational risk of transmission of a variety of systemic chronic diseases. It has not been possible in contemporary Indian clinical practice to formulate a comprehensive response which is commensurate with the scale of problem that PCOS poses. This has been mainly due to a lack of strong public and academic discourse centered on the proper management of this gargantuan, yet ill-recognized problem. A strong evidentiary foundation is the cornerstone on which the academic discourse on PCOS must be based. In addressing a key driver that feeds the inertia surrounding PCOS, the current GCPR seek to fundamentally redefine the paradigms of PCOS care in India. The approach of current recommendations is to provide a strong rationale for harnessing the mutual synergies in a modern multidisciplinary clinical setting to deliver quality PCOS care while providing an evidence-based structure to standardize the approach to PCOS management across treatment settings. It is hoped that the current GCPR will fulfil a key role in helping current clinical practices to transition to a comprehensive PCOS care paradigm in India.

Adolescent Polycystic Ovary Syndrome

Vaishnavi Kulkarni, Niranjan Chavan

Department of Obstetrics and Gynaecology, LTMMC and Sion Hospital, Mumbai, Maharashtra, India

ABSTRACT

Adolescence is a crucial stage of development defined by the World Health Organization as spanning from 10 to 19 years of age. It is marked by significant physical, cognitive, emotional, and social changes, including puberty, which is a key aspect of this phase. Diagnosing polycystic ovary syndrome (PCOS) in adolescents can be challenging because symptoms such as irregular periods, acne, and weight changes can overlap with normal hormonal changes during puberty. Irregularities in menstrual cycle and hyperandrogenism are considered for the diagnosis of adolescent PCOS. Polycystic ovarian morphology on ultrasound should not consider for the diagnosis of adolescent PCOS. Emotional well-being is a crucial but often overlooked aspect in adolescent girls with PCOS. A holistic approach is essential in managing PCOS. While pharmacotherapy plays a role, it should be integrated with education, counseling, lifestyle interventions, and other options such as cosmetic therapy. This comprehensive approach addresses the physical, emotional, and psychological aspects of PCOS.

Key words: Adolescence, Combined oral contraceptive pill, Pharmacotherapy, Polycystic ovary syndrome, Ultrasound

INTRODUCTION

Polycystic ovary syndrome (PCOS) is indeed one of the most common endocrine disorders among women of reproductive age.^[1] It affects 6–18% of adolescent girls.^[2,3] Adolescence is a crucial stage of development defined by the World Health Organization as spanning from 10 to 19 years of age. It is marked by significant physical, cognitive, emotional, and social changes, including puberty, which is a key aspect of this phase. Diagnosing PCOS in adolescents can be challenging because symptoms such as irregular periods, acne, and weight changes can overlap with normal hormonal changes during puberty (irregular menstrual cycles, acne, and polycystic ovarian morphology on pelvic ultrasound) with adult PCOS diagnostic criteria.^[4,5] These challenges highlight the complexity surrounding the diagnosis and management of PCOS. Under-diagnosis, delayed diagnosis, and over-diagnosis can all impact the quality of care women receive. In addition, inconsistent and non-evidence-based approaches among health-care professionals further complicate matters. The lack of robust evidence exacerbates these challenges, emphasizing the need for standardized protocols and continued research to improve the understanding and treatment of PCOS.^[6,7]

CRITERIA REQUIRED FOR DIAGNOSIS

Irregular menstrual cycles and ovulatory dysfunction

When irregular menstrual cycles are present, a diagnosis of PCOS should be considered. During adolescence, variations in menstrual cycle intervals are common, especially in the early years after menarche. Anovulation is also typical during this time. The maturation of the hypothalamic-pituitary-ovarian axis progresses gradually during adolescence, leading to differences in ovulation and menstrual cycles compared to women of reproductive age. This underscores the importance of understanding the unique hormonal dynamics during adolescence when diagnosing conditions like PCOS.^[8-10] Ovarian dysfunction can occur in adolescents or women with apparently regular menstrual cycles. Measuring serum progesterone levels can indeed help confirm anovulation, which is a key aspect of PCOS diagnosis, even in those with seemingly normal menstrual cycles.

Definition of irregular menstrual cycles in adolescents according to time post-menarche

Time post-menarche	Definition of irregular menstrual cycles
<1-year post-menarche	Irregular menstrual cycles are normal pubertal transition
>1-<3-year post-menarche	<21 or >45 days
>3-year post-menarche	<21 or >35 days or <8 cycles per year

Time post-menarche	Definition of irregular menstrual cycles
More than 1-year post-menarche	>90 days for any one cycle

Hyperandrogenism

Biochemical

Assessing biochemical hyperandrogenism is an important aspect of diagnosing PCOS. Tests such as calculated free testosterone, free androgen index, or bioavailable testosterone can provide valuable information about androgen levels in the body.

Use of high-quality assays for assessing testosterone levels in PCOS, and how markers such as androstenedione and DHEAS can provide additional information. Androstenedione can help exclude other causes of hyperandrogenism, while DHEAS can reflect adrenal androgen activity, potentially indicating adrenal dysfunction or tumors. Careful interpretation of androgen levels is vital in diagnosing conditions like PCOS. Considering the reference ranges from the laboratory used and normal values based on well-phenotyped populations, while also factoring in age and pubertal-specific stages, ensures accurate assessment and diagnosis.

In cases where clinical hyperandrogenism is not evident, assessing biochemical hyperandrogenism using appropriate high-quality assays becomes even more important for an accurate diagnosis of conditions like PCOS.

Clinical

A comprehensive history and physical examination are essential for identifying symptoms and signs of clinical hyperandrogenism, particularly in adolescents, where manifestations such as severe acne and hirsutism are common indicators. The recommendation to prioritize this assessment was made due to the lack of evidence-based guidance and the understanding that certain presentations, like moderate-to-severe acne during early puberty or perimenarcheal years, are less common and more likely to be associated with clinical hyperandrogenism. Visual scales like the modified Ferriman-Gallwey score are preferred for assessing hirsutism in nine primarily androgen-dependent areas. Each area is visually scored from zero (no terminal hair visible) to four (terminal hair consistent with a well developed (male) with a level of $\geq 4-6$ indicating hirsutism, adjusted for ethnicity. It is worth noting that self-treatment practices are prevalent and can affect the clinical assessment.^[11]

INVESTIGATIONS NOT RECOMMENDED

Pelvic ultrasound for PCOS diagnosis

Since younger individuals may naturally have multi-follicular ovaries, using pelvic ultrasound alone may not provide an accurate diagnosis of PCOS in those with a gynecological age of <8 years.

Using adult polycystic ovarian morphology criteria for ultrasound diagnosis during adolescence may lead to inaccuracies and increase the risk of over-diagnosis of PCOS. It is crucial to

consider the natural variations in follicle numbers per ovary in adolescents and the potential impact on diagnostic criteria.

Anti-Müllerian hormone (AMH)

AMH has been increasingly used in the diagnosis of PCOS, particularly when pelvic ultrasound is not feasible. Since AMH is secreted by granulosa cells of the preantral and small antral ovarian follicles, it provides valuable information about ovarian reserve and follicular activity, aiding in the diagnosis of PCOS.

The significant overlap in serum AMH levels between individuals with polycystic ovarian morphology, PCOS, and those without these features underscores the complexity of using AMH as a standalone diagnostic marker. Factors such as variations in assays, life stages, and phenotypes of the populations studied, as well as different PCOS criteria, contribute to this heterogeneity. Thus, while AMH can provide valuable insights, its interpretation must be contextualized within the broader clinical picture.^[12,13]

EXCLUSION OF OTHER CONDITIONS

The diagnosis of PCOS relies on excluding other potential causes of menstrual irregularities and hyperandrogenism. This approach is crucial even though certain causes may be less common in adolescents. It ensures accurate diagnosis and appropriate management tailored to the individual's specific condition. The most important cause of amenorrhea in a sexually active adolescent is pregnancy.

Menstrual irregularities due to functional hypothalamic amenorrhea or secondary deficiency due to any systemic cause could be present.

Furthermore, hypothyroidism, hyperprolactinemia, glucocorticoid excess due to Cushing's disease, glucocorticoid resistance, and androgen-secreting ovarian or adrenal tumors can cause menstrual irregularity and/or hyperandrogenism.^[14]

A thorough history and physical examination are mandatory for the evaluation of the appropriate condition.

TREATMENT

Lifestyle modification

Lifestyle interventions are essential, particularly for individuals with PCOS and excess weight. Multi-component approaches, including dietary changes, increased physical activity, reduction in sedentary behavior, and behavioral strategies, can effectively target weight reduction, central adiposity, and insulin resistance. These interventions not only address the symptoms but also promote overall health and well-being in individuals with PCOS.

Pharmacological principles of treatment in PCOS

The combined oral contraceptive pill (COCP) and/or metformin are recommended pharmacological treatments for adolescents with PCOS. These medications can help manage symptoms

effectively in those with a clear diagnosis or in adolescents deemed “at risk” of PCOS. COCPs can regulate menstrual cycles and reduce androgen levels, while metformin can improve insulin sensitivity and help with weight management in adolescents with PCOS.

These practice points underscore the importance of personalized care when considering pharmacotherapy for adolescents with PCOS:

1. Individual characteristics, preferences, and values should be taken into account when recommending pharmacotherapy, ensuring a patient-centered approach
2. Both the benefits and potential adverse effects of medications, both in PCOS and in general populations, should be carefully considered
3. It is important to discuss with adolescents and their families that medications such as COCPs, metformin, and other pharmacological treatments are generally “off-label” for PCOS treatment. This discussion should include evidence and potential side effects to make informed decisions together.

A comprehensive approach is crucial in managing PCOS. Integrating pharmacotherapy with education, counseling, lifestyle adjustments, and even cosmetic therapy can significantly improve outcomes for individuals with PCOS.

ANTIANDROGENS

When COCPs are contraindicated or not well tolerated, and effective contraception is ensured, antiandrogens can be considered for treating conditions like hirsutism or androgen-related alopecia.

EMOTIONAL WELL-BEING

Healthcare providers should be vigilant about the increased risk of anxiety and depressive symptoms in individuals with PCOS. Implementing appropriate screening measures and offering management strategies can significantly improve the overall well-being and quality of life for those affected by PCOS. Early detection and intervention are key in addressing these mental health concerns effectively.

Emotional well-being is a crucial but often overlooked aspect in adolescent girls with PCOS. More research is necessary to understand the pathophysiology of emotional symptoms, their onset in adolescence, and the most effective treatment strategies. In addition, investigating how these symptoms might affect engagement with management strategies is essential for providing comprehensive care to adolescents with PCOS. By addressing emotional well-being alongside physical health, health-care providers can better support adolescents in managing their condition and improving their overall quality of life.

CONCLUSION

Diagnosis of PCOS during adolescence is both controversial and challenging due to the overlap of normal pubertal physiological changes.

Polycystic ovarian morphology on ultrasound should not consider for the diagnosis of adolescent PCOS.

Emotional well-being is a crucial but often overlooked aspect in adolescent girls with PCOS. A holistic approach is essential in managing PCOS. While pharmacotherapy plays a role, it should be integrated with education, counseling, lifestyle interventions, and other options such as cosmetic therapy. This comprehensive approach addresses the physical, emotional, and psychological aspects of PCOS.
