Abstract: Polycystic ovary syndrome (PCOS) is an increasingly common problem for women in the reproductive age throughout the entire world. A reduction diet with a low glycaemic index (GI) has proved to support the treatment of PCOS. The aim of the study was to analyse the influence of the diet on the level of vitamins soluble in water. The study included 55 women, 40 of which suffered from PCOS (identified by means of the Rotterdam Criteria) and 15 healthy women of the Caucasian race. The level of vitamins before and after the dietary intervention was measured. The diet was a reduction diet with a reduced glycaemic index (GI). Biochemical analyses were made on the basis of liquid chromatography—Infinity 1260 Binary liquid chromatography (LC) Agilent Technology. The level of vitamins in the serum was analysed together with the consumption before and after the dietary intervention. A higher level of vitamin C in the plasma was observed before and after the dietary intervention in the PCOS group in comparison to the control group despite the lower intake of this vitamin in the PCOS group. The remaining vitamins were at a comparable or lower level (B1, B3, B5, B6 and B12). After the dietary intervention, only B1 and B9 were at a clearly lower level (a trend of $p = 0.093$ and $p = 0.085$). A properly balanced reduction diet with reduced GI improves the supply of vitamins in women with PCOS. An additional recommendation should be the additional supplementation of B1, niacinamide and the combination of folates with inositol. The level of vitamin C in the plasma may not be a good marker of its supply in the PCOS group.

1. Introduction

Polycystic ovary syndrome (PCOS) is diagnosed on the basis of at least two out of three Rotterdam Criteria from 2003 [1]:

- hyperandrogenism,
- or its clinical manifestations, such as androgenic baldness, hirsutism, menstruation and ovulation disorders,
- enlarged (ovary volume $> 10 \text{ cm}^3$) or polycystic ovaries (at least 12 follicles) visible in an ultrasound image.

When it comes to metabolism, PCOS is characterised by disorders in carbohydrate metabolism, which is accompanied by insulin resistance [2]. Furthermore, the fat build-up of internal organs, particularly, the presence of NAFLD, is the domain of women [3,4]. A study published in 2017 proved that the implementation of a reduction diet combined with physical activity had an influence on the reduction in body mass in patients and on the improvement of biochemical parameters, mainly of the lipid profile, which is often disturbed [5]. Therefore, it seems that PCOS is a syndrome that includes numerous

disorders that originate in metabolic defects leading to the development of obesity. The presence of the symptoms depends on the effective functioning of the entire organism, while the dysfunction of ovaries is a consequence of metabolic disorders. Women with PCOS are also in the risk group of developing type 2 diabetes, which makes more sensitive to insulin. This is why metformin is often used in the treatment of PCOS. Unfortunately, this medicine has an influence on the reduction in vitamin B₁₂ levels after just a few months of intake and is accompanied by an increase in the concentration of homocysteine [6]. Moreover, the inability to get pregnant and random stillbirth in women with PCOS may also be a consequence of the clinical deficiency of B12 [7]. In addition, in patients with hyperhomocysteinemia, stillbirth was observed more frequently than in women with correct homocysteine concentration [8].

The authors have a hypothesis that vitamins soluble in water that have antioxidant properties and participate in metabolic transformations as regulators may be supplemented together with a reduction diet, thus being beneficial in the treatment of PCOS. In the available literature, we did not find information on the influence of a balanced reduction diet on the supplementation of nutritional deficiencies with regards to vitamins soluble in water in women with PCOS. We were interested whether the supply combined with a properly balanced reduction diet proves sufficient to negate the differences with the control group, whether this type of diet should also additionally include supplementation and if so—what vitamins should be selected. We were interested whether the supply with an appropriately balanced reduction diet is enough to eliminate the difference in comparison to the control group or whether this type of diet should also include supplementation with specific vitamins (which ones?).

We decided to check whether the reduction diet with a low glycaemic index (GI), but rich in vitamins can improve the status of vitamins soluble in water in women with PCOS. To do this, we compared the results to those of women with PCOS who did not decide to change the diet, as well as to healthy women with excluded PCOS.

2. Material and Methods

The study was approved by the Bioethics Committee of the Pomeranian Medical University in Szczecin and was conducted in accordance with the provisions of the Declaration of Helsinki, institutional policy, and national law. All study participants consciously expressed their consent to participate in the study.

2.1. Study Group

In total, 55 women of the Caucasian race participated in the study—40 patients aged 32.52 ± 7.12 years with polycystic ovary syndrome (PCOS-I) diagnosed on the basis of the Rotterdam criteria: 2 out of 3 of the following criteria—rare ovulations or lack of ovulations and/or biochemical symptoms of hyperandrogenism and/or image of polycystic ovaries in USG (Ultrasound Voluson 730, GE, Switzerland). The control group (CG) consisted of 15 women aged 31.23 ± 6.3 years and the correct BMI of 22.1 ± 1.5 without PCOS. All participants of the study were subjected to the measurements of anthropometric bioelectrical impedance (Akern, BIA-101, Firenze, Italy).

Only 18 women with polycystic ovary syndrome who followed the recommendations and diet were qualified for stage 2 of the study (PCOS-II). The verification was conducted on the basis of a nutritional interview and body mass reduction—a minimum of 2 kg in 3 months. Lastly, the measurement of the content of vitamins in the plasma was conducted and compared between the groups in accordance with Figure 1. All of the women were in the childbearing age and their anthropometric parameters are presented in Table 1.

2.2. Quantitative Dietary Assessment

The following methods were used to gather data on product consumption: food diary referring to the last 3 days at the start of the study. The focus was on a one-day food record from the last 24-h dietary interview when the patient returned for a control visit. The

data collected from the diaries and interviews included the following: quantity, way of preparation, the time of consumption of each meal and the ingredients that were used. The menus were taken on Thursday and Friday as well as on Saturday or Sunday. Using computer software Dieta 6D (National Food and Nutrition Institute, Warsaw, Poland), we analysed a total of 162 dietary menus of women suffering from PCOS.

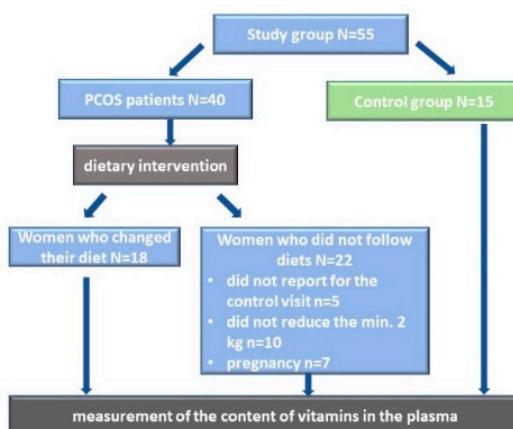

Figure 1. Study design.

Table 1. The characteristics of the study group and the control group.

Parameter	PCOS Patients	Control Group (CG)	p
Age (year)	32.52 ± 7.12	30.23 ± 6.31	NS
Height (m)	1.67 ± 0.06	1.68 ± 0.06	NS
Body mass (kg)	82.75 ± 15.6	62.76 ± 6.67	1×10^{-6}
BMI (kg/m^2)	29.65 ± 6.76	22.22 ± 1.52	1×10^{-6}
Fat mass (%)	39.54 ± 8.08	25.65 ± 3.96	1×10^{-6}
Waist circumference (cm)	99.87 ± 15.65	74.75 ± 5.01	1×10^{-6}
Hip circumference (cm)	109.45 ± 8.96	95.85 ± 4.88	1×10^{-6}
WHR	0.92 ± 0.08	$0.78 \pm 0.03 *$	1×10^{-6}

WHR—waist-to-height ratio; BMI—body mass index; *—it does not seem necessary to apply WHR in patients with correct body mass; NS—no statistically significant differences.

2.3. Dietary Intervention

Recommendations pertaining to the change of lifestyle and a 7-day menu were provided to each female participant [9,10]. The caloricity of the diet was reduced by 600 kcal with reference to the daily caloric needs. Moreover, 5 meals per day were included in the diet, and the products were given in grams. Sources of carbohydrates (5 portions per day) included: brown rice, oatmeal, coarse-grained groats, wholegrain rye bread or graham bread and—sporadically—potatoes as well as wholemeal pasta featuring lowered glycaemic indexes. The diets recommended the following products as sources of proteins: lean meat without skin (turkey or chicken), fish (sole, salmon and tuna), eggs, semi-skimmed milk (fat content: 2%), dairy products (quark and natural yoghurt) and legumes (soy, red lentils, beans or peas). Fat sources (2 portions per day) included—nuts and seeds (pumpkin seeds, almonds, sunflower seeds, sesame seeds, and chia seeds), oily fruits, e.g., avocado, and raw cold oils (e.g., linseed oil, olive oil, and rapeseed oil). From October to April, it is recommended to consume cod liver oil as Poland is situated in a temperate, warm transitional climate as people here often have problems with vitamin D deficiency.

Low GI fruits and vegetables were also included in the menus with the aim of supplementing the diet with minerals and vitamins. The recommended methods of food

preparation were braising, roasting, cooking in water and steaming. Furthermore, every participant was advised to drink about 2 L of fluids every day, especially water and herbal infusions. The final recommendation was to increase physical activity to a minimum of 3 h a week.

2.4. Reagents for Biochemical Analyses

Reagents (NaHCO_3 , NaOH , HK_2PO_4 , methanol and acetonitrile) of the highest HPLC quality were purchased from Sigma Aldrich (St. Louis, MO, USA). Millipore water (Millipore, Billerica, MA, USA) was used to prepare the buffers. Vitamins were isolated using amber-coloured Eppendorf tubes. To secure vitamins against photo-oxidation, the samples were isolated in a dark room in amber Eppendorf tubes. After the collection of 400 μL of blood plasma, an equal amount of acetonitrile was added together with 100 μL of internal standard (100 ng/mL theobromine). The reagents were mixed for 2 min and then centrifuged for 15 min at 4000 rpm. The formed supernatant was then transferred to new tubes in order to evaporate the acetonitrile. The water phase was moved to solid phase extraction columns that included a C-18 silica cartridge (Thermo Scientific, Waltham, MA, USA), which was activated earlier by means of 1 mL of methanol and 1 mL of clear water. The contents of the columns were subjected to elution using 85% methanol with 1.5 mL water. The formed solution was vacuum dried and—directly before HPLC analysis—was diluted in 100 μL buffer, 25 mM HK_2PO_4 [11,12].

2.5. The Analysis of Vitamins Soluble in Water with HPLC

HPLC Infinity 1260 Binary LC (Agilent Technologies, Waldbronn, Germany) was used to conduct the analysis. Subsequently, vitamins were separated using the gradient method with 25 mM HK_2PO_4 buffer with the pH of 7.0 and 100% methanol buffer. A and B buffer proportions for the times 0.0, 2.5 and 16 min were 97%:3%, while for 7.2 and 14 min they were 70%:30%. The separation of vitamins was conducted using BDB Hypersil C-18 (Thermo Scientific) column at 35 °C. The buffers moved through the column at the rate of 0.9 mL/min, and the injection volume was 10 μL [13]. The identification of specific vitamins in the studied samples was conducted on the basis of the observation of retention times of standard peaks. The data were analysed using ChemStation taking into account standard curves (ascorbic acid-C, thiamine-B1, riboflavin-B2, nicotinic acid-B3, calcium pantothenate-B5, pyridoxine-B6, biotin-B7, folic acid-B9, cyanocobalamin-B12, niacinamide-PP) with a correction for the internal standard (theobromine with the concentration of 100 mg/mL) [14].

2.6. Statistical Analysis

Statistica 12.0 (StatSoft, Cracow, Poland) was used to analyse the results. The average values (Avg) and standard deviation (SD) were calculated. As the distribution in most cases deviated from normal (Shapiro–Wilk test), non-parametric tests were used: the Mann–Whitney test for group comparisons (PCOS and CG) in which $p < 0.05$ was considered statistically significant.

3. Results

The average consumption of vitamins in the analysed diets in the PCOS-I group and—especially—in the PCOS-II group significantly differed in comparison to the control group (Table 2). The participants of the PCOS-I group consumed less vitamins in comparison to the control group, but statistical significance was observed only in terms of vitamin C and folates. The PCOS-II group consumed statistically significantly higher amounts of all of the analysed vitamins in comparison to PCOS-I. When comparing the consumption of vitamins in PCOS-II with the control group, statistically significant differences or trends were also observed in terms of the higher consumption of vitamins, except for cobalamin (Table 2).

Table 2. The comparison of the consumption of vitamins with reference to the analysed groups (PCOS-I, PCOS-II, and CG).

Vitamins	PCOS-I N = 40	PCOS-II N = 18	CG N = 15	P PCOS-I vs. PCOS-II	P PCOS-I vs. CG	P PCOS-II vs. CG
C (mg)	68.53 ± 38.22	234.61 ± 87.3	101.37 ± 73.04	1 × 10 ⁻⁶	0.017	1 × 10 ⁻⁵
B1 (mg)	1.21 ± 0.33	1.64 ± 0.29	1.12 ± 0.32	1 × 10 ⁻⁶	0.195	1 × 10 ⁻⁵
B2 (mg)	1.33 ± 0.29	1.76 ± 0.59	1.41 ± 0.39	0.0004	0.564	0.041
niacin (mg)	15.42 ± 4.18	21.2 ± 4.65	15.06 ± 4.58	1 × 10 ⁻⁶	0.771	0.0001
B6 (mg)	2.08 ± 0.63	2.64 ± 0.78	2.16 ± 0.91	0.002	0.718	0.049
Folates (μg)	221.2 ± 65.4	321.3 ± 72.3	262.8 ± 78.56	1 × 10 ⁻⁵	0.041	0.074 *
B12 (μg)	3.30 ± 2.13	3.72 ± 1.05	3.03 ± 2.34	0.323	0.651	0.168

PCOS I—polycystic ovary syndrome group before dietary intervention; PCOS II—polycystic ovary syndrome group after dietary intervention; CG—control group; *—trend.

When investigating the supply of vitamins soluble in water, we based our analysis on their concentration in blood plasma. After the dietary intervention, the concentration of some of the vitamins changed significantly (Figure S1A–C; Table 3). Most vitamin levels in the analysed cases were significantly different between PCOS-I and the control group (CG) (Figure S1B; Table 3). This was true for vitamin C, thiamine, B3, B5, pyridoxine, folates and cobalamin—in the last case, a trend was observed. However, the concentrations of vitamin C and B3 were lower in the control group. After the introduction of a balanced reduction diet, vitamin C and B3 levels in the PCOS-II group still remained significantly lower than in CG (which was surprising), but they did improve insignificantly (Figure S1C; Table 3). Furthermore, the average level of the remaining vitamins was increased in comparison to PCOS-I, but the results were not statistically significant (Table 3).

Table 3. The average concentration of vitamins analysed in the plasma before and after the dietary intervention with reference to the analysed groups (PCOS-I, PCOS-II, and CG).

Vitamin [μg/mL]	PCOS-I N = 40	PCOS-II N = 18	CG N = 15	P PCOS-I vs. PCOS-II	P PCOS-I vs. CG	P PCOS-II vs. CG
C	1.032 ± 1.236	1.006 ± 0.581	0.667 ± 0.115	0.287	0.043	0.050
B1	0.256 ± 0.275	0.336 ± 0.282	0.560 ± 0.416	0.241	0.023	0.095 *
B2	0.004 ± 0.002	0.005 ± 0.002	0.006 ± 0.004	0.279	0.112	0.428
B3—nicotinic acid	0.496 ± 0.449	0.153 ± 0.367	0.062 ± 0.050	0.018	0.001	0.370
PP—niacinamide	0.721 ± 0.212	0.756 ± 0.163	0.849 ± 0.201	0.418	0.173	0.292
B5	0.479 ± 0.230	0.606 ± 0.191	0.722 ± 0.192	0.126	0.002	0.116

PCOS I—polycystic ovary syndrome group before dietary intervention; PCOS II—polycystic ovary syndrome group after dietary intervention; CG—control group; *—trend.

4. Discussion

When analysing vitamin levels in the plasma, we took into account their supply and the needs of the human body depending on age, physical activity and accompanying illnesses associated with increased needs. The polycystic ovary syndrome is associated with the presence of a chronic inflammation and increased oxidative stress. This is why,

the supply of antioxidants, including vitamins, is particularly important. Vitamins that have antioxidant properties include ascorbic acid, the fastest reacting antioxidant, as well as vitamin E, carotenoids and flavonoids [15]. Ascorbic acid (AA) is present in high concentrations in the pituitary gland. Therefore, it can play a significant role in the secretion of the anterior pituitary hormones, including follicle stimulating hormone (FSH), luteinizing hormone (LH) and prolactin (PRL) [16]. Moreover, it has been determined that AA deficiency (caused by low consumption) increases insulin resistance, which accompanies women with PCOS. This is why, the diet offered to women with PCOS was rich in this constituent (the average consumption of 230 mg/day/person). In our opinion, the observed higher concentration of vitamin C in the plasma of women with PCOS both before and after the dietary intervention is associated with the organism's response to oxidative stress and the competition with glucose for the joint transporter GLUT1 and GLUT3 to cell interior [17]. Due to the fact that vitamin C level in the plasma—regardless of its supply with the diet—remained at the same level (PCOS-I and PCOS-II), it seems that the measurement of AA levels in the plasma of these patients cannot serve to measure the supply of this vitamin to the organism. The problem was already described earlier by the authors in 2019 [14]. Additionally, in the same study group, an increased level of several eicosanoids was observed after the introduction of a reduction diet with reduced GI. The same authors explained the mechanism as activation/amplification of repair processes [18].

Group B vitamins belong to the category of vitamins whose main function is regulation, which means that they participate in important processes and reactions located within tissues and cells. Due to the possibility of dysbiosis in the course of PCOS, it seems very important to supplement the supply of these vitamins [14,19]. In the study, in the case of most B vitamins, the increase in their supply with the diet lead to the expected result in the form of their increased level in the plasma of women with PCOS. This effect was not observed for vitamin B3, and the levels of B2 and thiamine were not as satisfactory as in the case of the remaining vitamins. This is why the authors decided to analyse the cause of this effect. It has been documented that the insufficient supply of vitamin B₃ is associated with the development of inflammatory diseases [20]. Some examples of this type of disorders that accompany the pathogenesis of PCOS include insulin resistance and lipid disorders that promote atherosclerosis, as well as the increased risk of cardiovascular diseases [21,22]. Therefore, the delayed removal of fat from circulation in women with PCOS is another factor supporting the occurrence of this syndrome. It has been shown that nicotinic acid therapy reduces the frequency of occurrence of stroke and myocardial infarction and alleviates coronary artery revascularisation in patients suffering from the metabolic syndrome [23]. Niacin is important for the increase in HDL, the decrease in plasma TG and low-density lipoprotein (LDL) [24]. Radmila Lyubarova et al. (over 3000 patients) state that extended-release niacin (ERN) is associated with the decrease in the activity of lipoprotein-associated phospholipase A₂ (LpPLA₂) and hence, with the risk of cardiovascular (CV) events [25]. Furthermore, nicotinamide and its metabolite N1-Methylnicotinamide (MNAM) alleviate endocrine and metabolic abnormalities in ovarian and fat tissues in the rat model of PCOS [26]. It has been observed that MNAM production is significantly higher in the cumulus cells of PCOS patients. It has also been demonstrated that its administration in the rat model of PCOS helped solve the problem of hyperandrogenism and ovarian adenosine monophosphate-activated protein kinase (AMPK). This is possible via aldehyde oxidase 1 (AOX1), which is a detoxifying enzyme that metabolises MNAM through the transient elevation of ROS [27]. Nicotinamide is a direct precursor used in the synthesis of NAD⁺ and NADP⁺, which are important coenzymes of redox reactions. Data shows that nicotinic acid is not formed from nicotinamide in the human body. On the contrary, nicotinic acid has to be transformed into nicotinamide [28]. Therefore, in our study, due to the protective effect with reference to vascular endothelium and the antithrombotic potential, it seems that the introduction of a balanced reduction diet rich in antioxidants lead to the activation of repair mechanisms resulting in the observation of a reduction in the level of nicotinic acid in the plasma of women with PCOS. Therefore, it seems that additional supplementation of

women with PCOS would be recommended, especially with the methylated form [29,30]. It is known that, in this group, there is a higher probability of women with the adverse methylene tetrahydrofolate reductase (MTHFR) polymorphism [30].

Contrary to expectations, the concentrations of the two remaining vitamins (thiamine and folates) in the plasma did not increase. Thiamine plays a key role in metabolism because it is a cofactor in the transformation reactions of carbohydrates, fats, and amino acids with a branched chain [31]. Due to the disorders of fat and carbohydrate metabolism in women with PCOS, thiamine deficiency supports the development of type 2 diabetes, cardiovascular diseases and dyslipidaemia in patients with PCOS [32]. Other authors have also observed that thiamine level is inversely related to the level of glucose and that it is an important factor in the prevention of the adverse processes of glycation with the production of advanced glycation end products (AGE) [33]. It has also been observed that hyperglycaemia and oxidative stress accelerate the formation of AGE [34]. Furthermore, thiamine supplied with food is a compound that is soluble in water, which makes it more difficult to absorb and it is rather quickly removed from the body through kidneys. This is why it is recommended to supply PCOS patients with benfotiamine, similarly to patients suffering from diabetes [35]. Benfotiamine is a synthetic derivative of thiamine, soluble in fats, that eventually becomes an active form of vitamin B1—thiamine diphosphate, which participates in tissue enzymatic systems of metabolic processes. Thiamine deficiency is associated with the presence of diabetic neuropathy. Diabetic neuropathy is the damage of peripheral nerves in women with PCOS in the early stages before diabetes. The proof of this is the observed elevated level of nerve acid in women with PCOS, also in this particular study group [36]. Women with PCOS and carbohydrate metabolism disorders are often treated with metformin that normalises glycaemia. Its chronic intake is additionally associated with the deficiency of thiamine and cobalamin [7,37]. This is why one of the ideas promoted by the authors of this article is to include supplementation with thiamine and/or benfotiamine while remembering that proper bioavailability in tissues requires the application of high doses [38]. The potential activation of transketolase through benfotiamine contributes to the inhibition of 3 out of 4 mechanisms that damage blood vessels, reducing the risk of cardiovascular disease (CVD) [39]. Another CVD factor in PCOS is the frequently existing elevated level of homocysteine in the plasma [40]. Furthermore, in women with PCOS, the level of homocysteine is inversely correlated with the level of transporting protein (SHBG), with circulatory system diseases and infertility [40]. In order to reduce the level of homocysteine, the triplet of vitamins—B6, B9 and B12 is supplied, and it is worth highlighting that folic acid has the highest influence on the normalisation of its level. Other studies have shown that the synergistic effect of myo-inositol, L-tyrosine, selenium and chromium after 6 months of use restores proper menstruation cycle and ovulation, and it also reduces the body mass of these patients [41,42]. Inositol was introduced as a new agent sensitising towards insulin and androgens in the treatment of patients with PCOS. Contrary to metformin, it does not cause any side effects [43,44]. Furthermore, L-methylfolate increases peripheral sensitivity to insulin, maintaining stable folatemia, thus restoring the normal level of homocysteine. Contrary to folic acid, L-methylfolate has higher bioavailability, no drug/food interference and high absorption level and is stable with reference to the effect of UV-A rays [45]. The supplementation with MI and folic acid has a positive influence on metabolic parameters, especially insulin resistance and the cardiovascular profile in women after 30 years of age, suffering from PCOS [46]. Supplementation with 5 mg of folate every day resulted in the reduction in Hcy in the HOMA-B plasma and a reduction in the concentration of high-sensitivity C-reactive protein (hs-CRP) and in malondialdehyde (MDA) in blood in comparison to folic-1 acid and placebo groups. Moreover, a significant increase in the total antioxidant capacity (TAC) in the plasma and glutathione levels (GSH) was also observed [47].

5. Conclusions

To summarise, it is necessary to include antioxidants in the diet of women with PCOS. A proper balanced reduction diet with low GI supplements the level of vitamins soluble in water. However, it is also recommended to include additional supplementation with thiamine (in the form of benfotiamine), niacinamide and folates with inositol, which increase peripheral sensitivity to insulin. The level of vitamin C in the plasma may not be a good marker for its supply in the PCOS group.

ABSTRACT

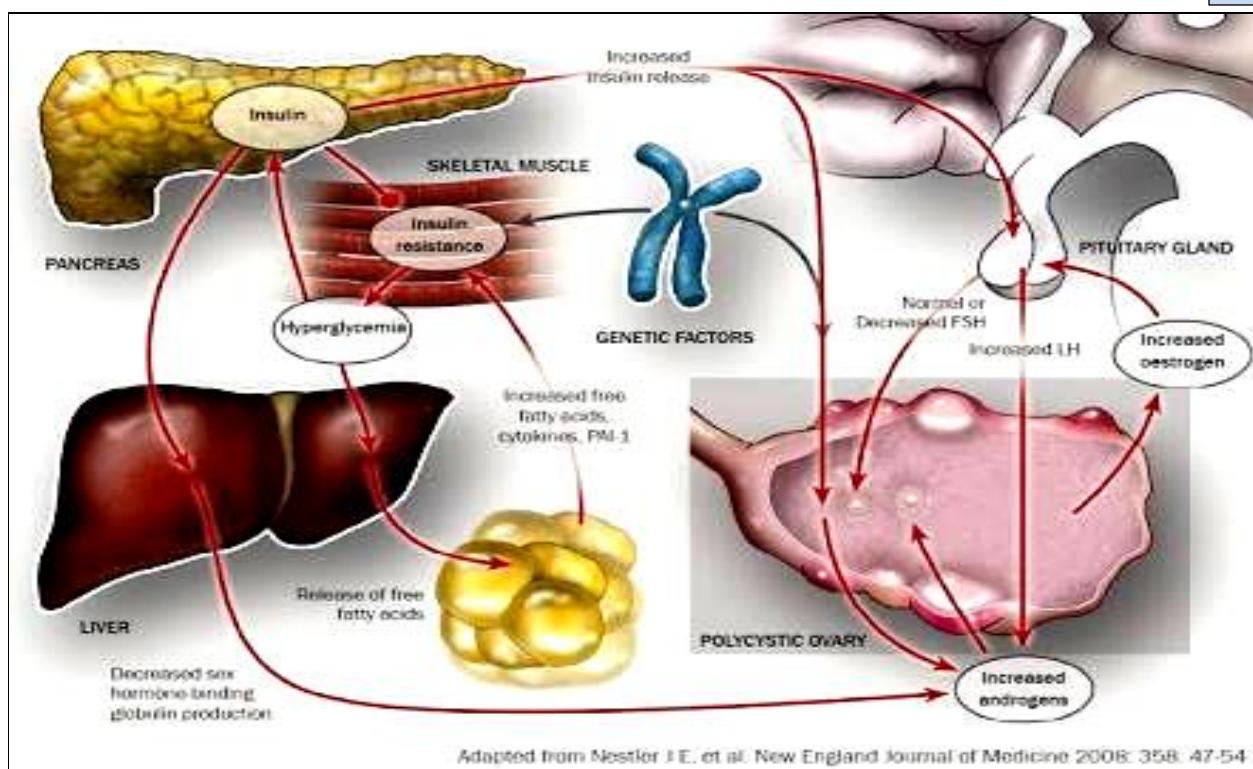

Poly-Cystic Ovary Syndrome (PCOS) is characterized by multiple small ovarian cysts, obesity, hypertension, diabetes, insulin resistance, and Hirsutism. The Study Aims to assess the role of Doctor Of Pharmacy in identification of risk factors in developing poly cystic ovarian syndrome among teenagers and minimizing them by life style modifications through advanced Patient counseling. The Main Objective of the present study is to prevent the following: To prevent the complications of PCOS who are suffering with PCOS in early of their age. To prevent the occurrence of PCOS to early females who are nearer for its occurrence. To minimize the symptoms and to improve the quality of life of females suffering with PCOS. Study Design: It is a observational and interventional study. Study Period: The Present study was conducted for a period of 6 months from January 2nd 2017 to July 31st 2017. Study site : The Present study was conducted in BAHUDHA WOMENS HOSTEL affiliated to Annamacharya college of Pharmacy, Rajampet, Kadapa, Andhra Pradesh, India. In The Present Study Out of total 600 women 530 enrolled to participate in the present study. After the collection of information by PCOS self assessment forms the scoring is given as 271 with scoring > 5 with percentile 51.1320 are with Chance for getting PCOS, 159 with scoring > 10 with percentile 30.01 are with high Chance for getting PCOS, 100 with scoring < 5 with percentile 18.8679 are Unpredictable to PCOS. The present study concludes that Doctor Of Pharmacy is very helpful in assessing the risk factors responsible in developing PCOS and also minimizing them by life style modifications through advanced patient counseling.

INTRODUCTION

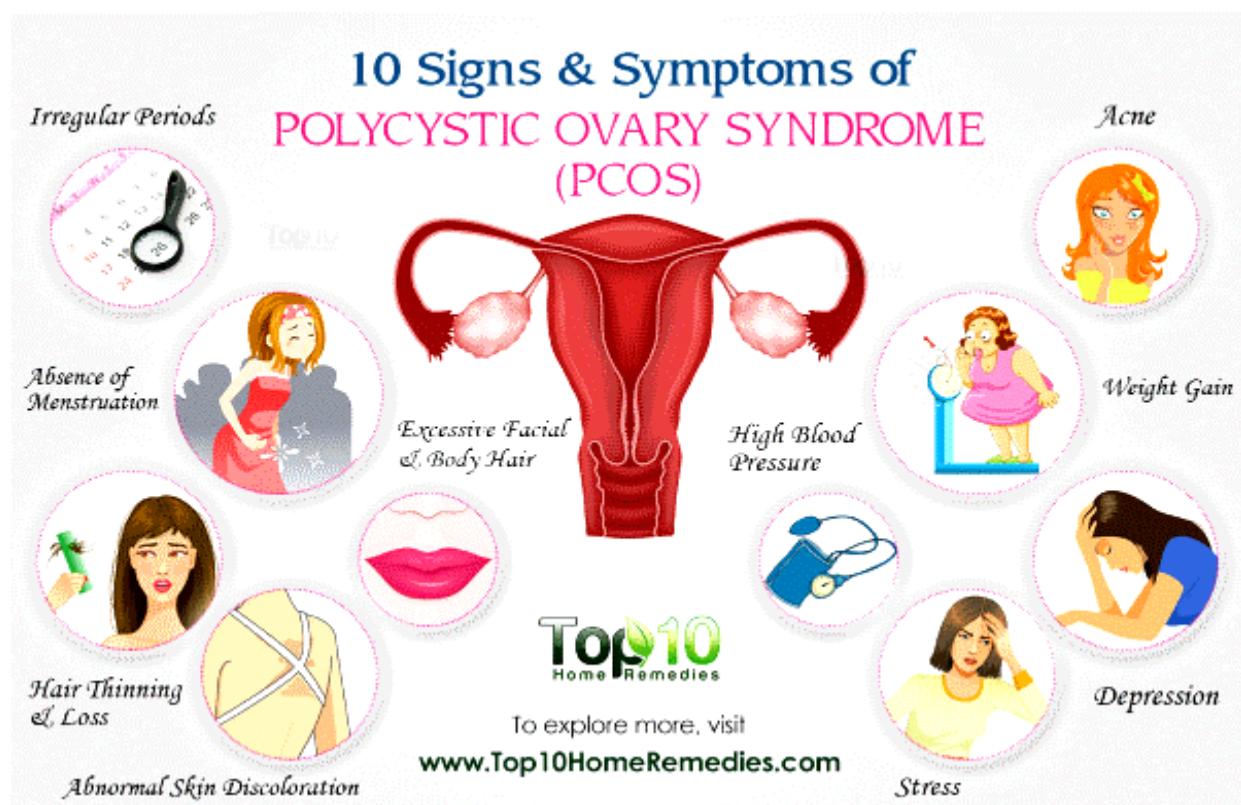

DEFINITION: Poly-Cystic Ovary Syndrome (PCOS) is characterized by multiple small ovarian cysts, obesity, hypertension, diabetes, insulin resistance, and Hirsutism.

SEQUENTIAL DIAGRAMATIC REPRESENTATION ETIO-PATHOPHYSIOLOGY OF PCOS:

DIAGRAMMATIC REPRESENTATION OF SIGNS AND SYMPTOMS

COMPLICATIONS

- Complete Infertility or in some cases difficulty to conceive.
- Cardiovascular diseases like hypertension ,atherosclerosis and other heart problems
- Type-2 diabetes mellitus.
- Hirustism which leads to unusual hair growth on body.
- Hormonal imbalances which leads to endocrine disorders and hyper-androgenism, etc.,,

ROLE OF DOCTOR OF PHARMACY IN MINIMIZING THE RISK FACTORS IN GETTING PCO

Doctor of pharmacy are health care professionals with complete knowledge on both disease/dicorder and treatment involved as well as on patient counselling and non pharmacological therapy that is helpful to prevent or reduce the complications of a particular disease/disorder, here in this study as a doctor of pharmacy student I have taken a study to control /to reduce/prevent the complications of PCOS in my hostel where I have been 5 years of my study.

AIM:

The Study Aims to assess the role of Doctor of Pharmacy in identification of risk factors in developing poly cystic ovarian syndrome among teenagers and minimizing them by life style modifications through advanced Patient counseling.

OBJECTIVES:

The Main Objective of the present study is to prevent the following:

- To prevent the complications of PCOS who are suffering with PCOS in early of their age.
- To prevent the occurrence of PCOS to early females who are nearer for its occurrence.
- To minimize the symptoms and to improve the quality of life of females suffering with PCOS.

METHODOLOGY:

Study Design: It is an observational and interventional study.

Study Period: The Present study was conducted for a period of 6 months from January 2nd 2017 to July 31st 2017.

Study site: The Present study was conducted in BAHUDHA WOMENS HOSTEL affiliated to Annamacharya college of Pharmacy, Rajampet, Kadapa, Andhra Pradesh, India.

Sample size: 600 women with age group ranging from 18-24 were selected for this study.

Source of Data: All the required data was collected through risk factors assessment forms.

Inclusion criteria:

Females aging between 18-24 and who are willing to participate in the study. ,(Out of total 600 530 were willing to participate in the present study).

Exclusion criteria:

Females aging between 18-24 and who are not willing to participate in the study,(Out of total 600 70 were not willing to participate in the present study).

PCOS SELF ASSESSMENT FORM**SELF TEST: DO YOU HAVE PCOS?**

(Poly-Cystic Ovary Syndrome (PCOS) is characterized by multiple small ovarian cysts, obesity, hypertension, diabetes, insulin resistance, and Hirsutism.)

NAME: _____ AGE: _____ OCCUPATION: _____

BODYWEIGHT: _____ HEIGHT: -----

ALREADY HAD PCOS: YES NO

QUESTIONARY FORM TO BE FILLED:

- YES NO 1. I crave carbohydrates and sugar.
- YES NO 2. I have had continuous weight gain.
- YES NO 3. I have always had difficulty with losing weight.
- YES NO 4. My waistline is greater than 35 inches.
- YES NO 5. I have or had problems in the past with acne.
- YES NO 6. My periods last longer than 35 days.
- YES NO 7. My periods are unpredictable.
- YES NO 8. My periods last longer than a week.
- YES NO 9. My periods are very heavy or prolonged.
- YES NO 10. I have with excess facial hair.
- YES NO 11. I feel extremely hungry, irritable, sleepy, or fatigued after eating sweets.
- YES NO 12. I have noticed skin color or pigmentation changes.
- YES NO 13. I have unusual amount of hair on my breasts.
- YES NO 14. I have hair growth on my upper thighs.
- YES NO 15. I have pubic hair that grows up my abdomen and around the navel.
- YES NO 16. My acne is worse at different times of my cycle.
- YES NO 17. I use to work/study under extreme stress conditions.

SCORE: ≥ 10 **high risk to get PCOS;** ≥ 5 **Chance for getting PCOS**

≤ 5 Unpredictable to PCOS.

NOTE: This Questionnaire form is prepared based On WHO Guidelines and Standard Text Books written to assess The Risk Factors Of PCOS.

RESULTS

Table1.1 AGE WISE DISTRIBUTION OF FEMALE POPULATION IN BAHUDHA HOSTEL.

AGE GROUP	NUMBEROF FEMALES	PERCENTAGE
18	95	17.9245
19	89	16.7924
20	87	16.4150
21	60	11.3207
22	40	7.5471
23	70	13.2075
24	89	16.7924
TOTAL=530.		TOTAL=100%

Fig 1.1 DIAGRAMATIC REPRESENTATION OF AGE WISE DISTRIBUTION OF FEMALE POPULATION IN BAHUDHA HOSTEL.

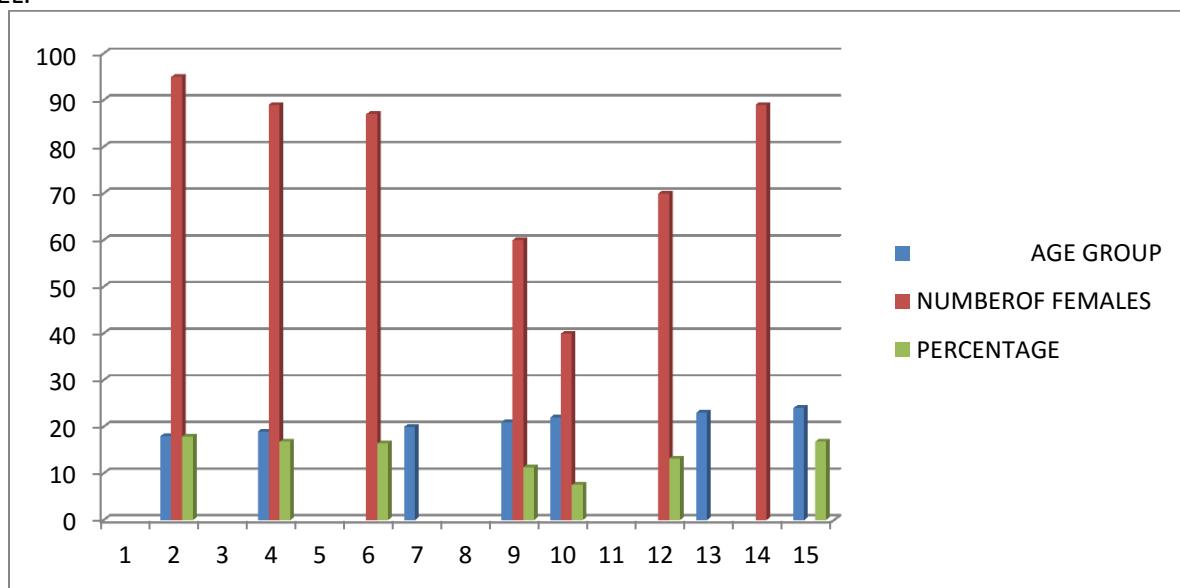

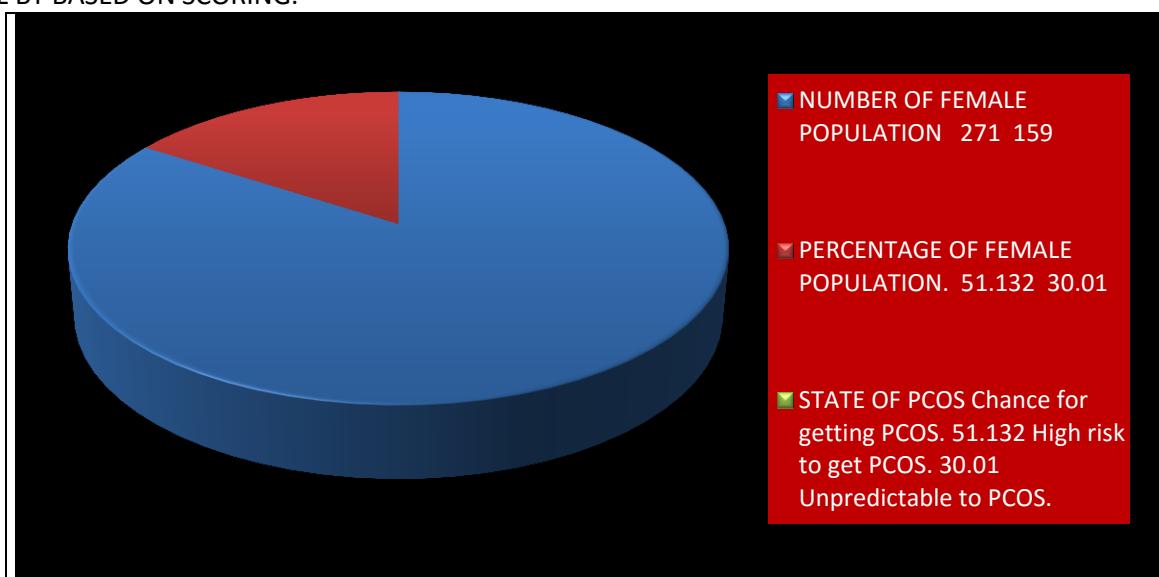

Table1. ANALYSIS OF PCOS STATE IN FEMALE POPULATION OF BAHUDHA HOSTEL BY BASED ON SCORING

NUMBER OF FEMALE POPULATION	SCORING	PERCENTAGE OF FEMALE POPULATION	STATE OF PCOS
271	≥ 5	51.1320	Chance for getting PCOS.
159	≥ 10	30.01	High risk to get PCOS.
100	<5	18.8679	Unpredictable to PCOS.
TOTAL=530			

Fig 1.2 DIAGRAMATIC REPRESENTATION OF ANALYSIS OF PCOS STATE IN FEMALE POPULATION OF BAHUDHA HOSTEL BY BASED ON SCORING.

PATIENT COUNSELLING TIPS ALONG WITH LIFE STYLE MODIFICATIONS PROVIDED BY DOCTOR OF PHARMACY TO FEMALE POPULATION WHO ARE AT CHANCE AND RISK OF GETTING PCOS

- Every women should Perform self test every month in order to assess the state of PCO occurance.
- Always reduce the intake of carbohydrate which can help to regulate menstrual cycles in regular manner.
- Always reduce the intake of fats with very low density lipoproteins that can helps to weight gain ultimately leads to insulin resistance.
- Always perform regular exercise& yoga to minimize the complications of PCO.
- Always should maintain proper BMI (body mass index).
- Use CARICA PAPAYA before one week of your menstruation date that can help to stimulate the growth of female Hormones like Oestrogen that will help to maintain proper menstruation cycles.
- Diet rich in iron like dates and fibre rich contents along with fruits and fresh vegetables must be taken .
- A balanced diet must be taken by based on body weight for example plate model meal.
- If one found if the complications are heavy they should immediately consult a Gynaecologist.

HOW DOCTOR OF PHARMACY IS HELPFUL IN ASSESING PCO?

Doctor of pharmacy are health care professionals with deep knowledge in assesing the risk factors, disease status, complications, drug selection, patient counseling. Here in this study a separate self assessment form is produced by doctor of pharmacy professionals as per standard guidelines of W.H.O and other international authorized guidelines, which is helpful for individuals to asses PCO on their own.

DISCUSSION

In The Present Study Out of total 600 women 530 enrolled to participate in the present study. Among them 95 were under the age group of 18 with percentile 17.9245, 89 were under the age group of 19 with percentile16.7924, 87 were under the age group of 20 with percentile 16.4150, 60 were under the age group of 21with percentile11.3207, and 40 were under the age group of 22 with percentile 7.5471, 70 were under the age group of 23with percentile 13.2075, 89 were under the age group of 24 with percentile 16.7924. After the collection of information by PCOS self assessment forms the scoring is given as **271 with scoring >5** with

percentile **51.1320** are with **Chance for getting PCOS, 159** with scoring ≥ 10 with percentile **30.01** are with **high Chance for getting PCOS, 100** with scoring ≤ 5 with percentile **18.8679** are **Unpredictable to PCOS**.

CONCLUSION

The present study concludes that PCOS occurrence is more in teenager females which can serve as major hurdle for their healthy life which ultimately leads to infertility as it is due to major risk factors like changes in the diet, stressful life, and unbalanced improper and unhealthy life style in females, hence the present study concludes that Doctor Of Pharmacy is very helpful in assessing the risk factors responsible in developing PCOS and also minimizing them by life style modifications through advanced patient counseling.

Abstract. – **OBJECTIVE:** Polycystic ovary syndrome (PCOS) is the most common endocrine-gynecologic disorder affecting women of childbearing age. It has a wide range of clinical manifestations, including menstrual irregularity, infertility, hirsutism, acne, and obesity. Studies have confirmed that PCOS can significantly reduce a patient's health-related quality of life (HRQoL). The pathophysiology of PCOS is poorly understood, but it is believed to be caused by the interaction of several factors. Moreover, there is a lack of information about HRQoL among PCOS women in Saudi Arabia. This study aims to assess the HRQoL of PCOS patients by using the Arabic Version of the Polycystic Ovarian Syndrome Health-Related Quality of life Questionnaire (AR-PCOSQ) in Riyadh city.

SUBJECTS AND METHODS: A descriptive cross-sectional study was conducted on 281 women in Riyadh city using the translated questionnaire (AR-PCOSQ) to explore PCOS quality of life among Saudi females. The eligibility criteria were Saudi female who had been diagnosed with PCOS, living in Riyadh city, aged 18 and above, and willing to participate. The sample size was estimated using the 10-events-per-variable rule for prediction models (REF). Informed consent was taken from all participants and a Google Form was used to create the survey and collect data.

RESULTS: The higher score represents poor QOL. However, the analysis revealed that higher scores of the weight-related QOL had the greatest impact on patients' quality of life in older age groups, including women aged 26 to 35 ($\beta = 0.143$, 95% CI, 0.023 to 0.304, p -value = 0.046) and women aged > 35 ($\beta = 0.229$, 95% CI, 0.039 to 0.428, p = 0.011). Other domains of QOL, such as emotions, body hair, infertility, and menstrual problems, were not significant-

ly predicted by any of the women's demographic characteristics.

CONCLUSIONS: The findings revealed that PCOS-related conditions such as weight problems, menstrual irregularity, and infertility were associated with a reduction in quality of life.

Key Words:

Quality of life, Arabic, PCOS.

Introduction

Polycystic ovary syndrome (PCOS) is the most prevalent endocrine-gynecological disorder and affects women at their reproductive age¹. It is widely spread in most parts of the world, with large variations between different regions. A retrospective study shows that the prevalence of PCOS is estimated between 4% and 20% worldwide². Moreover, the prevalence of PCOS is 16% among Saudi females³. The name polycystic ovary syndrome describes a condition where numerous small cysts in the ovaries produce elevated level of androgens, which can cause irregular menstrual cycle and many symptoms of PCOS⁴. According to ESHRE/ASRM criteria, PCOS is defined as the presence of two or more of the following three criteria: polycystic ovaries, oligo-/anovulation, and/or clinical or biochemical evidence of hyperandrogenism⁵. The

wide range of clinical manifestations, including menstrual irregularity, infertility, hirsutism, acne, and obesity, are all significant sources of psycho-social distress and lead to a reduction of life quality⁴. Numerous studies⁴⁻⁶ confirm the symptoms of PCOS can lead to a significant decrease in patients' health-related quality of life (HRQoL). According to a study conducted in Iran⁶, infertility is considered one of the most distressing symptoms of PCOS. In addition, a thorough review of the literature conducted by Bazarganipour et al⁷ show that hirsutism and menstruation are the main causes of HRQOL impairment in PCOS patients. The interaction between multiple factors is believed to be the cause of the hormonal disturbance seen in PCOS patients⁸. Additionally, genetic mutations are linked to PCOS, along with hypothalamic-pituitary dysfunction⁹. A genetic mutation of the aromatase enzyme deficiency may affect ovary functioning and elevate androgen level, leading to PCOS⁹. Despite this, research done to assess the quality of life of patients with PCOS is minimal, especially in Asian countries, even though it is the most common endocrine disorder in young females^{10,11}. Upon literature review, there has been minimal research assessing the HRQoL of PCOS patients in Saudi Arabia. HRQoL is culturally dependent⁶; therefore, the unique characteristics of social and cultural life contexts suggest that information on the HRQoL of PCOS patients in Saudi Arabia may be different from that of Western countries. Since there is a scarcity of information about the HRQoL among PCOS women in Saudi Arabia. This study aims to assess the HRQoL of PCOS patients by using the Arabic Version of the Polycystic Ovarian Syndrome Health-Related Quality of life Questionnaire (AR-PCOSQ) in Riyadh city. We hypothesize that women with PCOS, would show worse HRQoL compared to women without PCOS.

Subjects and Methods

A descriptive cross-sectional study using the translated questionnaire (AR-PCOSQ) was conducted to explore PCOS quality of life among the Saudi female population, through an anonymous online questionnaire using a snowball convenience sampling technique from January 2023 to March 2023. The eligibility criteria to participate in this study were Saudi females who had been diagnosed with PCOS, living in Riyadh city, aged 18 and above, and willing to participate in the study. Since we planned to conduct a multivariate

linear regression model of the primary outcome variable (QOL score), the sample size was estimated using the 10-events-per-variable rule for prediction models¹². Given that the PCOSQ scale consists of 26 items, a sample of 260 women was required in the current study. The total sample size comprised 281 participants. Before starting the study, approval was obtained from the Institutional Review Board (IRB) at Princess Nourah bint Abdulrahman University (PNU), Riyadh, Saudi Arabia (IRB log number: 23-0077). Informed consent was taken from all participants after being explained briefly about the study's objectives and informed that they have the full right to withdraw from the study without any obligation. A Google Form was used to create the survey and collect data. The link was then shared and circulated randomly across different social media platforms (i.e., WhatsApp, Telegram, Instagram, and Twitter). The majority of participants were strongly encouraged to share the invitation link with their personal and professional contacts.

Data Collection

In the current study, we employed the PCOSQ scale, which consists of 26 items and 5 domains, including emotions (eight items), body hair (five items), weight (five items), infertility (four items), and menstrual problems (four items)¹³. The mean scores of each domain were computed based on the items allocated to each domain after validation. Each item was graded on a seven-item Likert scale, where higher scores indicated a poorer quality of life. Since the scores of each domain are based on the mean values of respective items, they ranged between 1 and 7.

Statistical Analysis

The normal distribution of the QOL score was assessed using a Shapiro-Wilk test, which revealed non-normally distributed data (p -value = 0.0001). Statistical analysis was performed using RStudio (R version 4.2.2): Integrated Development for R. RStudio, PBC, Boston, USA. Categorical variables were expressed as frequencies and percentages, whereas numerical variables were presented as median and interquartile range (IQR). To assess the predictors of poor quality of life among PCOS participants, we carried out a bootstrapped partial least squares structural equation modeling technique using the five subscales as endogenous variables and the demographic characteristics of the participants as predictor variables. The internal consistency reliability of the model was asses-

sed using Cronbach's alpha coefficients and rhoC rhoA values. Furthermore, we used the average variance extracted (AVE) as a measure of the convergent validity in order to assess the degree to which each construct could have converged to express the indicators' variance. Beta coefficients and their respective 95% confidence intervals (95% CIs) were used to present the results of the structural model, and statistical significance was deemed at p -value < 0.05 .

Results of the structural paths showed that higher scores of the weight-related QOL (poor QOL due to weight concerns) were predicted by older age categories, including 26 to 35 years women ($\beta = 0.143$, 95% CI, 0.023 to 0.304, $p = 0.046$) and > 35 years women ($\beta = 0.229$, 95% CI, 0.039 to 0.428, $p = 0.011$). Other domains of QOL, including emotions, body hair, infertility, and menstrual problems, were not significantly predicted by any of the demographic characteristics of women (Table I).

Results

Demographic Characteristics

The responses of 281 women with PCOS were analyzed in the current study. All the participants were Saudi women residing in Riyadh city. The majority of them were between 18 and 25 years old (70.1%), were singles (72.2%), and had a bachelor's degree (73.7%). Approximately two-thirds of the participants were students (61.6%) and had an average monthly income of $< 5,000$ SAR (68.7%).

Out of the 26 items of the PCOSQOL survey, 24 items showed adequate loadings to their original constructs (bootstrapped factor loadings > 0.5). Therefore, two items were excluded from the validated model, including one item from the body hair subscale (QOL_11) and one item from the menstrual problem subscale (QOL_24). Furthermore, we combined single, divorced, and widowed categories into one category (single) and unemployed and retired categories into another category (unemployed/retired) to avoid the zero-variance error in the bootstrapped model. The final model exhibited excellent reliability indicators since the Cronbach's alpha values ranged between 0.751 and 0.935, and the values of rhoC and rhoA exceeded 0.70. Additionally, the AVE values of subscales were generally above 0.50, ranging between 0.551 and 0.794. This indicates that the constructs explained at least 55.1% of the

indicators' variance that formed the construct. Finally, there was no risk of multicollinearity since the values of the variance inflation factor (VIF) were generally below the threshold of 5 (Table II).

Validity and Reliability

Description of the PCOSQOL scale and subscales

The median (IQR) quality of life score for all the participants was 4.2 (2.8 to 5.2). Weight-related QOL had the highest median score (median = 4.8, IQR = 2.8 to 6.0), followed by menstrual problems-related QOL (median = 4.7, IQR = 3.3 to 5.3) and infertility-related QOL had the lowest score (median = 3.3, IQR = 2.0 to 4.8, Figure 1).

Discussion

PCOS HRQoL has been previously studied worldwide¹⁵⁻¹⁸. The purpose of this paper was to assess the PCOS HRQoL and to identify the predictors of poor HRQoL in a sample of Saudi females. It was found that women with PCOS have a lower HRQoL. This finding could be attributed to the fact that PCOS has metabolic, reproductive, and psychological features and consequences on health across the lifespan¹⁹. In this study, weight problems were the greatest concern reported by PCOS women. These results were in line with previous studies¹⁵⁻¹⁸. One possible explanation for this finding is that women with PCOS often report extreme difficulty in losing weight and maintaining weight loss, and interventions to lose weight are often failed and linked to high rates of weight gain¹⁷. Furthermore, two studies^{20,21} have reported that PCOS women have a worse body image and are dissatisfied with their weight, and consequently, have a poor quality of life. Noticeably, a weight reduction appears to improve HRQoL significantly²². Additionally, our study demonstrates that the weight-related QOL was significantly predicted by older age categories, including 26 to 35 years and > 35 years women. On the other hand, a systematic review by Jones et al²² revealed that weight-related QOL is significantly associated with the adolescent age group. It might be because there are few data on HRQoL in women with PCOS during their late reproductive years, with most prior studies focusing on women at younger ages²³.

Although menstrual disorders demonstrate a high negative association in PCOS patients on a

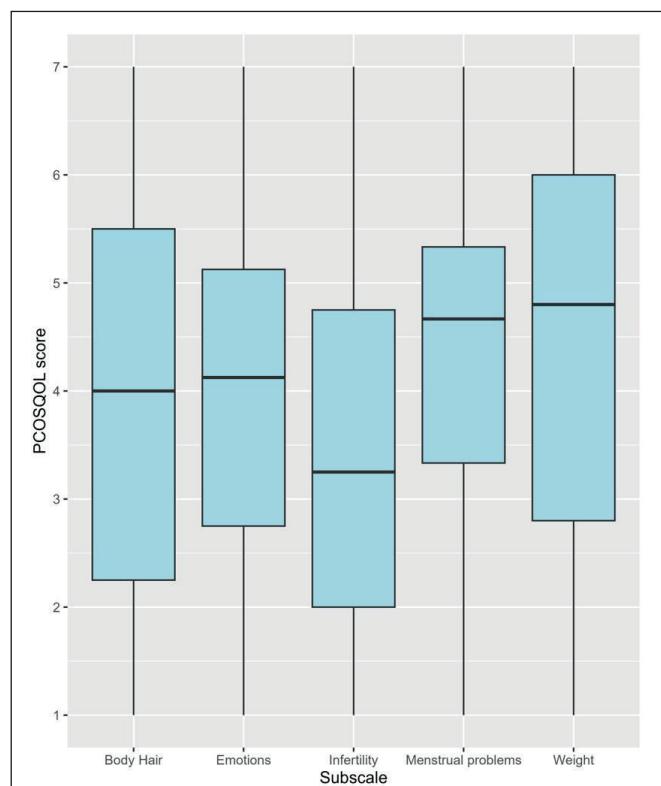

Figure 1. Description of the overall PCOSQOL scale and subscales.

clinical and biochemical basis²⁴, in some studies, it was not in the top three most affected domains⁷. The infertility outcome of this study shows the lowest score among the other domains. This finding explains that most of our participants are single, and infertility is not a big concern in this group. Another similar study²⁵ found an extremely low score for infertility in comparison to the other domains, although there is a significant negative impact on the quality of life of PCOS cases in relation to psychological distress, and this is because maternity has an effective role in the identity of women and the acceptance of society following marriage. Therefore, PCOS women can have sexual function issues where they sense less sexual satisfaction and desire due to long-term infertility and psychological stress¹⁵. Moreover, the Iranian study²⁶ displays the lowest score for infertility. Accordingly, infertility was detected as a concern of HRQOL because of the social pressure for childbearing.

Our study did not investigate a specific age group, but all females above 18 were included, which may affect the results since older females are more susceptible to health problems like metabolic syndrome. Also, symptoms might be affected by other factors, such as social stressors. Future studies should focus on specific age groups for a more accurate result.

Another limitation of the study is that the diagnoses of the disease were self-reported by the participants. This can be avoided by a validated diagnostic questionnaire to identify women with PCOS or by distributing the questionnaire from the primary healthcare and gynecological clinic to patients with a confirmed diagnosis of PCOS.

It should be noted that this study did not investigate any biochemical correlation related to PCOS cases and their HRQOL. Thus, it is suggested that future studies explore further correlations between HRQOL and PCOS cases.

The sample size was limited, and most participants were highly educated and might have had good health education regarding their self-care and health-seeking behaviors. Future researchers need to use large samples with various education and socioeconomic statuses.

Conclusions

In conclusion, this study provides evidence that HRQOL in patients with PCOS is impaired mostly by weight problems and menstrual irregularity,

while concerns about infertility had the lowest impact. Therefore, these problems must be considered by professional healthcare providers when dealing with PCOS patients, and more services need to be implemented to minimize the impact of PCOS on affected females.

Authors' Contributions

HAS has conceptualized the study and played a primary role in compiling, analyzing, and interpreting the data. RAS, BV, and CJJ did the manuscript preparation. SOA and RHA did the manuscript editing. JAA, LAA and MSA approved the final draft. RHA, JAA, MSA and LAA did the data cleaning and data analysis. LSMA and NA did the data collection. All the authors take complete responsibility for the content of the manuscript, and read and approve the final version of the manuscript.

Melatonin and its correlation with testosterone in polycystic ovarian syndrome

ABSTRACT

CONTEXT: Polycystic ovarian syndrome (PCOS) is considered to be the most common endocrine disorder affecting women. Melatonin, a small lipophilic indoleamine, and reproductive hormones may be interrelated. Melatonin influences sex steroid production at different stages of ovarian follicular maturation as melatonin receptors have been demonstrated at multiple sites in ovary and in intrafollicular fluid. It plays role as an antioxidant and free radical scavenger which protects follicles from oxidative stress, rescuing them from atresia, leading to complete follicular maturation and ovulation. **AIMS:** To study the role of melatonin in PCOS and to investigate its correlation with testosterone in patients suffering from PCOS. **SETTINGS AND DESIGN:** A total of 50 women with PCOS (Rotterdam criteria, 2003) and 50 age and weight matched healthy controls were selected and serum melatonin estimation was done in both the groups and correlated with serum total testosterone levels. **MATERIALS AND METHODS:** In a case-control study, detailed history, clinical examination and hormonal evaluation [basal levels of leutinizing hormone, follicle-stimulating hormone, thyroid-stimulating hormone, prolactin, insulin, total testosterone, progesterone and melatonin] were carried out in all the participants including both cases and controls. For melatonin estimation, blood samples were collected between 12:00 am and 04:00 am on day 2nd of menstrual cycle and analyzed by using commercially available enzyme-linked immunosorbent assay kit. **STATISTICAL ANALYSIS:** Student's t-test was used to compare the significant difference in mean values between cases and control groups. Chi-square test was used to test the significant association between the qualitative variables. Linear correlation coefficient and regression analysis were done to see the amount and direction of relationship between quantitative variables. **RESULTS:** The mean melatonin level was observed to be significantly increased in patients (63.27 ± 10.97 pg/mL) than in controls (32.51 ± 7.55 pg/mL). Melatonin was found to be raised in all the cases of PCOS (above cut-off value of ≥ 45 pg/mL, $P < 0.001$). Total testosterone level was also raised in 72% of patients. Melatonin levels were found to be positively associated with increased testosterone ($P < 0.001$). In regression analysis using melatonin as dependent variable and testosterone as an independent variable, the value of $R^2 \times 100$ (percent variation) was found to be 72.1%. **CONCLUSIONS:** Women with PCOS have significantly raised serum melatonin levels and hyperandrogenemia along with increased number of atretic follicles. Further studies are required to establish a definite role of melatonin in PCOS cases with disturbed hormonal milieu. This could open up the way for therapeutic role of melatonin in treatment of patients suffering from PCOS.

KEY WORDS: Hyperandrogenemia, infertility, melatonin, Polycystic ovarian syndrome

INTRODUCTION

Polycystic ovarian syndrome (PCOS) is considered to be the most common endocrine disorder affecting women.^[1] It is the most common cause of anovulatory infertility and hirsutism.^[2,3] About 15% women of reproductive age group are affected.^[4] Women with PCOS in long term are known

to exhibit adverse Cardiovascular risk profile such as obesity, dyslipidemia, hypertension, insulin resistance and hyperinsulinemia,^[5] with an increased risk of premature coronary artery disease.^[6]

The role of melatonin (N-acetyl-5-methoxytryptamine), a small lipophilic indoleamine,^[7] in human reproduction is

still unknown. A large body of information suggests that melatonin and the reproductive hormones are interrelated. This concept is based on observation of increased melatonin levels in hypogonadal patients with gonadotropin-releasing hormone (GnRH) deficiency,^[8] in patients of hypothalamic amenorrhea, and in anorexia nervosa.^[9] Increased melatonin has been seen to influence sex steroid production at different stages of ovarian follicular maturation.^[10]

Melatonin, as well as its metabolites, are claimed to be broad-spectrum antioxidants and free radical scavengers,^[11,12] and their role is to quench reactive oxygen species (ROS) as well as reactive nitrogen species.^[13] Elevated melatonin in preovulatory follicles, as seen in normal women, is likely to protect granulosa cells and oocyte from free radicals that are induced during ovulation. In addition, melatonin regulates the antioxidant enzymes and antiapoptotic/proapoptotic protein gene expression.^[10]

Melatonin is detectable in virtually every compartment of body and its wide distribution allows melatonin to carry out its pleiotrophic actions. Till now, only few studies [Luboshitzky *et al.*, 2001; 2003; Prata Lima *et al.*, 2004; Tamura *et al.*; 2009; 2012] have been carried out to show association between melatonin and PCOS in human population. Since no study of such type has been done on Indian population, we, therefore, have designed this study in an effort to investigate the role of melatonin and its correlation with testosterone in PCOS patients.

MATERIALS AND METHODS

A prospective case-control study was designed taking 50 PCOS patients and 50 age- and weight-matched healthy controls, attending outpatient department of Department of Obstetrics and Gynecology, Sir Sunderlal Hospital, Banaras Hindu University, Varanasi from September 2011 to December 2012. Sample size was calculated and it came out to be 50 by taking the level of significance 1%, power of study 80% and combined standard deviation 10.

Inclusion criteria for selection of cases

The Rotterdam European Society for Human Reproduction and Embryology/American Society for Reproductive Medicine-sponsored PCOS consensus criteria was used to diagnose PCOS and women with presence of any two of the following three features were included in the study:

1. Oligomenorrhea and/or amenorrhea (oligoamenorrhoea >45 days or <8 cycles per year and amenorrhea >3 months in a women with previous periodic menses) for a period of 6 months
2. Clinical and/or biochemical hyperandrogenemia, presence of acne, hirsutism (FG score >8), and alopecia
3. Polycystic ovaries on sonography (>12 follicles in one

or both ovaries, 2-9 mm in diameter and/or increased ovarian volume >10 mL).

Inclusion criteria for selection of controls

1. Regular menstrual cycle
2. Absence of hirsutism, alopecia, and acne
3. Absence of polycystic ovary on sonography
4. Normal hormonal parameters including thyroid-stimulating hormone (TSH), testosterone, prolactin, luteinizing hormone (LH), follicle-stimulating hormone (FSH), LH: FSH ratio.

Exclusion criteria

All patients with diabetes mellitus, hypertension, hyperprolactinaemia, thyroid disorder, cushing's syndrome, acromegaly, premature ovarian failure, virilising adrenal or ovarian tumors, and history of using oral contraceptive pill within last 6 months were excluded from the study. None of the subjects were alcoholic or smoker.

A written and informed consent was taken from all the participants.

Biochemical and hormonal analysis

Blood samples were drawn on day 2 of menstrual cycle or progesterone-induced bleeding after an overnight fast. Plasma LH, FSH, prolactin, total testosterone, progesterone and insulin were measured by chemiluminescent enzyme immunoassay using commercially available kits (Immuli 1000 systems, Siemens). Plasma Glucose was measured by glucose oxidase peroxidase method (selectra XL analyzer, Vital Scientifics, Holland). Serum cholesterol, triglycerides, low-density lipoprotein, and low-density lipoprotein levels were measured using kits by ERBA diagnostic, Mannheim, Germany. TSH levels were measured using IRMA kit (BARC, Mumbai, India). Cut off points for diagnosis of hyperandrogenemia was set at ≥ 118 ng/dL (according to chemiluminescent enzyme immunoassay), for insulin resistance it was set at a fasting glucose/insulin (G: I) ratio ≤ 4.5 and for hypersecretion of LH, LH: FSH ratio ≥ 2 was considered to be a cut-off point.

Sonography

Pelvic sonography (Nermio 30, Toshiba, Japan) was carried out on day 2 of menstrual cycle in both cases and controls.

Melatonin estimation

Blood samples for melatonin estimation were collected between 12:00 am and 04:00 am on day 2nd of menstrual cycle. A total of 5 mL of heparinized blood was taken and samples centrifuged for 15 min at 2500 RPM within 30 min of collection. Plasma was separated and stored samples in aliquot at -20°C or -80°C. Plasma melatonin concentration was measured using a commercially available enzyme-linked immunosorbent assay kit for melatonin

(Manufacturers: USCN Life Science Inc, USA). This assay employs the competitive inhibition enzyme immunoassay technique.

Statistical analysis

SPSS 16.0 version for Windows was used for statistical analysis. All quantitative variables were expressed as mean \pm standard deviation, while qualitative data were shown in the form of number and percentage. Student's t-test was used to compare the significant difference in mean values between cases and control groups. Chi-square test was used to test the significant association between the qualitative variables. Linear correlation coefficient and regression analysis were done to see the amount and direction of relationship between quantitative variables. A P value less than 5% ($P < 0.05$) was considered statistically significant.

RESULTS

The demographic, anthropometric, biochemical, and hormonal parameters of the study population (cases and controls) were compared [Table 1].

Melatonin concentration in PCOS patients varied from 47.9 pg/mL to 87.6 pg/mL, whereas in controls it ranged from 20.0 pg/mL to 44.04 pg/mL. Mean melatonin level was 63.27 ± 10.97 pg/mL in PCOS cases as compared with 32.51 ± 7.55 pg/mL in controls. Cut off level of melatonin was found to be 45 pg/mL. We found that all PCOS patients had significantly elevated serum melatonin levels (above cut-off value of 45 pg/mL, $P < 0.001$ and $t = 16.33$).

The mean melatonin level was shown in relation to demographic, anthropometric, biochemical, and hormonal profile of PCOS patient [Table 2].

Mean melatonin level in PCOS patients having regular menstrual cycle was 68.31 ± 11.18 pg/mL and in patients with oligomenorrhea, it was 61.84 ± 10.62 pg/mL. The difference in mean levels of melatonin between the groups was not statistically significant ($P = 0.84$ and $t = 1.76$) [Table 2].

We observed a significant positive correlation of serum melatonin with serum total testosterone levels in PCOS patients. Mean Melatonin level was 74.53 ± 10.99 pg/mL in patients with serum total testosterone level 128-140 ng/dL, whereas it was 53.28 ± 3.78 pg/mL in patients with total testosterone levels of ≤ 118 ng/dL. Thus, significant difference has been observed in mean melatonin level among different testosterone categories ($P < 0.001$, Chi-square = 20.97 and df = 2). Melatonin level was also correlated with serum LH: FSH ratio and fasting glucose: insulin ratio (G: I). Mean melatonin level in patients with LH:

FSH ratio ≥ 2 was 59.35 ± 10.02 pg/mL, whereas it was 71.24 ± 8.89 pg/mL in patients with LH: FSH ratio < 2 . These two variables seem to be inversely correlated ($P = 0.013$). We did not find any significant correlation between serum melatonin level and fasting glucose: Insulin ratio ($P = 0.290$) [Table 2].

Figure 1 represents the linear correlation coefficient (R) (cases: 0.85; controls: 0.06), percent variation explained ($R^2 \times 100$) (cases: 72.1%; controls: 3%), regression constant (cases: -101.0; controls: 29.57) and regression coefficient (cases: $\times 1.337$; controls: $\times 0.034$) for melatonin as dependent

Table 1: Demographic, anthropometric, biochemical, and hormonal parameters of the study population (polycystic ovarian syndrome cases and controls)

Parameters	Study population		<i>P</i> value
	PCOS (n=50)	Control (n=50)	
Age (years)	24.87 \pm 4.43	22.60 \pm 4.033	0.161
BMI (kg/m ²)	28.19 \pm 2.31	27.38 \pm 2.46	0.352
Waist: hip ratio	1.63 \pm 0.49	1.00 \pm 0.00	<0.001*
LH (mIU/mL)	16.13 \pm 7.95	7.18 \pm 1.97	<0.001*
FSH (mIU/mL)	5.43 \pm 1.53	6.60 \pm 2.86	0.106
LH/FSH ratio	3.10 \pm 1.69	1.15 \pm 0.25	<0.001*
TSH (IU/mL)	2.45 \pm 0.97	2.66 \pm 1.09	0.563
Prolactin (ng/mL)	14.7 \pm 4.48	13.35 \pm 3.26	0.380
Total testosterone (ng/dL)	122.84 \pm 6.96	84.71 \pm 12.75	<0.001*

Glucose insulin ratio	4.38 \pm 0.43	5.91 \pm 1.37	<0.001*

*P<0.05 was considered statistically significant. BMI=Body mass index, FSH=Follicle-stimulating hormone, LH=Luteinizing hormone, PCOS=Polycystic ovarian syndrome, TSH=Thyroid-stimulating hormone

Table 2: Distribution of melatonin in relation to demographic, anthropometric, biochemical, and hormonal profile of polycystic ovarian syndrome patient

Parameters	Melatonin (pg/mL)		<i>P</i> value
	Mean \pm SD		
Regular menstrual cycle	68.31 \pm 11.18	1.761	0.84
Oligomenorrhea	61.84 \pm 10.62		
Primary infertility	66.33 \pm 11.83	1.481	0.162
Secondary infertility	56.74 \pm 8.12		
Obese (>30 kg/m ²)	60.89 \pm 10.45	0.319	0.752
Overweight (25-<30 kg/m ²)	62.21 \pm 11.25		
LH: FSH ratio <2	71.24 \pm 8.89	2.649	0.013*
LH: FSH ratio ≥ 2	59.35 \pm 10.02		
Glucose insulin ratio ≤ 4.5	63.71 \pm 12.66	1.078	0.290
Glucose insulin ratio ≥ 4.5	59.46 \pm 8.07		
Testosterone (ng/dL) <118	53.28 \pm 3.78	12.68	0.001*
Testosterone (ng/dL) 118-128	62.45 \pm 6.74		
Testosterone (ng/dL) 128-140	74.53 \pm 10.99		

*P<0.05 was considered statistically significant. FSH=Follicle-stimulating hormone, LH=Luteinizing hormone, SD=Standard deviation

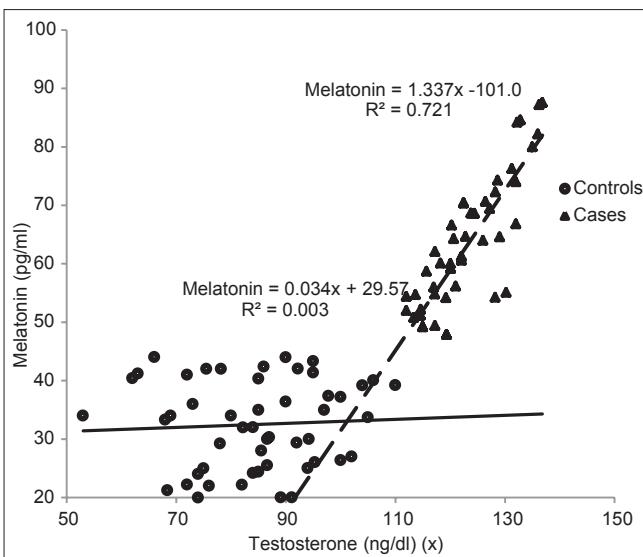

Figure 1: Linear regression of melatonin with testosterone

variable and testosterone as independent variable in both cases and controls. Testosterone explained 72.1% of total variability of melatonin in PCOS cases.

DISCUSSION

In present study, we found that patients with PCOS had significantly raised plasma melatonin levels ($>$ cut off value of 45 pg/mL) as compared with age- and weight-matched controls ($P < 0.001$). Melatonin is normally synthesized in the ovary, as both melatonin synthesizing enzymes AANAT (arylalkylamine N-acetyltransferase) and HIOMT (hydroxyindole-O-methyl transferase) are present in ovarian tissue.^[14] Melatonin, synthesized by the ovary, may be released into the follicular fluid. However, the bulk of melatonin detected in the ovary and preovulatory follicular fluid is derived from the circulation.^[10] There may be a reduction in the uptake of melatonin from circulation into the ovarian follicles of PCOS cases due to anovulation and increased number of atretic follicles and consequently serum melatonin concentration may increase in PCOS as a feedback response to decreased follicular concentration.^[10] Studies done by Luboshitzky *et al.*,^[9,15] gave the consistent results of raised plasma melatonin production in PCOS. They found that mean level of urinary 6-sulfatoxymelatonin (α MT6s), a major enzymatic metabolite of melatonin, in their study was $54.0 \pm 20.3 \mu\text{g}/24\text{ h}$ ($P = <0.001$). The study carried out by Lima *et al.*,^[16] confirmed the development of ovarian cysts in rats similarly to that observed in human PCOS under conditions of melatonin deficiency caused due to pinealectomy or continuous light in female rats.^[16]

Melatonin is a documented powerful free radical scavenger and a broad-spectrum antioxidant.^[11,12] Atresia is an apoptotic process that is highly regulated by proapoptotic

and antiapoptotic factors. In PCOS, ROS generation from mononuclear cells and serum lipid peroxidation products are significantly elevated,^[17,18] and levels of antioxidants superoxide dismutase, glutathione peroxidase, catalase get reduced, which ultimately may contribute to oxidative stress mediated apoptosis in atretic follicles.^[19] Melatonin has also been shown to regulate the gene expression of antioxidant enzymes superoxide dismutase, glutathione peroxidase, catalase and antiapoptotic/proapoptotic protein Bcl2 and Casp3. Melatonin prevents apoptosis by inducing Bcl2 expression and reducing Casp3 activity.^[10] Melatonin also acts as antioxidant by increasing insulin-like growth factor-1^[20] and transforming growth factor - beta (TGF- β) production.^[21] Normally, insulin-like growth factors act as mitogenic and antiapoptotic peptides. Thus, normally the increase in follicular melatonin concentration in the growing follicle could be an important factor in avoiding atresia. The follicle may be rescued by melatonin and this would allow a preovulatory follicle to fully develop and provide an oocyte for fertilization.^[10]

Melatonin influences sex steroid production at different stages of ovarian follicular maturation.^[10] It (100 mM) has been shown to increase progesterone and androgen production in mouse preantral follicles after incubation for 12 days.^[22] and melatonin (100 ng/mL) also stimulates progesterone and androgen production in 30-h cultures of porcine antral follicles without having any effect on estrogen levels.^[23] Similarly, the raised serum melatonin level seen in our PCOS cases was then found to be positively associated with serum testosterone level ($P < 0.001$). However, it has been seen that melatonin gets decreased in ovarian follicular fluid of PCOS patients and this intrafollicular decrease in melatonin is responsible for follicular atresia because of increased oxidative stress and consequent follicular damage in PCOS.^[10] These atretic follicles, escape full maturation and lead to formation of multiple small follicular cysts, surrounded by hyperplastic theca cells. Atretic follicles ultimately contribute to an expanding stroma that increases in volume over time, further increasing the cellular mass producing androgens, sets in another self-propagating cycle that predisposes to chronic anovulation and leads to increased concentration of androgens.^[24] Thus, melatonin correlates with hyperandrogenemia and anovulation in PCOS as found in our study ($R^2 = 0.721$). Women with ovarian hyperandrogenism have increased melatonin production only, which remains normal in women with hyperandrogenemia due to idiopathic hirsutism.^[9]

Hyperandrogenism is the key feature of PCOS, resulting primarily from excess androgen production in the ovaries and, to a lesser extent, in the adrenals. The primary mechanisms driving increased ovarian androgen production in PCOS include hypersecretion of LH and increased LH

bioactivity, hyperinsulinemia due to insulin resistance and increased volume of theca cells in an expanded ovarian stroma.^[24] In our study, serum melatonin was found to be positively associated with serum total testosterone levels, whereas it was inversely correlated with LH: FSH ratio and no correlation has been seen with fasting glucose: insulin ratio. This can be explained by diverse mode of action of melatonin, first by a direct action at receptors MT1 and MT2 leading to alteration in ovarian steroidogenesis and secondly by an action at follicular level as antioxidant.^[25]

High level of melatonin in the follicular fluid is essential for follicle growth, ovulation, and oocyte quality, whereas reduced follicular melatonin concentration may be responsible for anovulation and poor oocyte quality in PCOS. Follicles fail to mature fully and become atretic. Small follicles respond poorly to gonadotropins and undergo atresia.^[10]

Infertility is a major concern in PCOS patients and important causes of infertility in PCOS are follicular atresia, anovulation, and consequent hyperandrogenemia. Thus, melatonin can be used as a therapeutic agent to treat infertile patients undergoing *in vitro* fertilization in whom infertility occurs due to poor oocyte quality and anovulation and can create a new ray of hope for infertile patients. Melatonin may become the medicine of choice for improving oocyte quality for women who are unable to become pregnant because of poor oocyte quality.^[10,26] Melatonin works as a potent radical scavenger and antioxidant and thus may increase oocyte yield. In future, this may translate into improved oocyte quality as well. However, this needs further research and validation from larger studies.

Lacunae

Being the first study of its kind in India, we did not measure melatonin level in follicular fluid of PCOS patients. Correlation with midnight levels of melatonin was another hindrance in the study.

Scope of study

Future field of research would be to find out correlation between serum melatonin level and the level of antioxidants in PCOS patients. Determination of the quality of oocytes in relation to melatonin would be another area of exploration in patients of PCOS suffering from infertility.

Correspondence: Aysel Özdemir, Lecturer in Public Health Nursing, Uludağ University, Shcool of Health Sciences, 16059 Bursa, Turkey e-mail: ayozdemir@uludag.edu.tr**Abstract**

Obesity is public health burden and affects all age groups, including children and adolescents. For children aged between 2 and 19 years having a BMI $\geq 85^{\text{th}}$ percentile but $< 95^{\text{th}}$ percentile is defined as being overweight. Being obese is defined as having a BMI $\geq 95^{\text{th}}$ percentile. Nutrition during early development is directly associated with future obesity. In case of having an obese mother; offspring's obesity onset occurs earlier regardless of race or ethnic groups. Obesity brings psychosocial problems with itself. Obese children may have difficulties in interacting socially with environment; may have problems particularly with their age groups. Withdrawal from the society may be a major problem. Preventive measures focusing parents, family and environment should begin at preconception. Maternal factors of childhood obesity can be eliminated, and risk factors for developing adolescent and adult obesity may be avoided. These measures may help us first to decrease the rate of obesity and achieve a downward trend in prevalence. This in turn; may decrease the number of people with obesity and obesity related diseases.

Keywords: Adolescent; Obesity**Adolescent Obesity****Definition of Adolescent Obesity**

Obesity can be defined as having excessive body fat. Williams et al. in their study that involved 3320 children aged between 5 and 18 years stated that; risk factors for cardiovascular disease was more common in case of having at or above 25% fat in males and at or above 30% fat in females even after adjusting for age, race, fasting status, and trunkal fat pattern (D. P. Williams et al., 1992). For children aged between 2 and 19 years having a BMI $\geq 85^{\text{th}}$ percentile but $< 95^{\text{th}}$ percentile is defined as being overweight. Being obese is defined as having a BMI $\geq 95^{\text{th}}$ percentile (Barlow, 2007).

Epidemiology

Obesity is a global pandemic (WHO, 1998). It a matter of public health burden and spreading to all the age groups, including children and adolescents. A global epidemic of obesity occurred in recent years among adolescents, and prevalence of obesity is continuing to rise in this population (Reilly, 2006). Given the high prevalence and chronic nature of obesity, coordinated models of care for health-service delivery for the management of paediatric obesity are needed (Baur et al., 2011). In a study conducted by Freedman et al. (1999) the rate of being overweight was 10.8% in examined school children, while a 10.5% obesity prevalence was

found in more recently studied school population in Greece (Jelastopulu et al., 2012).

Age-standardized prevalence of overweight was 17.8% among boys and 15.8% among girls in a study conducted in India (Ramachandran et al., 2002). Though obesity prevalence increases as a global problem; a study based on data from 1998 through 2011 conducted in Denmark, showed that the prevalence rates of overweight and obesity in infants, children and adolescents were largely still on a plateau with tendencies for a decline among children and adolescents (Schmidt Morgen et al., 2013). But this may be far from representing the global picture.

In the Jelastopulu et. al (2012) study which was conducted in Greece, it was found that the prevalence of overweight and obesity in the studied population of 10–13 year old children it was 32% and 10.5%, respectively, while in children with parents of lower educational level, the odds of being overweight/obese was higher.

In all paediatric age groups there is an increasing prevalence of being overweight and obese. National Health and Examination Surveys (NHANES) in the US showed constant increases in the prevalence of overweight among children and adolescents at age 2 to 18 years. According to the data approximately 14% of children aged 2 to 5 years and 19% of

children aged 6 to 11 years were overweight (Ogden et al., 2006).

Nutrition during early development is directly associated with future obesity. The monthly family income, self-attitude toward obesity, taking extra salt and spending time with computer all are part of a vicious cycle that lead children and adolescents toward obesity (Ghosh, 2007). In a study, it was reported that breakfast skipping was associated with BMI strongly compared to other factors. Missing breakfast increased consumption of snacks and fast foods (Ghosh, 2014). In case of having an obese mother; offspring's obesity onset occurs earlier regardless of race or ethnic groups. And the combination of having an obese mother and an earlier onset of obesity affects young adulthood causing higher BMI and weight (Gordon-Larsen et al., 2007). The environmental factors are very effective in children. The proximity of fast food restaurants to the schools clearly causes bad eating habits and being overweight (Davis and Carpenter, 2009). For development of obesity many factors are described like intrauterine conditions, diabetes mellitus, smoking of the mother, breast-feeding duration, feeding during early life, weight gain in early childhood and at puberty (Fisberg et al., 2004).

Both genetic and environmental factors are effective in body mass index and waist circumference in children as a result of a study carried out in twin pairs at age of 8 to 11 years (Wardle et al., 2008).

An interesting result was the finding of decrease in the prevalence of obesity among adolescents with high-socioeconomic status, where among the low-socioeconomic status adolescents' obesity prevalence was continuing to increase (Frederick et al., 2014). This may be due to the fact that obesity is highly influenced from environment. Probably the social environment is better in adolescents with high socio-economic status. This in turn may be supported with the finding that obesity in school-aged children is associated with parental factors like parental obesity and health literacy (Chari et al., 2014).

Related clinical problems

Adolescent obesity is associated with increased mortality and morbidity related to a variety of chronic diseases later in life (Must et al., 1992). Obesity brings up many problems which affect the whole life span of the youngster and has adverse effects on the lipid, insulin, and blood pressure levels (Berenson et al., 1993; Freedman et al., 1985; D P Williams et al., 1992). Adiposity causes fatty streaks, raised lesions, and calcifications in the aorta

and coronary arteries in adolescents and young adults (Berenson et al., 1998; Mahoney et al., 1996; McGill et al., 1995). Overweight children are also at increased risk for various chronic diseases in later life and some evidence suggests that this association may exist independently of obesity status in adulthood (Must et al., 1992; Power et al., 1997). Also in a study that enrolled 1076 adolescents aged 14-16 years, birth weight and attained size at 20th and 43rd months were related to being overweight and having obesity during adolescence period. However; four of five obese adolescents were normal weight during childhood and that makes us to focus on normal weight children with bad eating habits or environmental conditions that are prone to become obese in adolescence (Monteiro et al., 2003).

Among 3,861 school children in the age group 5-15 years 292 (7.56%) were identified as obese in a study by Gupta. Further, 10 (3.4%) of the 292 obese subjects were detected to have sustained elevations in BP levels suggesting a close association between childhood obesity and essential hypertension (Gupta and Ahmad, 1990). Release of non-esterified fatty acids, cytokines and other factors from the adipose tissue in obese individuals causes development of insulin resistance. Addition of pancreatic islet beta cell dysfunction causes failure in blood glucose control (Kahn et al., 2006).

Being overweight during childhood is related to having type 2 diabetes mellitus, adult obesity, cardiac disease, low self-esteem and depressive disorders (Fisberg et al., 2004). Obesity brings psychosocial problems with itself. Obese children may have difficulties in interacting socially with environment; may have problems particularly with their age groups. Withdrawal from the society may be a major problem. They may have less self-confidence due to perception of their body shape. Obesity in adolescence is associated with depression or anxiety. In a study conducted in adolescents; obesity was a predictor of an increased risk for developing major depressive disorder in females but not males (Anderson et al., 2007). In adolescent females obesity but not being overweight was significantly associated with future depressive symptoms but not major depression in a study that was conducted in 2010. The authors said "these results suggest that weight status could be considered a factor along the pathway of development of depression in some adolescent females" (Boutelle et al., 2010). According to Goodman and Whitaker; having depression in adolescence, increases risk of obesity in adolescence and persistency of it. In conclusion

they said "understanding the shared biological and social determinants linking depressed mood and obesity may inform the prevention and treatment of both disorders" (Goodman and Whitaker, 2002).

Treatment

In adolescence obesity; the main approach should be prevention. We are now aware that Preconception maternal factors have much more influence on child obesity than prenatal factors (Ehrenthal et al., 2013). We must consider effect of social environment and friends on adolescent health. Adolescents develop certain behaviours probably to feel comfortable. This may be the explanation of overweight adolescents having twice as likely to have overweight friends as reported by Valente et al. (Valente et al., 2009). Interventions focusing behavioural changes must be a part of preventive therapy. Interventions may cause modest changes and modifying TV watching, physical activity, eating behaviours must be some of the goals. Of course not only the adolescent but parents, grandparents, sibling must also be targeted. The social environment, school has great effect and must be in scope. But this is a global burden and the governments must take serious preventive measures to prevent and treat the disease itself. Education of mother or woman of child-bearing age may provide control early at preconception. Maternal factors of childhood obesity can be eliminated, and risk factors for developing adolescent and adult obesity may be avoided. These measures may help us first to decrease the rate of obesity and achieve a downward trend in prevalence. This in turn; may decrease the number of people with obesity and obesity related diseases. Orlistat; a pancreatic lipase inhibitor, reduces fat absorption and used in treatment of obesity is used in adolescents in combination with diet, exercise and behavioural modification without safety issues but with more common gastrointestinal side effects (Chanoine et al., 2005). Sibutramine also was used in adolescents and caused significantly more weight loss compared to behavioural therapy and placebo (Berkowitz et al., 2003). Metformin; combination of caffeine and ephedrine all reduced body weight index in adolescents (Freemark and Bursey, 2001; Molnár et al., 2000). Surgical procedures are applied when more conservative treatment options fail (Kumar et al., 2012).

Conclusion

Adolescent obesity is a global health burden which will affect future generations' health. Treatment options are diverse but pharmacological and surgical

therapies posses' serious disadvantages in this age group. Preventive measures focusing parents, family and environment should begin at preconception. Interventional strategies should cover all population and the main objective should be eliminating causative factors.

Abstract: Circulating melatonin is elevated in women with polycystic ovary syndrome (PCOS); whether circadian disruptions coincide with sleep disturbances in women with PCOS or their symptom severity is unclear. The objective of this observational pilot study was to determine whether altered patterns of melatonin excretion are associated with reduced sleep quality in women with versus without PCOS. Participants underwent a clinical assessment, transvaginal ultrasound, and reproductive hormone testing. Morning and evening urine samples were assayed for urinary 6-sulfatoxymelatonin (MEL) as a proxy for melatonin production. The night (morning MEL)-to-day (evening MEL) ratio, or N:D ratio, was determined to approximate the rhythm of MEL production. Sleep quality and duration were assessed using the Pittsburgh Sleep Quality Index (PSQI) and wrist actigraphy. No differences were detected in overnight MEL, daytime MEL, or the N:D ratio in participants with PCOS versus controls. The PCOS group experienced reduced weekend sleep efficiency vs. controls (81% vs. 88% $p < 0.05$). The number of follicles per ovary (FNPO) was positively associated with overnight MEL ($r = 0.359$, $p < 0.05$). Weekend sleep time and overnight MEL concentrations were dependent on PCOS status. Therefore, diagnostic features of PCOS were associated with MEL production and sleep disturbances, suggesting that women with a more severe clinical presentation of PCOS may be more likely to experience altered MEL production or sleep disturbances.

Keywords: polycystic ovary syndrome; melatonin; sleep; sleep quality; ovary; circadian rhythm

1. Introduction

Polycystic ovary syndrome (PCOS) is a reproductive disorder characterized by oligo-anovulation, hyperandrogenism, and polycystic ovarian morphology that affects approximately 10% of reproductive-aged females [1]. PCOS is associated with significant metabolic and psychological sequelae [2]—both of which are factors that have been linked to impaired sleep [3,4]. Females with PCOS are more likely to experience sleep disorders such as obstructive sleep apnea, as well as abnormalities in sleep architecture (i.e., a reduction in the percentage of rapid eye movement sleep) when compared to those without PCOS [5]. Prior studies have also shown that those with PCOS experience lower sleep quality, reduced sleep efficiency, and greater daytime sleepiness relative to healthy controls [5–10]. In addition to negatively impacting quality of life, impaired sleep may have far-reaching health implications for those living with PCOS, as aberrant sleep patterns have been associated with a more severe metabolic profile, including obesity and insulin resistance [6]. Therefore, the relevance of sleep in the pathophysiology of PCOS and its associated comorbidities is of growing interest.

Melatonin is synthesized and secreted by the pineal gland and predominantly functions as a chronobiotic to synchronize and facilitate entrainment of behavioral and physiological rhythms [11,12]. Melatonin is primarily excreted in urine as 6-sulfatoxymelatonin (MEL), which closely reflects plasma concentrations [13]. Melatonin is also hypothesized to exhibit endocrinologic effects beyond its circadian role, with recent evidence demonstrating antioxidant activity within the ovary [5]. Specifically, melatonin has been implicated in the regulation of ovarian sex hormone production and in the reduction in local reactive oxygen species (ROS), thereby preventing follicular atresia [14]. Therefore, it is plausible that disruptions in melatonin secretion may impact not only circadian rhythms but also reproductive function. Indeed, there is evidence for disrupted melatonin secretion among women with reproductive dysfunction, including those with PCOS. Namely, elevated 24 h total [13], morning [6,15], and nighttime [8] melatonin concentrations have been documented in women with PCOS. Further, women with PCOS were shown to have a reduced night-to-day (N:D) ratio of MEL, driven by increased daytime MEL concentrations [16]. Given that the N:D ratio can serve as a proxy for the circadian rhythm of MEL production, a lower N:D ratio or dampened magnitude of the night-to-day shift of MEL implies that the physiological control of melatonin secretion by the circadian timing system may be altered in the context of PCOS. Factors impacting altered melatonin dynamics in PCOS are unclear, as are their alignment with the degree of disordered sleep common in this condition. The role of androgens is inconsistent, as both positive [6] and negative [13] associations between melatonin and hyperandrogenism have been reported. Evidence linking the degree of menstrual cycle dysfunction and/or ovarian dysmorphology to altered melatonin secretion is also largely unexplored. Interestingly, analysis of ovarian granulosa cells obtained from infertile women with PCOS has demonstrated blunting of the rhythmic expression of some circadian clock genes, highlighting the critical impact such disruptions may have on gonadal function [17]. Ultimately, more data are needed to corroborate that disrupted circadian rhythms may occur concurrently with and/or contribute to the pathophysiology of PCOS while simultaneously contributing to the appearance of marked sleep disturbances in these women.

To address this knowledge gap, the primary objective of this observational pilot study was to determine whether altered patterns of day and night MEL excretion coincided with reduced sleep quality among women with PCOS. A secondary objective was to determine whether disrupted MEL production was associated with the diagnostic features of PCOS.

2. Materials and Methods

2.1. Study Subjects

In this ancillary study, participants were prospectively recruited at the University of Rochester or Cornell University (ClinicalTrials.gov NCT01859663, NCT01927432, NCT01927471, NCT01785719) from 2015–2019. Existing study protocols already collecting relevant reproductive and metabolic endpoints were amended to include sleep and circadian endpoints uniquely for this study. Participants were phenotyped according to criteria supported by the 2018 International Guideline for PCOS [18]. Specifically, participants with PCOS met at least two out of the three criteria: menstrual irregularity, biochemical or clinical hyperandrogenism (HA), and/or polycystic ovarian morphology on ultrasound (PCOM). Menstrual irregularity was defined as <21 or >35 days between menses based on self-reporting during hormone-free intervals. Biochemical HA was defined as either Free Testosterone (T) > 0.815 ng/dL, bioavailable T > 19.06 ng/dL, or free androgen index (FAI) >6%; clinical HA was defined using a modified Ferriman Gallwey (mFG) score of ≥6. PCOM was defined as at least one ovary with an ovarian volume (OV) > 10mL or >9 follicles in a single cross-section of the ovary (FNPS)—the latter of which has been shown to have high diagnostic accuracy for PCOS on ultrasound [19]. Exclusionary criteria included the use of medications known or suspected to interfere with reproductive function within 2 months of enrollment, melatonin supplementation, elevated prolactin (PRL), thyroid stimulating hormone (TSH), or follicle-stimulating hormone (FSH),

current pregnancy or active breastfeeding. The non-PCOS reference group exhibited no more than one of the diagnostic criteria and is herein referred to as the control group.

2.2. Ethical Considerations

Written informed consent was obtained from the participants before any procedures were conducted. All parent protocols and study-specific amendments were approved by the Institutional Research Boards at Cornell University and the University of Rochester. Study procedures occurred at the Human Metabolic Research Unit (Cornell University, Ithaca, NY, USA) or Strong Fertility and Clinical Research Center (University of Rochester, Rochester, NY, USA).

2.3. Procedures

Participants attended a clinical research unit after an overnight fast for the following clinical assessments and procedures: (a) transvaginal ultrasound of the ovaries (b) reproductive and medical health history, (c) 75 g oral glucose tolerance test (OGTT), (d) physical exam and participant self-report to grade terminal hair growth using the modified Ferriman-Gallwey scoring system and (e) vitals and anthropometry assessment (waist and hip circumference, height, weight, blood pressure). Blood glucose was measured on-site using a glucometer (Accu-chek Aviva, Roche, Basel, Switzerland), and values were used to calculate the homeostatic model assessment for insulin resistance (HOMA-IR; $(\text{Insulin}_{0\text{hr}} * \text{Glucose}_{0\text{hr}})/22.5$) [20,21].

Participants with self-reported regular menstrual cycles were evaluated during the early follicular phase. Participants with self-reported irregular menstrual cycles were evaluated at random times. Participants were asked to reschedule their clinical assessments if investigators (1) observed the presence of a large follicle (>10 mm) or (2) had evidence of recent ovulation on the day of the ultrasound. Voluson ultrasound systems (GE, Milwaukee, WI, USA) using either a RIC5-9W-RS, RIC5-9A-RS, or RIC6-12-D endovaginal transducer were used to capture volumes of the ovaries. Images of the right and left ovaries were analyzed in 2D offline using a grid overlay [22] by trained members of the research team who achieved excellent agreement [intraclass correlation coefficient >0.9]. Follicle number per ovary (FNPO) represented the mean number of antral follicles 2–9 mm across both ovaries. Ovarian volume was determined using the following formula: $[\pi * (\text{average of all four linear measurements in orthogonal planes})]$ and reported as the mean of both ovaries, based on an internal study comparing different formulae to calculate ovarian volume in 2D versus 3D measures. If a dominant follicle was identified in one ovary, ovarian data from the other ovary were used in the event a follow-up ultrasound could not be scheduled. When poor image quality prevented reliable assessments in one of two ovaries, only the values of the ovary that could be visualized were analyzed by investigators.

2.4. Sleep-Related Endpoints

Sleep quality was assessed using the Pittsburgh Sleep Quality Index (PSQI), which is a valid and reliable 10-item questionnaire that reflects sleep habits for the most recent month based on self-report [23]. A score of less than or equal to 5 on the PSQI is associated with good sleep quality, whereas a score above 5 is associated with poor sleep quality.

Sleep measures were evaluated using a wrist-worn triaxial accelerometer. Participants were instructed to wear a triaxial accelerometer around their wrists at night and remove the device when out of bed for six consecutive nights. Participants recorded the dates and times the accelerometer was put on and taken off. The Sadeh Sleep Model [24] was used to compute overall, weekday night, and weekend night total sleep time and sleep efficiency. Sleep efficiency was reported as the percent of the time spent asleep divided by the time spent in bed. Participants were also instructed to obtain urine samples at home, collecting their first-morning void and evening (18:00–21:00) urine for two consecutive mornings and evenings during the week of wrist accelerometer wear. Participants were asked to record the dates and times of urine collection. Urine samples were stored in participants' home

freezers and were brought into their local clinical research unit on the ice. Urine samples were brought to room temperature for aliquoting and stored at -80°C until analysis.

2.5. Assays

Urinary 6-sulfatoxymelatonin (MEL) was measured using the Buhlmann ELISA kit in triplicate (inter- and intra-assay variability <10%). Urinary MEL concentrations were adjusted for urinary creatinine. The average of the replicates was computed for analysis. The N:D ratio was computed as mean overnight MEL divided by mean daytime MEL for each of the two 24 h periods of data collection, totaling two N:D ratios. Follicle-stimulating hormone (FSH), luteinizing hormone (LH), estradiol (E2), sex hormone binding globulin (SHBG), prolactin (PRL), and thyroid stimulating hormone (TSH) were measured from serum using chemiluminescence immunoassay, Siemens Medical Solutions Diagnostics, Deerfield, IL (inter- and intra-assay variability <10%). Total testosterone was measured using LC/MS/MS by a laboratory associated with the Centers for Disease Control and Prevention's Hormone Standardization Project (CDC-HoST) (Brigham Research Assay Core, Boston, MA, USA). FAI was calculated as Total T/SHBG (%). Free T and bioavailable testosterone were computed as described previously [25].

2.6. Statistical Analyses

Data were evaluated for normality, and the log was transformed as needed to meet statistical assumptions. Group comparisons were conducted using independent *t*-tests for continuous variables and Fisher's exact tests for categorical variables. Associations between the diagnostic features of PCOS and sleep-related endpoints were evaluated using Pearson partial correlations after adjusting for BMI (Table A1). To test whether associations between sleep quality (i.e., PSQI) or accelerometer-defined sleep measures and MEL concentrations (day, night, or night-to-day ratio) differed between PCOS and control groups, multiple linear regression analyses were conducted. The dependent variables were MEL or N:D ratio, and the predictors included a sleep measure-by-PCOS interaction term. Data are presented as mean \pm standard deviation (SD). Analyses were conducted using JMP Pro 14 (Cary, NC, USA). Statistical significance was set at $p < 0.05$. If participants had incomplete data collection for certain variables, they were still utilized in the analyses for which they had data. The original observational pilot sample size was determined via a power calculation to detect a difference in the mean N:D MEL ratio, which showed that six participants per group gave a statistical power of greater than 95% [16]. This sample size was preliminary, assuming a three-fold difference across groups, and was intended to generate effect sizes to inform a larger study.

3. Results

A total of forty-two participants were enrolled, with seven excluded due to oral contraceptive use ($N = 6$) and melatonin supplementation ($N = 1$). Twenty-two individuals met the criteria for PCOS, and thirteen met the criteria for controls. The demographic and clinical features of each group are shown in Table 1. There were no differences between groups with respect to BMI or age. By design and compared to controls, women with PCOS had significantly longer mean menstrual cycle lengths ($p < 0.05$), larger ovaries ($p < 0.0001$), increased follicle counts (FNPO, $p = 0.0016$, FNPS, $p = 0.003$), and were hyperandrogenic, as defined by hirsutism ($p = 0.033$) and TT ($p = 0.03$). Furthermore, 2 h insulin following an OGTT was higher ($p = 0.01$), and 2 h glucose also tended to be greater ($p = 0.051$) in PCOS versus controls.

Table 1. Demographic and clinical features.

	Control		PCOS		<i>p</i> Value
	Mean	Std Dev	Mean	Std Dev	
N	13		22		
Age (y)	28.0	5.8	28.3	5.5	NS
Age at menarche (y)	12.2	0.9	13.1	1.1	0.018
Anthropometry and glucoregulation					
BMI (kg/m^2)	31.3	4.49	30.9	9.41	NS
WHR	0.83	0.08	0.82	0.08	NS
Body fat (%)	39.4	5.43	39.7	10.21	NS

p-values reflect two-sided *t*-tests. Variables were transformed as needed (logarithmic or square root) to meet assumptions. Ovarian analyses reflect mean values, except when a dominant follicle (DF) or corpus luteum (CL) was present, then the ovarian data reflect the ovary that did not contain the DF or CL. Abbreviations: BMI, body mass index; WHR, waist-hip ratio; HOMA-IR, homeostasis model assessment for insulin resistance; MCL, mean cycle length; TT, total testosterone; FAI, free androgen index; FT, free testosterone; BIOT, bioavailable testosterone; Mean OV, mean ovarian volume; Mean FNPO, mean follicle number per ovary; Mean FNPS, mean follicle number per single cross-section; LH, luteinizing hormone; FSH, follicle stimulating hormone; SHBG, sex hormone binding globulin; Fasting glucose and insulin levels (0HR) prior to administration of a 75 g oral glucose tolerance test (OGTT) and 2 h afterward (2HR).

Differences in sleep-related endpoints between groups are presented in Table 2. No differences in MEL-related or PSQI-defined sleep variables were detected between PCOS and controls (*p* > 0.05). With respect to the accelerometer-defined sleep variables, women with PCOS had significantly reduced weekend sleep efficiency when compared to controls (81% vs. 88%, *p* = 0.01). Regression analyses with a sleep measure-by-PCOS interaction term revealed that the association between overnight MEL concentration and accelerometer-defined sleep time on the weekend differed between those with and without PCOS (Figure 1; *p*_{interaction} = 0.0416). Similarly, the association between N:D MEL ratio and weekend sleep efficiency varied by PCOS status (*p*_{interaction} = 0.0017, N:D MEL (1); *p*_{interaction} = 0.0028, N:D MEL (2)). There were no statistically significant interactions between PCOS status and PSQI or other accelerometer-defined sleep measures on any MEL outcomes (*p* > 0.05). With respect to data collection, 5 participants had incomplete MEL data sets, 1 participant did not complete the PSQI, and four did not have accelerometer-defined sleep data.

Table 2. Differences in sleep-related endpoints between PCOS and controls.

Urinary Melatonin Variables	Controls		PCOS		<i>p</i> Value	
	Mean	Std Dev	Mean	Std Dev		
Mean overnight MEL (ng MEL/mg CRE)	6213.07	4146.26	6972.42	3584.04	NS	
Mean daytime MEL (ng MEL/mg CRE)	865.93	643.20	1297.28	1122.41	NS	
Night/day ratio (1)	15.76	16.06	13.41	8.72	NS	
Night/day ratio (2)	13.60	13.01	11.49	8.57	NS	
PSQI-defined sleep variables						
PSQI total	5	2.7	7	4.0	NS	
Good sleep quality, N (%)	9 (69)		12 (55)		NS	
Poor sleep quality, N (%)	4 (31)		10 (45)			
Accelerometer-defined sleep variables						
Total sleep time (h/day)	6.5	0.80	6.5	0.94	NS	
Total weekday sleep time (h/day)	6.3	1.28	6.5	1.05	NS	
Total weekend sleep time (h/day)	7.1	1.16	6.5	1.46	NS	
Total sleep efficiency (%)	84	6.9	82	7.7	NS	
Weekday sleep efficiency (%)	82	10.1	81	7.6	NS	
Weekend sleep efficiency (%)	88	5.0	81	8.3	0.010	

Variables were transformed as needed (logarithmic or square root) to meet assumptions. Means and SD reflect raw data. Implausible values (sleep efficiency > 100%) were excluded from their endpoint-specific analyses. Categorical analyses were conducted using Fisher's Exact tests (two-sided). A PSQI score of >5 is categorized as poor sleep quality. MEL, 6-sulfatoxymelatonin; CRE, serum creatinine; PSQI, Pittsburgh Sleep Quality Index.

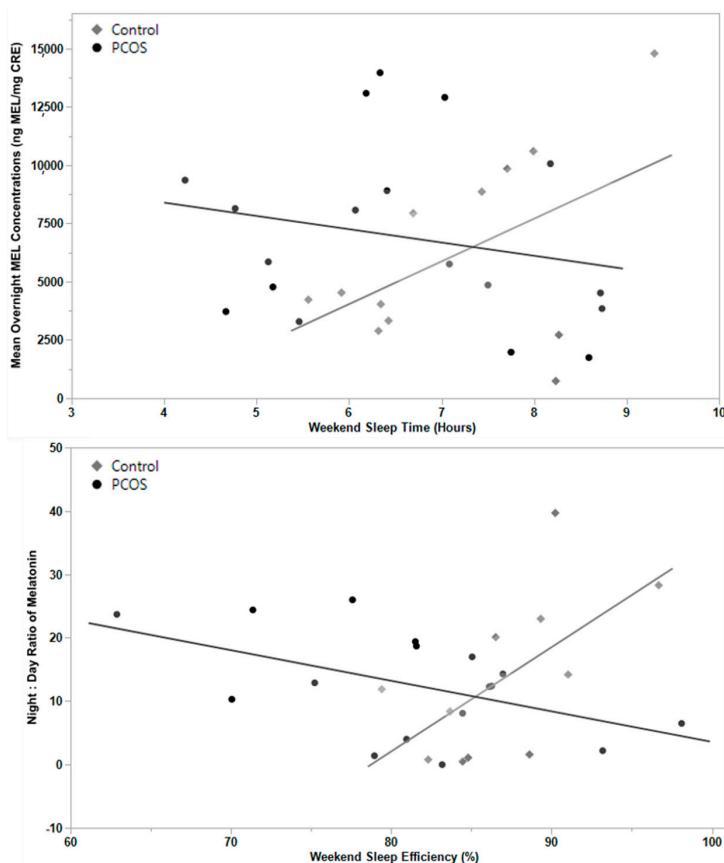

Figure 1. Associations between melatonin concentrations and weekend sleep quality are dependent on PCOS status. Associations between overnight melatonin production estimated using morning urinary MEL concentration and increasing weekend sleep time differ based on PCOS status (top panel; *p* < 0.05). Similarly, the association between N:D MEL ratios and weekend sleep efficiency differs based on PCOS status (bottom panel; *p* < 0.05).

Partial correlations were performed to assess the independent association between the diagnostic features of PCOS and urinary MEL endpoints, adjusting for BMI, which may have confounded the associations (Table A1). FNPO was positively associated with mean overnight MEL concentrations ($p < 0.05$; Table 3). No other significant associations between menstrual cyclicity, biochemical hyperandrogenism, or ovarian morphology and MEL endpoints were observed ($p > 0.05$).

Table 3. Associations between diagnostic features of PCOS and urinary melatonin.

	MCL	TT	FT	FAI	Bio T	OV	FNPS	FNPO
Mean overnight MEL (ng MEL/mg CRE)	−0.016	0.082	0.131	0.137	0.127	0.120	0.298	0.359 *
Mean daytime MEL (ng MEL/mg CRE)	0.177	0.074	0.093	0.087	0.092	0.215	0.137	0.206
N:D ratio (1)	0.134	0.136	0.208	0.218	0.204	0.123	0.299	0.246
N:D ratio (2)	−0.215	−0.001	−0.069	−0.076	−0.070	−0.114	0.047	0.074

Partial correlations between urinary melatonin concentrations and diagnostic features of PCOS. Partial correlations were adjusted for any potential confounding effects of BMI (Table A1). In the cases of women with dominant follicles, ovarian data from the other ovary were reported ($N = 6$) or excluded if in the luteal phase ($N = 1$). In this case, ovarian endpoints from the other ovary are presented. One participant was excluded from all ovarian analyses because both ovaries had DFs. Abbreviations: MEL, melatonin; CRE, creatinine; MCL, mean menstrual cycle length; TT, total testosterone; FT, free testosterone; FAI, free androgen index; Bio T, bioavailable testosterone; OV, ovarian volume; FNPS, follicle number per single cross-section; FNPO, follicle number per ovary; CRE, serum creatinine. *, $p < 0.05$.

4. Discussion

In this observational pilot study, we examined sleep quality in women with and without PCOS and tested whether an altered circadian rhythm output (i.e., urinary melatonin) is uniquely associated with poor sleep quality in individuals with PCOS. We also determined whether the degree of urinary melatonin excretion was associated with the severity of the diagnostic features of PCOS. Our data demonstrate that weekend sleep efficiency was lower in women with PCOS and that the association between weekend sleep time and overnight MEL concentrations is dependent on PCOS status. Furthermore, we report that FNPO is positively associated with mean overnight MEL concentration, which, to our knowledge, has not been previously reported.

Among all participants, mean overnight MEL was positively associated with FNPO but not hyperandrogenism, which was somewhat unexpected. The precise relationship between MEL and hyperandrogenism remains controversial, with previous studies reporting positive [6,26] or negative [13] associations between circulating androgens and MEL in PCOS. The relationship between MEL and ovarian morphology is also poorly established. We note two possible explanations for the associations between FNPO and MEL. First, it is plausible that in the present study, the degree of follicle excess (FNPO) may serve as a proxy for the phenotypic severity of PCOS [27] and that the severity of PCOS is associated with the magnitude of circadian rhythm disruption [15]. The severity of a PCOS phenotype may be related to the degree of circadian disruption as prior studies have demonstrated associations between melatonin and increased cardiovascular risk [16] and the degree of hyperandrogenism [6]—albeit not consistently. Second, increased MEL excretion may reflect ovarian inflammation and not hyperandrogenism. PCOS is characterized by a state of high oxidative stress [8], and melatonin has an antioxidant role as a free radical scavenger within the ovary [14]. Therefore, higher serum melatonin concentrations reported in PCOS may be a consequence of reduced intra-follicular melatonin concentrations via a negative feedback mechanism [14]. Furthermore, low intrafollicular melatonin has been associated with chronic anovulation and poor oocyte quality secondary to oxidative stress and a pro-inflammatory state [14]. A prior study examining human ovarian follicular fluid following in vitro fertilization cycles found that women with PCOS have lower intrafollicular melatonin levels than controls [28]. We posit that an increased FNPO in these patients may be indicative of pronounced ovarian dysfunction secondary to greater ovarian oxidative stress from a lower intrafollicular concentration of melatonin. The combination of

these features, therefore, may contribute to aberrant folliculogenesis. However, the degree to which MEL (the urinary metabolite of melatonin) reflects the intra-ovarian melatonin milieu is not well established and was not measured in this study; therefore, additional research is needed to corroborate this hypothesis. To contextualize this argument, PCOS has been described as a pro-inflammatory state, with prior studies demonstrating elevated C-reactive protein levels in addition to markers of oxidative stress [29]. Furthermore, a study examining the impact of 12 weeks of oral supplementation with melatonin in patients with PCOS demonstrated a reduction in serum inflammatory markers [29]. With respect to possible clinical implications of these findings, a future exploration of whether oral melatonin supplementation impacts intrafollicular melatonin levels and whether this correlates with a decrease in FNPO and/or an improvement in menstrual cyclicity would allow elucidation of a possible therapeutic pathway.

We also observed a misalignment between overnight MEL and sleep efficiency in participants with PCOS. In women without PCOS, overnight MEL increased as anticipated alongside increased sleep duration relative to the time spent in bed (sleep efficiency). However, in participants with PCOS, as sleep efficiency increased, the magnitude of the overnight MEL rise relative to the daytime was significantly blunted. This observation supports previous reports of circadian misalignment in this population. An increased MEL [13,26], increased morning MEL [15], and a delayed MEL offset after wakening [6] have all been observed in women and adolescents with PCOS. We should note that not all studies report concomitant sleep disruptions in women with PCOS, which we posit may be attributed to heterogeneity in how circadian rhythms and sleep patterns are assessed across studies. With that said, our study contributes to a growing body of evidence that sleep quality, assessed quantitatively, and MEL may be misaligned in women with PCOS. Whether disrupted melatonin production and MEL excretion are a cause or a consequence of poor sleep quality in PCOS (in our case, reduced sleep efficiency) remains unclear and warrants further investigation.

In a departure from previous studies, we did not detect group differences in PSQI-defined measures of sleep quality [8]. Similarly, we did not detect differences between PCOS and non-PCOS groups with respect to measures of circadian rhythm (as represented by overnight MEL, daytime MEL, or the N:D ratio), which contrasts previous studies reporting such findings [6,16]. However, our finding that weekend sleep efficiency is significantly reduced in the PCOS group is consistent with other studies [6,8,30]. Our null findings were unexpected, as co-morbid sleep disorders are known to be common in women with PCOS [7,9]. Likewise, insulin resistance is associated with both obstructive sleep apnea [7,31] and PCOS. Indeed, women in the PCOS group had higher insulin levels following an OGTT. However, as a group, they did not exhibit worse sleep quality. It is plausible that our participant pool—both the PCOS and control groups—may have blunted any effects of PCOS status. On average, neither group met the nightly sleep recommendation defined by the American Academy of Sleep Medicine (7–9 h per night) during the period of data collection, which is likely to have diluted any possible effect attributed to PCOS status [32]. It is also plausible that our definition of controls may have reduced the effect size attributed to PCOS status. Controls were defined as having no more than 1 of the diagnostic features of PCOS; therefore, they may have exhibited some mild evidence of reproductive dysfunction. As an observational pilot study, direct clinical correlations cannot be drawn from our results; however, our findings of a misalignment between MEL and sleep efficiency in participants with PCOS, as well as reduced weekend sleep efficiency, highlight the importance of discussing sleep and sleep hygiene during routine clinical evaluation. This is especially relevant, given the association between abnormal sleep, metabolic derangements, and insulin resistance—factors with well-established links to PCOS [6].

The study had several strengths. Participants were prospectively recruited and well-phenotyped by the research team using detailed reproductive health histories, standardized testosterone assays, and rigorous ovarian imaging. We conducted a comprehensive assessment of metrics to assess sleep quality and circadian rhythm, which enabled comprehensive

assessments of qualitative and quantitative sleep quality alongside MEL. The study also had limitations. Although we provided instructions for week-long accelerometer wear, participant compliance represented a significant challenge in capturing sleep and circadian shifts, and therefore, wrist-worn accelerometer wear was varied (total number of weekday nights data obtained: 3 to 5; total number of weekend nights data obtained: 1 to 2). Moreover, because the timing of urine can greatly reflect the degree to which overnight MEL production is captured or missed [33], it is plausible that the null findings may be partially attributed to inconsistent timing of urine collection (first morning voids among participants ranged from 04:00–12:00). We acknowledge that measurement of urinary 6-sulfatoxymelatonin in urine using ELISA may significantly overestimate circulating MEL levels [34] and that our approach abrogates any definitive conclusions regarding the exact timing and amplitude of MEL secretion. Future studies would benefit from the assessment of dim light onset MEL (DLMO) in plasma or salivary samples collected every 30 min to 1 h during a constant dim light protocol and assayed using mass spectrophotometry. Reduced compliance also resulted in missing values, which may further reduce the ability to detect differences across groups. The nature of this observational pilot study did not allow for subdivision by PCOS phenotype; therefore, the impact of phenotypic severity per se, on circadian disruption could not be elucidated. With respect to sample size, our analysis determined that we were sufficiently powered to detect a statistically significant difference when investigating the mean N:D MEL ratio as an outcome. However, future research should include larger sample sizes to establish clinically meaningful differences (i.e., threshold of clinical significance) to investigate among the different PCOS phenotypes. Finally, one participant reported a history of obstructive sleep apnea during study participation, which may lower sleep quality due to nighttime awakening. Although it is unlikely that one participant could drive an effect size, future studies should carefully screen participants for sleep-disordered breathing at the time of enrollment, given the increased risk of OSA in women with PCOS, even after controlling for BMI [5].

5. Conclusions

In summary, we report reduced weekend sleep efficiency and evidence of misalignment between circadian rhythms and sleep quality in participants with PCOS. We also report that the degree of overnight MEL is positively associated with increasing follicle number, suggesting that the severity of a PCOS phenotype may be linked to circadian disruption. Due to the heterogeneity in sample collection, additional research is needed to corroborate these findings. However, these data provide formative evidence that the pathophysiology of PCOS may be closely related to circadian disruption, and there is fertile ground for further clinical investigation.

Author Contributions: All authors have contributed actively to this manuscript, critically evaluated the final version, and agree with its submission. Conceptualization, M.E.L. and K.H.; Formal analysis, A.T.E., H.V.B. and J.S.L.; Funding acquisition, H.V.B., B.Y.J., M.E.L. and K.H.; Investigation, H.V.B., J.S.L., B.Y.J., A.W.L., M.E.L. and K.H.; Methodology, M.E.L. and K.H.; Supervision, M.E.L. and K.H.; Writing—original draft, A.T.E. and H.V.B.; Writing—review and editing, J.S.L., B.Y.J., A.W.L., M.E.L. and K.H. Funding: Funded in part by a research award from the Richard W. and Mae Stone Goode Foundation, National Institutes of Health (R56-HD089962 to K.H., R01-HD093748 to M.E.L., T32-DK007158 to B.Y.J.) and Canadian Institutes of Health Research (FRN 146182 to H.V.B.).

Institutional Review Board Statement: To conduct this observational pilot investigation, the study team designed an auxiliary study, which was amended onto four prospective ongoing studies (NCT01927432, NCT01927471, NCT01859663, NCT01785719) to obtain sleep-specific endpoints uniquely for this study. Written informed consent was obtained from the participants before any procedures were conducted. Both parent protocols and study-specific amendments were approved by the Institutional Research Boards at Cornell University and the University of Rochester. Study procedures occurred at the Human Metabolic Research Unit (Cornell University, Ithaca, NY, USA) or Strong Fertility and Clinical Research Center (University of Rochester, Rochester, NY, USA).

Informed Consent Statement: Written informed consent was obtained from the participants before any procedures were conducted.

Data Availability Statement: The data presented in this study are available upon reasonable request from the corresponding author.

International evidence-based guideline for the assessment and management of polycystic ovary syndrome 2018

Publication approval

Australian Government

National Health and Medical Research Council

The guideline recommendations on pages 16 to 34 of this document were approved by the Chief Executive Officer of the National Health and Medical Research Council (NHMRC) on 2 July 2018 under section 14A of the *National Health and Medical Research Council Act 1992*. In approving the guideline recommendations, NHMRC considers that they meet the NHMRC standard for clinical practice guidelines. This approval is valid for a period of five years.

NHMRC is satisfied that the guideline recommendations are systematically derived, based on the identification and synthesis of the best available scientific evidence, and developed for health professionals practising in an Australian health care setting.

This publication reflects the views of the authors and not necessarily the views of the Australian Government.

Disclaimer

The Centre for Research Excellence in Polycystic Ovary Syndrome (CREPCOS) research in partnership with the European Society of Human Reproduction and Embryology (ESHRE) and American Society of Reproductive Medicine (ASRM), and in collaboration with professional societies and consumer advocacy groups internationally, developed the evidence-based guideline to provide evidence-based recommendations to improve the quality of healthcare, health outcomes and quality of life of women with PCOS. The guideline represents the integration of the best evidence available at the time of preparation, multidisciplinary, international clinical perspectives and patient preferences. In the absence of scientific evidence in PCOS, evidence from the general population was considered and a consensus between the engaged stakeholders was obtained.

The aim of evidenced-based guideline is to aid healthcare professionals and consumers in decisions about appropriate and effective care, although recommendations are generalised and application requires consideration of individual patient characteristics and preferences. All recommendations and practice points need to be considered in the context of regional regulations.

Adherence to the guideline does not guarantee a successful or specific outcome in an individual or override the healthcare professional's clinical judgment or patient preference in diagnosis and treatment of individual patients. Ultimately, healthcare professionals must make their own clinical decisions on a case-by-case basis, using their clinical judgment, knowledge, and expertise, and taking into account the condition, circumstances, and perspectives of the individual patient, in consultation with that patient and/or the guardian or carer.

The guideline partners make no warranty, express or implied, regarding the guideline and specifically excludes any warranties of merchantability and fitness for a particular use or purpose. The partners shall not be liable for direct, indirect, special, incidental, or consequential damages related to the use of the information contained herein. While the partners have made every effort to compile accurate current information, however we cannot guarantee the correctness, completeness, and accuracy of the guideline in every respect at all times. Guidelines do not necessarily represent the views of all clinicians that are members of the partner and collaborating societies. The information provided in this document does not constitute business, medical or other professional advice, and is subject to change.

Preface

This International evidence-based guideline for the assessment and management of Polycystic Ovary Syndrome (PCOS), designed to provide clear information to assist clinical decision making and support optimal patient care, is the culmination of the work of over 3000 health professionals and consumers internationally. The vast majority gave of their time and expertise voluntarily. We fully appreciate the considerable contributions of the guideline development group members and particularly of the project board ([Appendix I](#)), international advisory board ([Appendix II](#)) and most importantly to the chairs, co-chairs and members of the international, multidisciplinary guideline development groups ([Appendix III](#)).

Acknowledgement goes to the tireless efforts, commitment, dedication and drive of the Project Manager, Ms Linda Downes, Evidence lead Dr Marie Misso, Translation lead Dr Rhonda Garad, Project Board Chair, Professor Robert Norman, and the guideline evidence team for their contribution. We acknowledge the enthusiasm and engagement of the health professionals and women affected by PCOS, our partners European Society of Human Reproduction and Embryology and American Society for Reproductive Medicine and our collaborating and engaged professional societies and consumer advocacy and support organisations internationally. These stakeholders have guided scope, identification of gaps and needs, prioritisation of clinical questions and outcomes of importance, review of evidence, formulations of recommendations and the guideline, as well as development and implementation of the dissemination and translation program.

Professor Helena Teede MBBS, PhD, FRACP, FAAHMS.

Director, National Health and Medical Research Council Centre of Excellence in PCOS International PCOS Guideline lead
Director, Monash Centre for Health Research and Implementation (MCHRI),
Monash Public Health and Medicine, Monash University
Executive Director, Monash Partners Academic Health Sciences Centre
Endocrinologist, Monash Health

Abstract

Objective: To develop and translate rigorous, comprehensive evidence-based diagnosis, assessment and treatment guidelines, to improve the lives of women with polycystic ovary syndrome (PCOS) worldwide.

Participants: Extensive health professional and patient engagement informed guideline priority areas. International Society-nominated panels included consumers, paediatrics, endocrinology, gynaecology, primary care, reproductive endocrinology, psychiatry, psychology, dietetics, exercise physiology, public health, project management, evidence synthesis and translation experts.

Evidence: Best practice evidence-based guideline development involved extensive evidence synthesis and the Grading of Recommendations, Assessment, Development, and Evaluation (GRADE) framework covered evidence quality, feasibility, acceptability, cost, implementation and ultimately recommendation strength.

Process: Governance included an international advisory board from six continents, a project board, five guideline development groups with 63 members, consumer and translation committees. The Australian Centre for Research Excellence in PCOS, funded by the National Health and Medical Research Council (NHMRC), partnered with European Society of Human Reproduction and Embryology and the American Society for Reproductive Medicine. Thirty seven organisations across 71 countries collaborated with 23 face to face international meetings over 15 months. Sixty prioritised clinical questions involved 40 systematic and 20 narrative reviews, generating 166 recommendations and practice points. Convened Committees from partner and collaborating organisations provided peer review and the guideline was approved by the NHMRC.

Conclusions: We endorse the Rotterdam PCOS diagnostic criteria in adults (two of clinical or biochemical hyperandrogenism, ovulatory dysfunction, or polycystic ovaries on ultrasound) and where irregular menstrual cycles and hyperandrogenism are present, highlight that ultrasound is not necessary in diagnosis. Within eight years of menarche, both hyperandrogenism and ovulatory dysfunction are required, with ultrasound not recommended. Ultrasound criteria are tightened with advancing technology. Anti-Müllerian hormone levels are not yet adequate for diagnosis. Once diagnosed, assessment and management includes reproductive, metabolic and psychological features. Education, self-empowerment, multidisciplinary care and lifestyle intervention for prevention or management of excess weight are important. Depressive and anxiety symptoms should be screened, assessed and managed with the need for awareness of other impacts on emotional wellbeing. Combined oral contraceptive pills are first-line pharmacological management for menstrual irregularity and hyperandrogenism, with no specific recommended preparations and general preference for lower dose preparations. Metformin is recommended in addition or alone, primarily for metabolic features. Letrozole is first-line pharmacological infertility therapy; with clomiphene and metformin having a role alone and in combination. In women with PCOS and anovulatory infertility, gonadotrophins are second line. In the absence of an absolute indication for IVF, women with PCOS and anovulatory infertility, could be offered IVF third line where other ovulation induction therapies have failed. Overall evidence is low to moderate quality, requiring significant research expansion in this neglected, yet common condition. Guideline translation will be extensive including a multilingual patient mobile application and health professional training.

Executive Summary

This international guideline and translation program addresses health professional and consumer priorities. The guideline integrates the best available evidence with international, multidisciplinary clinical expertise and consumer preferences to provide health professionals, consumers and policy makers with guidance. The guideline and translation program promote accurate and timely diagnosis and optimal and consistent assessment and treatment of polycystic ovary syndrome (PCOS), with prevention of complications and improved patient experience and health outcomes for the one in ten women worldwide with PCOS.

Context and background

Polycystic ovary syndrome (PCOS) is a significant public health issue with reproductive, metabolic and psychological features. PCOS is one of the most common conditions in reproductive aged women affecting 8-13% of reproductive-aged women [1-4] with up to 70% of affected women remaining undiagnosed [3]. Presentation varies by ethnicity and in high-risk populations such as Indigenous women, prevalence and complications are higher [4, 5]. Women with PCOS present with diverse features including psychological (anxiety, depression, body image) [6-8], reproductive (irregular menstrual cycles, hirsutism, infertility and pregnancy complications) [9] and metabolic features (insulin resistance (IR), metabolic syndrome, prediabetes, type 2 diabetes (DM2) and cardiovascular risk factors) [10, 11].

Diagnosis and treatment of PCOS remain controversial with challenges defining individual components within the diagnostic criteria, significant clinical heterogeneity generating a range of phenotypes with or without obesity, ethnic differences and variation in clinical features across the life course. These factors contribute to variation in diagnosis and care across geographical regions and health professional groups [12]. This culminates in delayed diagnosis, poor diagnosis experience and dissatisfaction with care reported by women internationally [13]. These challenges are exacerbated by a lack of recognition of the diverse features of PCOS, inadequate funding for quality research and a lack of comprehensive international evidence-based guidelines [14]. In this context, there was a compelling need for development and translation of an international evidence-based guideline for assessment and management of PCOS, addressing psychological, metabolic and reproductive features of PCOS, promoting consistent evidence-based care and guiding and encouraging research in PCOS.

The extensive international guideline network across our partners and collaborators engaged in prioritisation of clinical questions and outcomes, identification of gaps in knowledge and care and into translation preferences and information needs for health professionals and consumers. This stakeholder engagement directly informed the guideline and translation program and involved over 3000 health professionals and consumers with PCOS. Our partners and collaborators contributed members to the guideline governance, development and translation committees. They formed special interest groups with considerable expertise in PCOS to provide feedback during the public consultation process and are engaged in translation and evaluation. Partners and collaborators have agreed that the National Health and Medical Research Council (NHMRC) is the single approving body for the guideline.

Governance included international representation across the Advisory Committee, Project Board, Consumer Reference Group, Translation Committee and five multidisciplinary Guideline Development Groups comprising partner and collaborator nominated experts, practising clinicians and consumers ([Figure 1](#), [Figure 2](#) and [Appendix I-III](#)). Guideline development groups and special interest groups/experts were nominated by the partner and collaborator organisations. The Australian Centre for Research Excellence in PCOS (CREPCOS), funded by the National Health and Medical Research Council (NHMRC), led and primarily funded the guideline development. In this endeavour, we partnered with the European Society of Human Reproduction and Embryology (ESHRE) and the American Society for Reproductive Medicine (ASRM) to fund and complete the guideline.

Guideline development engagement and processes were extensive and followed best practice. Four project board and 15 guideline development group face to face meetings occurred across Europe, USA and Australia over 15 months, and enabled training, guideline development and informed translation. Sixty prioritised clinical questions were addressed with 40 systematic and 20 narrative reviews, generating 166 recommendations and practice points.

International best practice comprehensive methods for evidence review and guideline development were applied, aligned with the NHMRC and ESHRE requirements. A highly experienced team undertook evidence synthesis with a focus on study designs least susceptible to bias; *a priori* criteria for inclusion and appraisal of studies, stakeholder prioritised clinical questions and outcome measures, extraction of study data; quality appraisal and meta-analysis where appropriate. Recommendations were formulated using the considered judgement process in the Grading of Recommendations, Assessment, Development, and Evaluation (GRADE) framework [15] across the quality of available evidence, integrating clinical expertise and consumer preference, and considering the applicability, feasibility, equity, cost effectiveness, implementation and value for consumers and health professionals through the GRADE framework. Implementation issues and international health systems and settings were also considered. Special interest groups of world experts and affected women were formulated to review and provide feedback on the guideline, with subsequent refinement and guideline development group approval. The guideline was then appraised independently by independent evidence synthesis experts and submitted to NHMRC for consideration of approval.

Guideline purpose and aims

The purpose of this international evidence-based guideline is to integrate the best available evidence with multidisciplinary expertise and consumer preferences to provide health professionals, consumers and policy makers with transparent evidence-based guidance on timely diagnosis, accurate assessment and optimal treatment of PCOS, to reduce variation in care, optimise prevention of complications and improve health outcomes.

The guideline aims to ensure that women with PCOS receive optimal, evidence-based care by:

- engaging multidisciplinary international expert representation in PCOS care nominated by partner and collaborator societies;
- including international consumer and primary care representatives;
- following rigorous Appraisal of Guidelines for Research and Evaluation (AGREE) II-compliant evidence-based guideline processes;
- developing an international comprehensive guideline on diagnosis, assessment and management of PCOS;
- providing a single source of international evidence-based recommendations to guide clinical practice and reduce variation worldwide, with the opportunity for adaptation in relevant health systems as needed;
- providing a basis for improving patient outcomes;
- identifying knowledge gaps and promoting research and translation into practice and policy;
- co-developing resources to upskill health professionals and empower consumers, including a mobile app and online resources; and
- delivering an international translation program with in-depth evaluation.

Key principles

Principles that underpinned the development and interpretation of all evidence-based guidelines are:

- the need for consumers and health professionals to recognise the life course implications of PCOS;
- partnership between health professionals and women in managing PCOS;
- individual differences, preferences and modulating or exacerbating factors are understood;
- metabolic, reproductive and psychological features of PCOS are all considered;
- education, optimal lifestyle and emotional wellbeing are important in PCOS; and
- Indigenous and high-risk ethnic populations are considered.

Patient population

This guideline is relevant to the assessment and management of adolescents, reproductive age and postmenopausal women who have PCOS, including women with PCOS who are infertile.

Setting and audience

The guideline is designed to apply in a broad range of health care settings and to a broad audience including:

- Patients
- General practitioners/primary care physicians
- Obstetricians and gynaecologists
- Endocrinologists
- Dermatologists
- Allied health professionals - psychologists, dietitians, exercise physiologists, physiotherapists
- Community care practitioners
- Indigenous health care workers
- Nurses
- Policy makers
- Community support groups (i.e. POSAA)
- General public
- Students

When translating the guideline into practice, issues such as cost, accessibility, availability and ethnic considerations are required.

Governance

A formal international governance process was established as outlined in [Figure 1](#).

Figure 1: Governance

Evidence-based guideline for assessment and management of PCOS update project governance

International Strategic Advisors Group

(Chair Prof Bart Fauser)

CRE Co-Director (Prof Rob Norman), CALD Advisor, international consumer representative(s), Evidence-based guidelines lead, international society representatives including ESHRE and ASRM and geographical representation

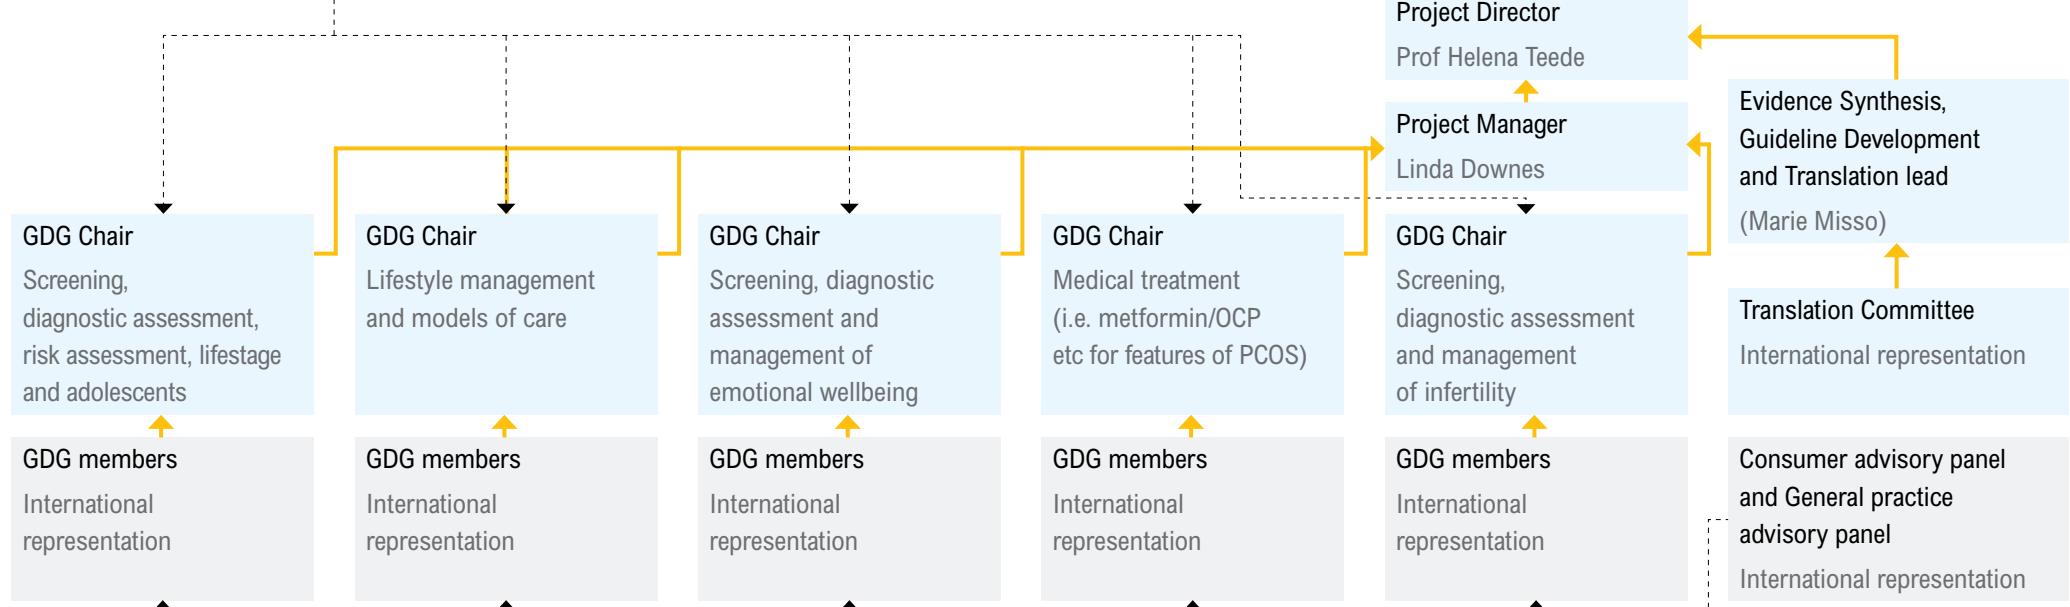

CRE in PCOS Steering Committee / Monash University (Chair Rob Norman)

Project Board

Project Owner and Project Director CRE Co-Director of CRE (Prof Helena Teede)

Senior User – PCOS consumer; GP; representation from clinical specialties and allied health, Chair – International Strategic Advisors Group

Senior Suppliers – GDG Chairs; Guideline Development Lead; representatives from international organisations **contributing at least 10% project funding** (ESHRE X 2 and ASRM X 1 included)

Definitions:

Project Owner:

Person ultimately accountable for the success of the project and owns the business case. Has the final say in decision making process.

Senior User:

Represents end users of the delivered service. Chairs Project User Group if there is one.

Senior Supplier:

Senior representative of project's suppliers. There may be more than one.

Project Director:

Project Owner's eyes and ears on the job. Undertakes day to day management and decisions on behalf of the Project Owner.

Strategic Advisors Group:

Represents key stakeholders with valid interest, but not sufficiently central to project success to warrant a seat on the Project Board.

Concerns and issues in this group have a direct conduit to the Project Board.

Decision making path

Advisory and feedback path

Guideline Development Groups

Guideline development groups (GDGs) were formed based on skills (clinical and academic interests), expertise, geographical spread **and were nominated by partner or collaborator organisations**. The GDGs encompassed the broad range of clinical expertise involved in the care of women with PCOS as well as consumers. Over 100 members were engaged across the governance, guideline development and translation committee. Whilst this does not encompass all leaders internationally with expertise in PCOS, these were engaged in the consultation process through online surveys and in providing feedback into the guideline through special interest groups formed across the partner and collaborator organisations. Representatives from all continents engaged in the process, however given primary funding was from the Australian Government, diverse Australian organisations engaged.

Prioritised clinical questions

Prioritisation of guideline clinical questions was informed by an International Delphi exercise and by the multidisciplinary GDGs, with final questions (detailed in the methods section) addressed across:

GDG 1 Screening, diagnostic assessment, risk assessment and life-stage

GDG 2 Prevalence, screening, diagnostic assessment and management of emotional wellbeing

GDG 3 Lifestyle management and models of care

GDG 4 Medical treatment

GDG 5 Screening, diagnostic assessment and management of infertility

What the guideline does not address

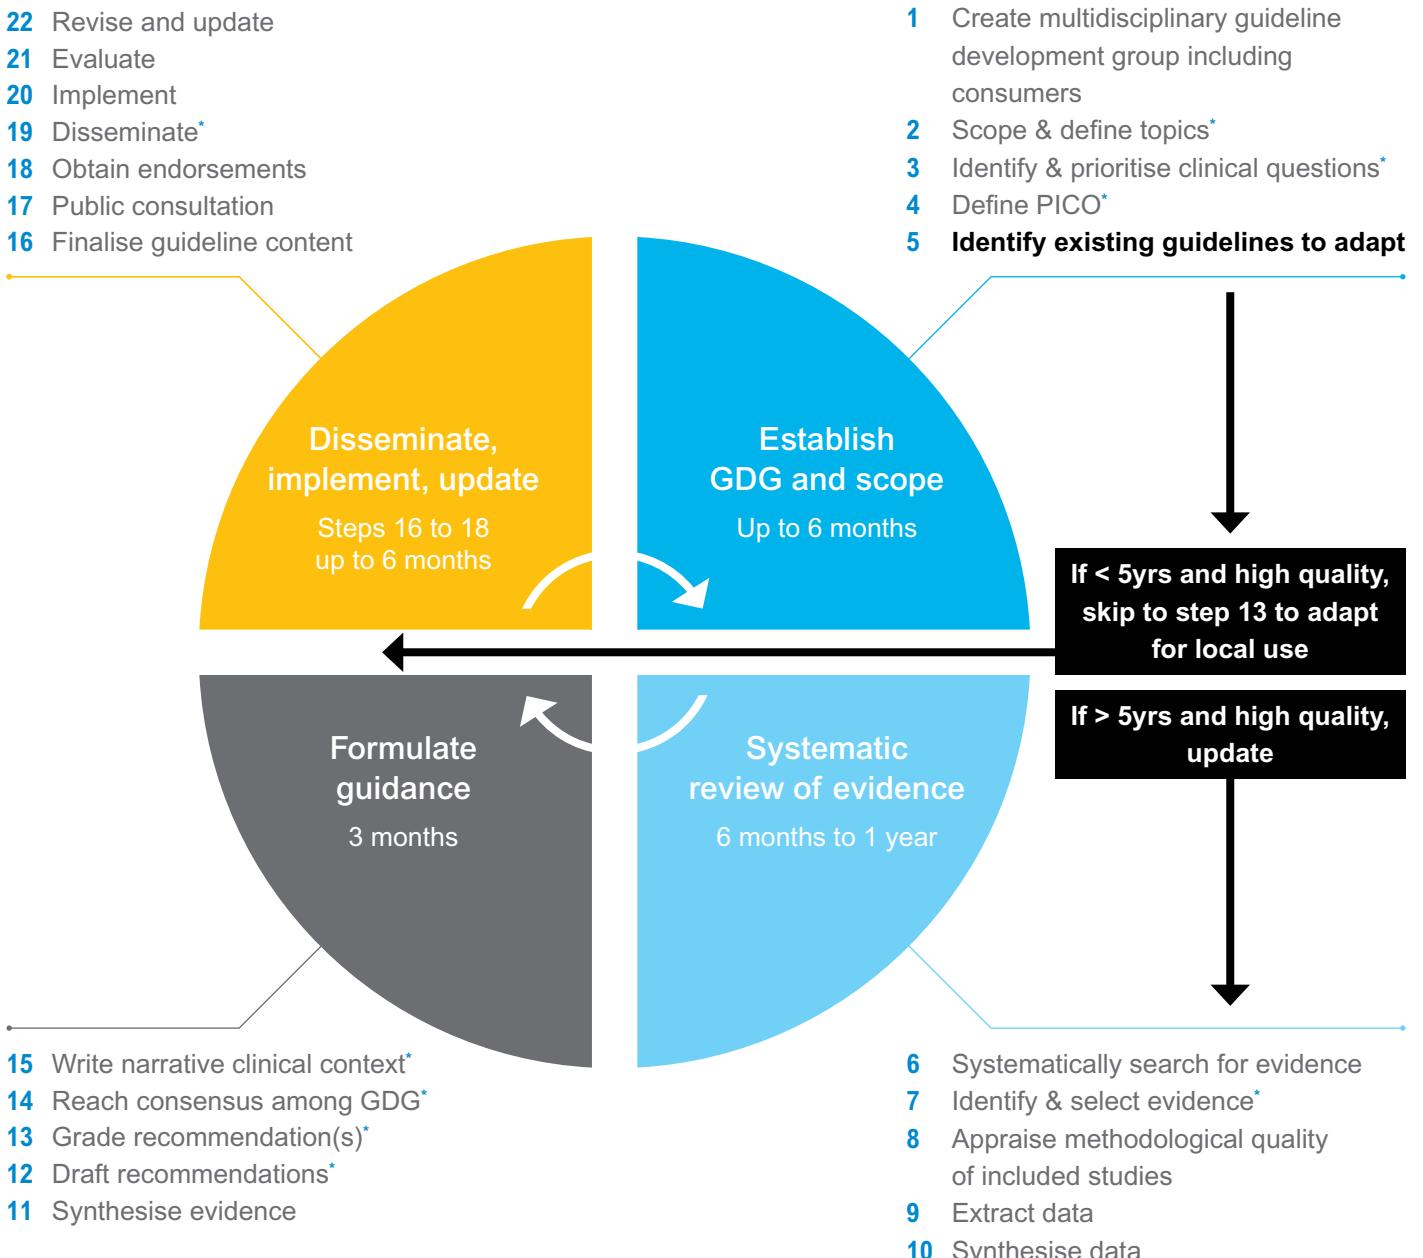

This guideline does not seek to provide full safety and usage information on pharmacological and surgical interventions. The pharmacological and surgical interventions recommended in the guideline should not be applied without consideration of the patient's clinical profile and preferences. We recommend that the reader consults relevant regional bodies for prescribing information including indications, drug dosage, method and route of administration, contraindications, supervision and monitoring, product characteristics and adverse effects. All recommendations and practice points need to be considered in the context of regional regulations. This guideline does not include a formal analysis of cost effectiveness or economic feasibility, however the potential impact of cost on recommendations was considered in GRADE process.

Guideline development methods

Methods used to develop this guideline align with international best practice, and follow comprehensive evidence-based guideline development processes and criteria including the Appraisal of Guidelines for REsearch & Evaluation (AGREE II), the Australian National Health and Medical Research Council (NHMRC) and ESHRE criteria. The steps are summarised in Figure 2, with details found in [Chapter 6: Guideline Development Methods](#).

Figure 2: Guideline development process

(adapted from Misso and Teede, Knowledge Transfer: Practice, Types and Challenges 2012, Nova Publishers)

* Time points and tasks where prioritisation of engagement from GDG is required.

Community and consumer engagement

Extensive engagement and formative research on unmet needs of women with PCOS was a key driver for this work. Far-reaching engagement included focus groups and then surveys of over 1500 women with PCOS. We adopted the International Association for Public Participation (IPA), Public Participation Spectrum framework, in which consumer's capacity to participate was built and enhanced throughout the process. Consumers were engaged in all phases as active contributors within a distributed decision making environment, ensuring that the lived experiences of women with PCOS were prioritised. Consumer representatives were informed about the process of participation and at GDG meetings were present to embed consumer perspectives within the GRADE decision-making process. Consumers were empowered to ensure that all decisions optimised participation in care. Consumer organisations proactively participated in feedback and public consultation processes and have co-designed and will continue to guide and influence the implementation, translation and dissemination program.

Funding

The Australian NHMRC funded guideline development through the NHMRC Centre for Research Excellence in Polycystic Ovary Syndrome (APP1078444), administered through Monash University and University of Adelaide, Australia. Guideline partners, European Society of Human Reproduction and Embryology (ESHRE) and American Society for Reproductive Medicine (ASRM) provided additional funding and assisted in guideline development activities.

Editorial independence and disclosures of interest

This guideline is editorially independent. The primary funders, NHMRC, were not involved in the development of the guideline and have not influenced the scope. They set standards for guideline development and based on independent peer review approved the guideline process. ESHRE and ASRM nominated experts in PCOS who participated in the project board and GDGs. ESHRE and ASRM formed special interest groups to provide feedback on the guideline during public consultation and all feedback was reviewed by the project board and GDGs, blinded by the organisation providing the feedback. All members of committees and GDGs publicly disclosed all relevant interests and these were reviewed at each meeting and considered when making recommendations.

Guideline translation

A comprehensive, international translation program will disseminate, translate and amplify the impact of the international evidence-based guideline on the assessment and management of PCOS (see [Dissemination and implementation](#)).

The aims of the translation program are to:

- build capability of health professionals to deliver high-quality, evidence-based assessment and management of PCOS;
- augment the health literacy of PCOS health consumers, optimising diagnosis and improving health outcomes; and
- promote best-practice evidence-based PCOS care.

The guiding principles of the comprehensive international translation and dissemination program are:

- components are informed by the needs and preferences of women with PCOS;
- resources are co-created with, and attuned to, the needs of end-users; and
- dissemination strategies are multi-faceted, multi-modal and refined to the communication channels of end-users.

Central to the translation and dissemination program is active engagement of 37 partner and collaborator organisations ([see acknowledgements](#)) and leading engaged health experts who will leverage their extensive reach and influence to promote guideline uptake. Leading consumer groups internationally and translation organisations are strongly engaged and committed to translation and impact. The program is supported by a comprehensive evaluation framework, measuring international impacts and outcomes.

Context statement on diagnosis: Prelude to the guideline

In the international evidence-based guideline for the assessment, diagnosis and management of PCOS, we endorse the Rotterdam diagnostic criteria in adults and recommend tighter criteria requiring both hyperandrogenism and irregular cycles, with ultrasound not indicated in adolescents, due to overlap with normal reproductive physiology. Exclusion of thyroid disease (thyroid stimulating hormone), hyperprolactinemia (prolactin), and non-classic congenital adrenal hyperplasia (17-hydroxy progesterone) is recommended with further evaluation recommended in those with amenorrhea and more severe clinical features including consideration of hypogonadotropic hypogonadism, Cushing's disease, or androgen producing tumours.

We acknowledge the challenges in defining specific diagnostic features, including around menarche and menopause, where diagnostic features naturally evolve.

The guideline aims to facilitate timely and appropriate diagnosis for women with PCOS, whilst avoiding over diagnosis, especially in adolescents. Specific recommendations of relevance here include:

- ultrasound is now not recommended in diagnosis in those within 8 years of menarche;
- young women "at risk" can be identified, where diagnosis is unclear, with follow-up reassessment
- diagnostic features are refined to limit overlap with those without PCOS to improve diagnostic accuracy

Resource use in diagnosis will also be reduced with a stronger focus on clinical features in diagnosis, more limited indications for ultrasound and simpler tests for biochemical hyperandrogenism.

We endorse the recommendation of the National Institutes of Health (NIH) evidence-based methodology workshop of PCOS 2012 that specific phenotypes should be reported explicitly in all research [16]. The natural history and clinical implications of the phenotypes remain unclear at this stage:

- Androgen excess + ovulatory dysfunction + polycystic ovarian morphology (Phenotype A)
- Androgen excess + ovulatory dysfunction (Phenotype B)
- Androgen excess + polycystic ovarian morphology (Phenotype C)
- Ovulatory dysfunction + polycystic ovarian morphology (Phenotype D)

We recognise that PCOS is an insulin resistant and metabolic disorder; tests for insulin resistance, however, lack accuracy and should not be incorporated into the diagnostic criteria for PCOS at this time.

We recognise PCOS has psychological features and poorer quality of life and whilst assessment is vital, these are not currently included in PCOS diagnostic criteria.

The value and optimal timing of assessment and diagnosis of PCOS should be discussed with the individual patient, taking into account psychosocial and cultural factors and patient preferences. Education is vitally important to women at the time of diagnosis, including reassurance about the potential for prevention of complications and about good general reproductive potential and family size, acknowledging some medical assistance may be required. As a general guiding principle, in partnering with women with PCOS in their diagnosis and care, self-empowerment is a priority and personal characteristics, preferences, culture and values should be considered when undertaking assessment, providing information or recommending intervention or treatments.

Interpreting the recommendations

Detailed methods for stakeholder engagement and guideline development can be found in [Chapter six: Guideline development methods](#). In developing and interpreting the guideline, evidence has been evaluated alongside multidisciplinary health professional expertise and consumer perspectives throughout all stages from conceptualisation, prioritisation, development, review and translation. Variability in resources, health systems and access to health professionals, investigations and therapies were considered across international settings and consistent with best practice, adaptation may be required in translation. The process for adaptation is available at [website link to be inserted here](#).

To assist in interpreting guideline recommendations, these are presented by **category, terms used, GRADE and quality of evidence**. The **category of the recommendations** includes evidence-based or consensus recommendations and have accompanying relevant clinical practice points as described in table 1. When sufficient evidence was available in PCOS, an evidence-based recommendation was made, where there was insufficient evidence in PCOS, evidence in general or other relevant populations was also considered and if appropriate and there was consensus, the GDG made clinical consensus recommendations. Clinical practice points highlighted important clinical and implementation issues arising from GDG consideration of evidence-based or clinical consensus recommendations and from peer review.

Table 1: Categories of the PCOS guideline recommendations

EBR	Evidence based recommendations: Evidence sufficient to inform a recommendation made by the guideline development group.
CCR	Clinical Consensus Recommendations: In the absence of evidence, a clinical consensus recommendation has been made by the guideline development group.
CPP	Clinical Practice Points: Evidence not sought. A practice point has been made by the guideline development group where important issues arose from discussion of evidence-based or clinical consensus recommendations.

The **recommendation terms** include “should”, “could” and “should not”. These terms are informed by the nature of the recommendation (evidence or consensus), the GRADE framework and evidence quality and are independent descriptors reflecting the judgement of multidisciplinary GDG including consumers. They refer to overall interpretation and practical application of the recommendation, balancing benefits and harms. “Should” is used where benefits of the recommendation exceed harms, and where the recommendation can be trusted to guide practice. “Could” is used where either the quality of evidence was limited or the available studies demonstrate little clear advantage of one approach over another, or the balance of benefits to harm was unclear. “Should not” is used where there is either a lack of appropriate evidence, or the harms may outweigh the benefits.

The **GRADE of the recommendation** is determined by the GDG from structured consideration of the GRADE framework [15] including desirable effects, undesirable effects, balance of effects, resource requirements and cost effectiveness, equity, acceptability and feasibility and includes:

-
- ❖ Conditional recommendation against the option;
 - ❖❖ Conditional recommendation for either the option or the comparison;
 - ❖❖❖ Conditional recommendation for the option;
 - ❖❖❖❖ Strong recommendation for the option.
-

Quality of the evidence is categorised (see table 2) according to:

- information about the number and design of studies addressing the outcome;
- judgments about the quality of the studies and/or synthesised evidence, such as risk of bias, inconsistency, indirectness, imprecision and any other considerations that may influence the quality of the evidence: key statistical data;
- and classification of the importance of the outcomes.

The quality of evidence reflects the extent to which our confidence in an estimate of the effect is adequate to support a particular recommendation [15] and was largely determined by the expert evidence synthesis team.

Table 2: Quality (certainty) of evidence categories (adapted from GRADE [15]):

High	⊕⊕⊕⊕	Very confident that the true effect lies close to that of the estimate of the effect
Moderate	⊕⊕⊕○	Moderate confidence in the effect estimate: The true effect is likely to be close to the estimate of the effect, but there is a possibility that it is substantially different
Low	⊕⊕○○	Limited confidence in the effect estimate: The true effect may be substantially different from the estimate of the effect
Very Low	⊕○○○	Very little confidence in the effect estimate: The true effect is likely to be substantially different from the estimate of effect

GRADE note that quality of evidence is a continuum; any discrete categorisation involves a degree of arbitrariness. Nevertheless, advantages of simplicity, transparency, and vividness outweigh these limitations [15].

The recommendations summary table below applies the **category, descriptive terms, GRADE of the recommendations and the quality of the evidence**. Within the body of the guideline, we outline the clinical need for the question, the clinical question, the evidence summary, the recommendation and practice points and a summary of the justification developed by the GDG and modified by extensive international peer review. The comprehensive evidence reviews, profiles and GRADE frameworks supporting each recommendation, can be found in the supplementary Technical report.

Recommendations Summary

Table notes:

The recommendation number reflects the corresponding evidence section.

Clinical consensus recommendations (CCR) and clinical practice points (CPP) do not have a 'GRADE' rating.

NO.	CATE-GORY	RECOMMENDATION	QUALITY## AND GRADE
1		Screening, diagnostic assessment, risk assessment and life-stage	
1.1		Irregular cycles and ovulatory dysfunction	
1.1.1	CCR	<p>Irregular menstrual cycles are defined as:</p> <ul style="list-style-type: none"> • normal in the first year post menarche as part of the pubertal transition • > 1 to < 3 years post menarche: < 21 or > 45 days • > 3 years post menarche to perimenopause: < 21 or > 35 days or < 8 cycles per year • > 1 year post menarche > 90 days for any one cycle • Primary amenorrhea by age 15 or > 3 years post thelarche (breast development) <p>When irregular menstrual cycles are present a diagnosis of PCOS should be considered and assessed according to the guidelines.</p>	❖❖❖❖
1.1.2	CCR	In an adolescent with irregular menstrual cycles, the value and optimal timing of assessment and diagnosis of PCOS should be discussed with the patient, taking into account diagnostic challenges at this life stage and psychosocial and cultural factors.	❖❖❖❖
1.1.3	CPP	For adolescents who have features of PCOS but do not meet diagnostic criteria, an "increased risk" could be considered and reassessment advised at or before full reproductive maturity, 8 years post menarche. This includes those with PCOS features before combined oral contraceptive pill (COCP) commencement, those with persisting features and those with significant weight gain in adolescence.	
1.1.4	CPP	Ovulatory dysfunction can still occur with regular cycles and if anovulation needs to be confirmed serum progesterone levels can be measured.	
1.2		Biochemical hyperandrogenism	
1.2.1	EBR	Calculated free testosterone, free androgen index or calculated bioavailable testosterone should be used to assess biochemical hyperandrogenism in the diagnosis of PCOS.	❖❖❖❖ ⊕⊕○○
1.2.2	EBR	High quality assays such as liquid chromatography–mass spectrometry (LCMS)/mass spectrometry and extraction/chromatography immunoassays, should be used for the most accurate assessment of total or free testosterone in PCOS.	❖❖❖ ⊕⊕○○

CATE- NO.	CATE- GORY	RECOMMENDATION	QUALITY## AND GRADE
1.2.3	EBR	Androstenedione and dehydroepiandrosterone sulfate (DHEAS) could be considered if total or free testosterone are not elevated; however, these provide limited additional information in the diagnosis of PCOS.	❖❖❖ ⊕⊕○○
1.2.4	CCR	Direct free testosterone assays, such as radiometric or enzyme-linked assays, preferably should not be used in assessment of biochemical hyperandrogenism in PCOS, as they demonstrate poor sensitivity, accuracy and precision.	❖❖❖❖
1.2.5	CPP	Reliable assessment of biochemical hyperandrogenism is not possible in women on hormonal contraception, due to effects on sex hormone-binding globulin and altered gonadotrophin-dependent androgen production.	
1.2.6	CPP	Where assessment of biochemical hyperandrogenism is important in women on hormonal contraception, drug withdrawal is recommended for three months or longer before measurement, and contraception management with a non-hormonal alternative is needed during this time.	
1.2.7	CPP	Assessment of biochemical hyperandrogenism is most useful in establishing the diagnosis of PCOS and/or phenotype where clinical signs of hyperandrogenism (in particular hirsutism) are unclear or absent.	
1.2.8	CPP	Interpretation of androgen levels needs to be guided by the reference ranges of the laboratory used, acknowledging that ranges for different methods and laboratories vary widely. Normal values are ideally based on levels from a well phenotyped healthy control population or by cluster analysis of a large general population considering age and pubertal specific stages.	
1.2.9	CPP	Where androgen levels are markedly above laboratory reference ranges, other causes of biochemical hyperandrogenism need to be considered. History of symptom onset and progression is critical in assessing for neoplasia, however, some androgen-secreting neoplasms may only induce mild to moderate increases in biochemical hyperandrogenism.	
1.3		Clinical hyperandrogenism	
1.3.1	CCR	A comprehensive history and physical examination should be completed for symptoms and signs of clinical hyperandrogenism, including acne, alopecia and hirsutism and, in adolescents, severe acne and hirsutism	❖❖❖❖
1.3.2	CCR	Health professionals should be aware of the potential negative psychosocial impact of clinical hyperandrogenism. Reported unwanted excess hair growth and/or alopecia should be considered important, regardless of apparent clinical severity.	❖❖❖❖
1.3.3	CCR	Standardised visual scales are preferred when assessing hirsutism, such as the modified Ferriman Gallwey score (mFG) with a level $\geq 4 - 6$ indicating hirsutism, depending on ethnicity, acknowledging that self-treatment is common and can limit clinical assessment. (See recommendations on ethnic variation)	❖❖❖❖
1.3.4	CCR	The Ludwig visual score is preferred for assessing the degree and distribution of alopecia.	❖❖❖❖

NO.	CATE-	GORY RECOMMENDATION	QUALITY## AND GRADE	
1.3.5	CPP	There are no universally accepted visual assessments for evaluating acne.		
1.3.6	CPP	The prevalence of hirsutism is the same across ethnicities, yet the mFG cut-off scores for defining hirsutism and the severity of hirsutism varies by ethnicity.		
1.3.7	CPP	As ethnic variation in vellus hair density is notable, over-estimation of hirsutism may occur if vellus hair is confused with terminal hair; only terminal hairs need to be considered in pathological hirsutism, with terminal hairs clinically growing > 5mm in length if untreated, varying in shape and texture and generally being pigmented.		
1.4		Ultrasound and polycystic ovarian morphology (PCOM)		
1.4.1	CCR	Ultrasound should not be used for the diagnosis of PCOS in those with a gynaecological age of < 8 years (< 8 years after menarche), due to the high incidence of multi-follicular ovaries in this life stage.		
1.4.2	CCR	The threshold for PCOM should be revised regularly with advancing ultrasound technology, and age-specific cut off values for PCOM should be defined.		
1.4.3	CCR	The transvaginal ultrasound approach is preferred in the diagnosis of PCOS, if sexually active and if acceptable to the individual being assessed.		
1.4.4	CCR	Using endovaginal ultrasound transducers with a frequency bandwidth that includes 8MHz, the threshold for PCOM should be on either ovary, a follicle number per ovary of > 20 and/or an ovarian volume ≥ 10ml, ensuring no corpora lutea, cysts or dominant follicles are present.		
1.4.5	CPP	If using older technology, the threshold for PCOM could be an ovarian volume ≥ 10ml on either ovary.		
1.4.6	CPP	In patients with irregular menstrual cycles and hyperandrogenism, an ovarian ultrasound is not necessary for PCOS diagnosis; however, ultrasound will identify the complete PCOS phenotype.		
1.4.7	CPP	In transabdominal ultrasound reporting is best focused on ovarian volume with a threshold of ≥ 10ml, given the difficulty of reliably assessing follicle number with this approach.		
1.4.8	CPP	Clear protocols are recommended for reporting follicle number per ovary and ovarian volume on ultrasound. Recommended minimum reporting standards include: <ul style="list-style-type: none"> ● last menstrual period ● transducer bandwidth frequency ● approach/route assessed ● total follicle number per ovary measuring 2-9mm ● three dimensions and volume of each ovary ● reporting of endometrial thickness and appearance is preferred – 3-layer endometrial assessment may be useful to screen for endometrial pathology ● other ovarian and uterine pathology, as well as ovarian cysts, corpus luteum, dominant follicles ≥ equal 10mm 		
1.4.9	CPP	There is a need for training in careful and meticulous follicle counting per ovary, to improve reporting.		

NO.	CATE-	GORY RECOMMENDATION	QUALITY## AND GRADE
1.5		Anti-müllerian hormone (AMH)	
1.5.1	EBR	Serum AMH levels should not yet be used as an alternative for the detection of PCOM or as a single test for the diagnosis of PCOS.	❖❖❖ ⊕⊕○○
1.5.2	CPP	There is emerging evidence that with improved standardisation of assays and established cut off levels or thresholds based on large scale validation in populations of different ages and ethnicities, AMH assays will be more accurate in the detection of PCOM.	
1.6		Ethnic variation	
1.6.1	CCR	Health professionals should consider ethnic variation in the presentation and manifestations of PCOS, including:	❖❖❖❖
		<ul style="list-style-type: none"> ● a relatively mild phenotype in Caucasians ● higher body mass index (BMI) in Caucasian women, especially in North America and Australia ● more severe hirsutism in Middle Eastern, Hispanic and Mediterranean women ● increased central adiposity, insulin resistance, diabetes, metabolic risks and acanthosis nigricans in South East Asians and Indigenous Australians ● lower BMI and milder hirsutism in East Asians ● higher BMI and metabolic features in Africans 	
1.7		Menopause life stage	
1.7.1	CCR	Postmenopausal persistence of PCOS could be considered likely with continuing evidence of hyperandrogenism.	❖❖❖
1.7.2	CCR	A diagnosis of PCOS postmenopause could be considered if there is a past diagnosis of PCOS, a long-term history of irregular menstrual cycles and hyperandrogenism and/or PCOM, during the reproductive years.	❖❖❖
1.7.3	CPP	Postmenopausal women presenting with new-onset, severe or worsening hyperandrogenism including hirsutism, require further investigation to rule out androgen-secreting tumours and ovarian hyperthecosis.	
1.8		Cardiovascular disease risk (CVD)	
1.8.1	CCR	All those with PCOS should be offered regular monitoring for weight changes and excess weight, in consultation with and where acceptable to the individual woman. Monitoring could be at each visit or at a minimum 6-12 monthly, with frequency planned and agreed between the health professional and the individual (see 3.5).	❖❖❖❖
1.8.2	CCR	Weight, height and ideally waist circumference should be measured and BMI calculated with the following considered:	❖❖❖❖
		<ul style="list-style-type: none"> ● BMI categories and waist circumference should follow World Health Organisation guidelines, also noting ethnic and adolescent ranges. ● Consideration should be given for Asian and high-risk ethnic groups including recommended monitoring of waist circumference. 	
1.8.3	CCR	All women with PCOS should be assessed for cardiovascular risk factors and global CVD risk	❖❖❖❖

NO.	CATE- GORY	RECOMMENDATION	QUALITY## AND GRADE
1.8.4	CCR	If screening reveals CVD risk factors including obesity, cigarette smoking, dyslipidemia, hypertension, impaired glucose tolerance and lack of physical activity, women with PCOS should be considered at increased risk of CVD.	♦♦♦♦
1.8.5	CCR	Overweight and obese women with PCOS, regardless of age, should have a fasting lipid profile (cholesterol, low density lipoprotein cholesterol, high density lipoprotein cholesterol and triglyceride level at diagnosis). Thereafter, frequency of measurement should be based on the presence of hyperlipidemia and global CVD risk.	♦♦♦♦
1.8.6	CCR	All women with PCOS should have blood pressure measured annually, or more frequently based on global CVD risk.	♦♦♦♦
1.8.7	CPP	Health professionals need to be aware that CVD risk in women with PCOS remains unclear pending high quality studies, however prevalence of CVD risk factors is increased, warranting consideration of screening.	
1.8.8	CPP	Consideration needs to be given to the significant differences in CVD risk across ethnicities (see 1.6.1) when determining frequency of risk assessment.	
1.9	Gestational diabetes, impaired glucose tolerance and type 2 diabetes		
1.9.1	CCR	Health professionals and women with PCOS should be aware that, regardless of age, the prevalence of gestational diabetes, impaired glucose tolerance and type 2 diabetes (5 fold in Asia, 4 fold in the Americas and 3 fold in Europe) are significantly increased in PCOS, with risk independent of, yet exacerbated by, obesity	♦♦♦♦
1.9.2	CCR	Glycaemic status should be assessed at baseline in all women with PCOS. Thereafter, assessment should be every one to three years, influenced by the presence of other diabetes risk factors	♦♦♦♦
1.9.3	CCR	An oral glucose tolerance test (OGTT), fasting plasma glucose or HbA1c should be performed to assess glycaemic status. In high-risk women with PCOS (including a BMI > 25kg/m ² or in Asians > 23kg/m ² , history of impaired fasting glucose, impaired glucose tolerance or gestational diabetes, family history of diabetes mellitus type 2, hypertension or high-risk ethnicity), an OGTT is recommended.	♦♦♦♦
1.9.4	CCR	A 75-g OGTT should be offered in all women with PCOS preconception when planning pregnancy or seeking fertility treatment, given the high risk of hyperglycaemia and the associated comorbidities in pregnancy. If not performed preconception, an OGTT should be offered at < 20 weeks gestation, and all women with PCOS should be offered the test at 24-28 weeks gestation.	♦♦♦♦
1.10	Obstructive sleep apnea (OSA)		
1.10.1	CCR	Screening should only be considered for OSA in PCOS to identify and alleviate related symptoms, such as snoring, waking unrefreshed from sleep, daytime sleepiness, and the potential for fatigue to contribute to mood disorders. Screening should not be considered with the intention of improving cardiometabolic risk, with inadequate evidence for metabolic benefits of OSA treatment in PCOS and in general populations.	♦♦♦♦

CATE- NO.	GORY	RECOMMENDATION	QUALITY## AND GRADE
1.10.2	CCR	A simple screening questionnaire, preferably the Berlin tool, could be applied and if positive, referral to a specialist considered.	❖❖❖
1.10.3	CPP	A positive screen raises the likelihood of OSA, however it does not quantify symptom burden and alone does not justify treatment. If women with PCOS have OSA symptoms and a positive screen, consideration can be given to be referral to a specialist centre for further evaluation.	
1.11		Endometrial cancer	
1.11.1	CCR	Health professionals and women with PCOS should be aware of a two to six-fold increased risk of endometrial cancer, which often presents before menopause; however absolute risk of endometrial cancer remains relatively low.	❖❖❖
1.11.2	CPP	Health professionals require a low threshold for investigation of endometrial cancer in women with PCOS or a history of PCOS, with investigation by transvaginal ultrasound and/or endometrial biopsy recommended with persistent thickened endometrium and/or risk factors including prolonged amenorrhea, abnormal vaginal bleeding or excess weight. However, routine ultrasound screening of endometrial thickness in PCOS is not recommended.	
1.11.3	CPP	Optimal prevention for endometrial hyperplasia and endometrial cancer is not known. A pragmatic approach could include COCP or progestin therapy in those with cycles longer than 90 days.	
2		Prevalence, screening, diagnostic assessment and treatment of emotional wellbeing	
2.1		Quality of life	
2.1.1	CCR	Health professionals and women should be aware of the adverse impact of PCOS on quality of life.	❖❖❖❖
2.1.2	CCR	Health professionals should capture and consider perceptions of symptoms, impact on quality of life and personal priorities for care to improve patient outcomes.	❖❖❖❖
2.1.3	CPP	The PCOS quality of life tool (PCOSQ), or the modified PCOSQ, may be useful clinically to highlight PCOS features causing greatest distress, and to evaluate treatment outcomes on women's subjective PCOS health concerns.	
2.2		Depressive and anxiety symptoms, screening and treatment	
2.2.1	CCR	Health professionals should be aware that in PCOS, there is a high prevalence of moderate to severe anxiety and depressive symptoms in adults; and a likely increased prevalence in adolescents.	❖❖❖❖
2.2.2	CCR	Anxiety and depressive symptoms should be routinely screened in all adolescents and women with PCOS at diagnosis. If the screen for these symptoms and/or other aspects of emotional wellbeing is positive, further assessment and/or referral for assessment and treatment should be completed by suitably qualified health professionals, informed by regional guidelines.	❖❖❖❖

NO.	CATE-	GORY RECOMMENDATION	QUALITY## AND GRADE	
2.2.3	CCR	If treatment is warranted, psychological therapy and/or pharmacological treatment should be offered in PCOS, informed by regional clinical practice guidelines.	♦♦♦♦	
2.2.4	CPP	The optimal interval for anxiety and depressive symptom screening is not known. A pragmatic approach could include repeat screening using clinical judgment, considering risk factors, comorbidities and life events.		
2.2.5	CPP	Assessment of anxiety and or depressive symptoms involves assessment of risk factors, symptoms and severity. Symptoms can be screened according to regional guidelines, or by using the following stepped approach:		
Step 1: Initial questions could include:		Over the last 2 weeks, how often have you been bothered by the following problems?		
<ul style="list-style-type: none"> ● feeling down, depressed, or hopeless? ● little interest or pleasure in doing things? ● feeling nervous, anxious or on edge? ● not being able to stop or control worrying? 		Step 2: If any of the responses are positive, further screening should involve:		
<ul style="list-style-type: none"> ● assessment of risk factors and symptoms using age, culturally and regionally appropriate tools, such as the Patient Health Questionnaire (PHQ) or the Generalised Anxiety Disorder Scale (GAD7) and/or refer to an appropriate professional for further assessment. 				
2.2.6	CPP	Where pharmacological treatment for anxiety and depression is offered in PCOS, the following need consideration:	<ul style="list-style-type: none"> ● Caution is needed to avoid inappropriate treatment with antidepressants or anxiolytics. Where mental health disorders are clearly documented and persistent, or if suicidal symptoms are present, treatment of depression or anxiety need to be informed by clinical regional practice guidelines. ● Use of agents that exacerbate PCOS symptoms, including weight gain, need careful consideration. 	
2.2.7	CPP	Factors including obesity, infertility, hirsutism need consideration along with use of hormonal medications in PCOS, as they may independently exacerbate depressive and anxiety symptoms and other aspects of emotional wellbeing.		
2.3	Psychosexual function			
2.3.1	CCR	All health professionals should be aware of the increased prevalence of psychosexual dysfunction and should consider exploring how features of PCOS, including hirsutism and body image, impact on sex life and relationships in PCOS.	♦♦♦♦	
2.3.2	CCR	If psychosexual dysfunction is suspected, tools such as the Female Sexual Function Index can be considered.	♦♦♦♦	

NO.	CATE-GORY RECOMMENDATION	QUALITY## AND GRADE
2.4	Body image	
2.4.1	CCR Health professionals and women should be aware that features of PCOS can impact on body image.	♦♦♦
2.4.2	CPP Negative body image, can be screened according to regional guidelines or by using the following stepped approach:	
	Step 1: Initial questions could include:	
	<ul style="list-style-type: none"> ● Do you worry a lot about the way you look and wish you could think about it less? ● On a typical day, do you spend more than 1 hour per day worrying about your appearance? (More than 1 hour a day is considered excessive) ● What specific concerns do you have about your appearance? ● What effect does it have on your life? ● Does it make it hard to do your work or be with your friends and family? 	
	Step 2: If an issue is identified, health professionals could further assess by:	
	<ul style="list-style-type: none"> ● Identifying any focus of concern of the patient and respond appropriately ● Assessing the level of depression and/or anxiety ● Identifying distortion of body image or disordered eating 	
2.5	Eating disorders and disordered eating	
2.5.1	CCR All health professionals and women should be aware of the increased prevalence of eating disorders and disordered eating associated with PCOS.	♦♦
2.5.2	CCR If eating disorders and disordered eating are suspected, further assessment, referral and treatment, including psychological therapy, could be offered by appropriately trained health professionals, informed by regional clinical practice guidelines.	♦♦
2.5.3	CPP Eating disorders and disordered eating can be screened using the following stepped approach.	
	Step 1: The SCOFF (Sick, Control, One stone, Fat, Food) screening tool can be used or initial screening questions can include:	
	<ul style="list-style-type: none"> ● Does your weight affect the way you feel about yourself? ● Are you satisfied with your eating patterns? 	
	Step 2: If the SCOFF tool or any of these questions are positive, further screening should involve:	
	<ul style="list-style-type: none"> ● assessment of risk factors and symptoms using age, culturally and regionally appropriate tools; ● referral to an appropriate health professional for further mental health assessment and diagnostic interview. If this is not the patient's usual healthcare provider, inform the primary care physician. 	

CATE- NO.	GORY RECOMMENDATION	QUALITY## AND GRADE
2.6	Information resources, models of care, cultural and linguistic considerations	
2.6.1	CCR Information and education resources for women with PCOS should be culturally appropriate, tailored and high-quality, should use a respectful and empathetic approach, and promote self-care and highlight peer support groups.	❖❖❖❖
2.6.2	CCR Information and education resources for healthcare professionals should promote the recommended diagnostic criteria, appropriate screening for comorbidities and effective lifestyle and pharmacological management.	❖❖❖❖
2.6.3	CCR PCOS information should be comprehensive, evidence-based and inclusive of the biopsychosocial dimensions of PCOS across the life-span.	❖❖❖❖
2.6.4	CCR Women's needs, communication preferences, beliefs and culture should be considered and addressed through provision of culturally and linguistically appropriate co-designed resources and care.	❖❖❖❖
2.6.5	CCR Interdisciplinary care needs to be considered for those with PCOS where appropriate and available. Primary care is generally well placed to diagnose, screen and coordinate interdisciplinary care.	❖❖❖❖
2.6.6	CCR Care needs to be person centred, address women's priorities and be provided in partnership with those with PCOS and where appropriate, their families.	❖❖❖❖
2.6.7	CPP Guideline dissemination and translation including multimodal education tools and resources is important, with consultation and engagement with stakeholders internationally.	
3	Lifestyle	
3.1	Effectiveness of lifestyle interventions	
3.1.1	CCR Healthy lifestyle behaviours encompassing healthy eating and regular physical activity should be recommended in all those with PCOS to achieve and/or maintain healthy weight and to optimise hormonal outcomes, general health, and quality of life across the life course.	❖❖❖❖
3.1.2	EBR Lifestyle intervention (preferably multicomponent including diet, exercise and behavioural strategies) should be recommended in all those with PCOS and excess weight, for reductions in weight, central obesity and insulin resistance.	❖❖❖ ⊕⊕○○
3.1.3	CPP Achievable goals such as 5% to 10% weight loss in those with excess weight yields significant clinical improvements and is considered successful weight reduction within six months. Ongoing assessment and monitoring is important during weight loss and maintenance in all women with PCOS.	
3.1.4	CPP SMART (Specific Measurable, Achievable, Realistic and Timely), goal setting and self-monitoring can enable achievement of realistic lifestyle goals.	
3.1.5	CPP Psychological factors such as anxiety and depressive symptoms, body image concerns and disordered eating, need consideration and management to optimise engagement and adherence to lifestyle interventions.	

NO.	CATE- GORY	RECOMMENDATION	QUALITY## AND GRADE
3.1.6	CPP	Health professional interactions around healthy lifestyle, including diet and exercise, need to be respectful, patient-centred and to value women's individualised healthy lifestyle preferences and cultural, socioeconomic and ethnic differences. Health professionals need to also consider personal sensitivities, marginalisation and potential weight-related stigma.	
3.1.7	CPP	Adolescent and ethnic-specific BMI and waist circumference categories need to be considered when optimising lifestyle and weight.	
3.1.8	CPP	Healthy lifestyle may contribute to health and quality of life benefits in the absence of weight loss.	
3.1.9	CPP	Healthy lifestyle and optimal weight management appears equally effective in PCOS as in the general population and is the joint responsibility of all health professionals, partnering with women with PCOS. Where complex issues arise, referral to suitably trained allied health professionals needs to be considered.	
3.1.10	CPP	Ethnic groups with PCOS who are at high cardiometabolic risk as per 1.6.1 require greater consideration in terms of healthy lifestyle and lifestyle intervention.	
3.2	Behavioural strategies		
3.2.1	CCR	Lifestyle interventions could include behavioural strategies such as goal-setting, self-monitoring, stimulus control, problem solving, assertiveness training, slower eating, reinforcing changes and relapse prevention, to optimise weight management, healthy lifestyle and emotional wellbeing in women with PCOS.	♦♦♦♦
3.2.2	CPP	Comprehensive health behavioural or cognitive behavioural interventions could be considered to increase support, engagement, retention, adherence and maintenance of healthy lifestyle and improve health outcomes in women with PCOS.	
3.3	Dietary intervention		
3.3.1	CCR	A variety of balanced dietary approaches could be recommended to reduce dietary energy intake and induce weight loss in women with PCOS and overweight and obesity, as per general population recommendations.	♦♦♦♦
3.3.2	CCR	General healthy eating principles should be followed for all women with PCOS across the life course, as per general population recommendations.	♦♦♦♦
3.3.3	CPP	To achieve weight loss in those with excess weight, an energy deficit of 30% or 500 - 750 kcal/day (1,200 to 1,500 kcal/day) could be prescribed for women, also considering individual energy requirements, body weight and physical activity levels.	
3.3.4	CPP	In women with PCOS, there is no or limited evidence that any specific energy equivalent diet type is better than another, or that there is any differential response to weight management intervention, compared to women without PCOS.	
3.3.5	CPP	Tailoring of dietary changes to food preferences, allowing for a flexible and individual approach to reducing energy intake and avoiding unduly restrictive and nutritionally unbalanced diets, are important, as per general population recommendations.	

NO.	CATE-GORY RECOMMENDATION	QUALITY## AND GRADE
3.4	Exercise intervention	
3.4.1	CCR Health professionals should encourage and advise the following for prevention of weight gain and maintenance of health:	
	<ul style="list-style-type: none"> ● in adults from 18 – 64 years, a minimum of 150 min/week of moderate intensity physical activity or 75 min/week of vigorous intensities or an equivalent combination of both, including muscle strengthening activities on 2 non-consecutive days/week ● in adolescents, at least 60 minutes of moderate to vigorous intensity physical activity/day, including those that strengthen muscle and bone at least 3 times weekly ● activity be performed in at least 10-minute bouts or around 1000 steps, aiming to achieve at least 30 minutes daily on most days. 	
3.4.2	CCR Health professionals should encourage and advise the following for modest weight-loss, prevention of weight-regain and greater health benefits:	
	<ul style="list-style-type: none"> ● a minimum of 250 min/week of moderate intensity activities or 150 min/week of vigorous intensity or an equivalent combination of both, and muscle strengthening activities involving major muscle groups on 2 non-consecutive days/ week ● minimised sedentary, screen or sitting time. 	
3.4.3	CPP Physical activity includes leisure time physical activity, transportation such as walking or cycling, occupational work, household chores, games, sports or planned exercise, in the context of daily, family and community activities. Daily, 10000 steps is ideal, including activities of daily living and 30 minutes of structured physical activity or around 3000 steps. Structuring of recommended activities need to consider women's and family routines as well as cultural preferences.	
3.4.4	CPP Realistic physical activity SMART (Specific, Measureable, Achievable, Relevant, Time limited) goals could include 10 minute bouts, progressively increasing physical activity 5% weekly, up to and above recommendations.	
3.4.5	CPP Self-monitoring including with fitness tracking devices and technologies for step count and exercise intensity, could be used as an adjunct to support and promote active lifestyles and minimise sedentary behaviours.	
3.5	Obesity and weight assessment	
3.5.1	CCR Health professionals and women should be aware that women with PCOS have a higher prevalence of weight gain and obesity, presenting significant concerns for women, impacting on health and emotional wellbeing, with a clear need for prevention.	
3.5.2	CCR All those with PCOS should be offered regular monitoring for weight changes and excess weight as per 1.8.1 and 1.8.2.	

NO.	CATE-	GORY RECOMMENDATION	QUALITY## AND GRADE
3.5.3	CPP	When assessing weight, related stigma, negative body image and/or low self-esteem need to be considered and assessment needs to be respectful and considerate. Beforehand, explanations on the purpose and how the information will be used and the opportunity for questions and preferences need to be provided, permission sought and scales and tape measures adequate. Implications of results need to be explained and where this impacts on emotional wellbeing, support provided.	
3.5.4	CPP	Prevention of weight gain, monitoring of weight and encouraging evidence-based and socio-culturally appropriate healthy lifestyle is important in PCOS, particularly from adolescence.	
4	Pharmacological treatment for non-fertility indications		
4.1	Pharmacological treatment principles in PCOS		
4.1.1	CPP	Consideration of the individual's personal characteristics, preferences and values is important in recommending pharmacological treatment.	
4.1.2	CPP	When prescribing pharmacological therapy in PCOS, benefits, adverse effects and contraindications in PCOS and general populations need to be considered and discussed before commencement.	
4.1.3	CPP	COCPs, metformin and other pharmacological treatments are generally off label [#] in PCOS. However off label use is predominantly evidence-based and is allowed in many countries. Where it is allowed, health professionals need to inform women and discuss the evidence, possible concerns and side effects of treatment.	
4.1.4	CPP	Holistic approaches are required and pharmacological therapy in PCOS needs to be considered alongside education, lifestyle and other options including cosmetic therapy and counselling.	
4.2	Combined oral contraceptive pills (COCPs)		
4.2.1	EBR	The COCP alone should be recommended in adult women with PCOS for management of hyperandrogenism and/or irregular menstrual cycles.	❖❖❖ ⊕⊕○○
4.2.2	EBR	The COCP alone should be considered in adolescents with a clear diagnosis of PCOS for management of clinical hyperandrogenism and/or irregular menstrual cycles.	❖❖❖ ⊕⊕○○
4.2.3	EBR	The COCP could be considered in adolescents who are deemed "at risk" but not yet diagnosed with PCOS, for management of clinical hyperandrogenism and irregular menstrual cycles.	❖❖❖ ⊕⊕○○
4.2.4	EBR	Specific types or dose of progestins, estrogens or combinations of COCP cannot currently be recommended in adults and adolescents with PCOS and practice should be informed by general population guidelines.	❖❖❖ ⊕⊕○○

NO.	CATE-GORY	RECOMMENDATION	QUALITY## AND GRADE
4.2.5	CCR	The 35 microgram ethinyloestradiol plus cyproterone acetate preparations should not be considered first line in PCOS as per general population guidelines, due to adverse effects including venous thromboembolic risks.	❖
4.2.6	CPP	When prescribing COCPs in adults and adolescents with PCOS: <ul style="list-style-type: none"> various COCP preparations have similar efficacy in treating hirsutism the lowest effective estrogen doses (such as 20-30 micrograms of ethinyloestradiol or equivalent), and natural estrogen preparations need consideration, balancing efficacy, metabolic risk profile, side effects, cost and availability the generally limited evidence on effects of COCPs in PCOS needs to be appreciated with practice informed by general population guidelines (WHO Guidelines) the relative and absolute contraindications and side effects of COCPs need to be considered and be the subject of individualised discussion PCOS specific risk factors such as high BMI, hyperlipidemia and hypertension need to be considered. 	❖
4.3		Combined oral contraceptive pills in combination with metformin and/or anti-androgen pharmacological agents	
4.3.1	EBR	In combination with the COCP, metformin should be considered in women with PCOS for management of metabolic features where COCP and lifestyle changes do not achieve desired goals.	❖❖❖ ⊕⊕○○
4.3.2	EBR	In combination with the COCP, metformin could be considered in adolescents with PCOS and BMI $\geq 25\text{kg/m}^2$ where COCP and lifestyle changes do not achieve desired goals.	❖❖❖ ⊕⊕○○
4.3.3	CPP	In combination with the COCP, metformin may be most beneficial in high metabolic risk groups including those with diabetes risk factors, impaired glucose tolerance or high-risk ethnic groups.	
4.3.4	EBR	In combination with the COCP, antiandrogens should only be considered in PCOS to treat hirsutism, after six months or more of COCP and cosmetic therapy have failed to adequately improve symptoms.	❖❖ ⊕⊕○○
4.3.5	CCR	In combination with the COCP, antiandrogens could be considered for the treatment of androgen-related alopecia in PCOS.	❖❖
4.3.6	CPP	In PCOS, antiandrogens must be used with effective contraception, to avoid male foetal undervirilisation. Variable availability and regulatory status of these agents is notable and for some agents, potential liver toxicity requires caution.	
4.4		Metformin	
4.4.1	EBR	Metformin in addition to lifestyle, could be recommended in adult women with PCOS, for the treatment of weight, hormonal and metabolic outcomes.	❖❖❖ ⊕⊕○○
4.4.2	EBR	Metformin in addition to lifestyle, should be considered in adult women with PCOS with BMI $\geq 25\text{kg/m}^2$ for management of weight and metabolic outcomes.	❖❖❖ ⊕⊕○○

CATE- NO.	GORY	RECOMMENDATION	QUALITY## AND GRADE
4.4.3	EBR	Metformin in addition to lifestyle, could be considered in adolescents with a clear diagnosis of PCOS or with symptoms of PCOS before the diagnosis is made.	❖❖❖ ⊕⊕○○
4.4.4	CPP	Metformin may offer greater benefit in high metabolic risk groups including those with diabetes risk factors, impaired glucose tolerance or high-risk ethnic groups (see 1.6.1).	
4.4.5	CPP	Where metformin is prescribed the following need to be considered: <ul style="list-style-type: none"> ● adverse effects, including gastrointestinal side-effects that are generally dose dependent and self-limiting, need to be the subject of individualised discussion ● starting at a low dose, with 500mg increments 1-2 weekly and extended release preparations may minimise side effects ● metformin use appears safe long-term, based on use in other populations, however ongoing requirement needs to be considered and use may be associated with low vitamin B12 levels ● use is generally off label and health professionals need to inform women and discuss the evidence, possible concerns and side effects. 	
4.5 Anti-obesity pharmacological agents			
4.5.1	CCR	Anti-obesity medications in addition to lifestyle, could be considered for the management of obesity in adults with PCOS after lifestyle intervention, as per general population recommendations.	❖❖
4.5.2	CPP	For anti-obesity medications, cost, contraindications, side effects, variable availability and regulatory status need to be considered and pregnancy needs to be avoided whilst taking these medications.	
4.6 Anti-androgen pharmacological agents			
4.6.1	EBR	Where COCPs are contraindicated or poorly tolerated, in the presence of other effective forms of contraception, anti-androgens could be considered to treat hirsutism and androgen-related alopecia.	❖❖❖ ⊕○○○
4.6.2	CPP	Specific types or doses of antiandrogens cannot currently be recommended with inadequate evidence in PCOS.	
4.7 Inositol			
4.7.1	EBR	Inositol (in any form) should currently be considered an experimental therapy in PCOS, with emerging evidence on efficacy highlighting the need for further research.	❖ ⊕○○○
4.7.2	CPP	Women taking inositol and other complementary therapies are encouraged to advise their health professional.	

NO.	CATE-GORY RECOMMENDATION	QUALITY## AND GRADE
5	Assessment and treatment of infertility	
5.1	Assessment of factors that may affect fertility, treatment response or pregnancy outcomes	
5.1.1	CPP Factors such as blood glucose, weight, blood pressure, smoking, alcohol, diet, exercise, sleep and mental, emotional and sexual health need to be optimised in women with PCOS, to improve reproductive and obstetric outcomes, aligned with recommendations in the general population.	
	Refer to Lifestyle , Emotional Wellbeing and Diabetes risk sections	
5.1.2	CPP Monitoring during pregnancy is important in women with PCOS, given increased risk of adverse maternal and offspring outcomes.	
5.1.3	CCR In women with PCOS and infertility due to anovulation alone with normal semen analysis, the risks, benefits, costs and timing of tubal patency testing should be discussed on an individual basis.	♦♦♦
5.1.4	CCR Tubal patency testing should be considered prior to ovulation induction in women with PCOS where there is suspected tubal infertility.	♦♦♦
5.2	Ovulation induction principles	
5.2.1	CPP The use of ovulation induction agents, including letrozole, metformin and clomiphene citrate is off label in many countries. Where off label use of ovulation induction agents is allowed, health professionals need to inform women and discuss the evidence, possible concerns and side effects.	
5.2.2	CPP Pregnancy needs to be excluded prior to ovulation induction.	
5.2.3	CPP Unsuccessful, prolonged use of ovulation induction agents needs to be avoided, due to poor success rates.	
5.3	Letrozole	
5.3.1	EBR Letrozole should be considered first line pharmacological treatment for ovulation induction in women with PCOS with anovulatory infertility and no other infertility factors to improve ovulation, pregnancy and live birth rates.	♦♦♦♦
⊕⊕○○		
5.3.2	CPP Where letrozole is not available or use is not permitted or cost is prohibitive, health professionals can use other ovulation induction agents.	
5.3.3	CPP Health professionals and women need to be aware that the risk of multiple pregnancy appears to be less with letrozole, compared to clomiphene citrate.	

CATE- NO.	GORY RECOMMENDATION	QUALITY## AND GRADE
5.4	Clomiphene citrate and metformin	
5.4.1	EBR Clomiphene citrate could be used alone in women with PCOS with anovulatory infertility and no other infertility factors to improve ovulation and pregnancy rates.	❖❖❖ ⊕○○○
5.4.2	EBR Metformin could be used alone in women with PCOS, with anovulatory infertility and no other infertility factors, to improve ovulation, pregnancy and live birth rates, although women should be informed that there are more effective ovulation induction agents.	❖❖❖ ⊕⊕⊕○
5.4.3	EBR Clomiphene citrate could be used in preference, when considering clomiphene citrate or metformin for ovulation induction in women with PCOS who are obese (BMI is $\geq 30 \text{ kg/m}^2$) with anovulatory infertility and no other infertility factors.	❖❖❖ ⊕⊕○○
5.4.4	EBR If metformin is being used for ovulation induction in women with PCOS who are obese (BMI $\geq 30\text{kg/m}^2$) with anovulatory infertility and no other infertility factors, clomiphene citrate could be added to improve ovulation, pregnancy and live birth rates.	❖❖❖ ⊕⊕○○
5.4.5	EBR Clomiphene citrate could be combined with metformin, rather than persisting with clomiphene citrate alone, in women with PCOS who are clomiphene citrate-resistant, with anovulatory infertility and no other infertility factors, to improve ovulation and pregnancy rates.	❖❖❖ ⊕⊕○○
5.4.6	CPP The risk of multiple pregnancy is increased with clomiphene citrate use and therefore monitoring needs to be considered.	
5.5	Gonadotrophins	
5.5.1	EBR Gonadotrophins could be used as second line pharmacological agents in women with PCOS who have failed first line oral ovulation induction therapy and are anovulatory and infertile, with no other infertility factors.	❖❖❖ ⊕⊕○○
5.5.2	EBR Gonadotrophins could be considered as first line treatment, in the presence of ultrasound monitoring, following counselling on cost and potential risk of multiple pregnancy, in women with PCOS with anovulatory infertility and no other infertility factors.	❖❖❖ ⊕⊕○○
5.5.3	EBR Gonadotrophins, where available and affordable, should be used in preference to clomiphene citrate combined with metformin therapy for ovulation induction, in women with PCOS with anovulatory infertility, clomiphene citrate-resistance and no other infertility factors, to improve ovulation, pregnancy and live birth rates.	❖❖❖❖ ⊕⊕⊕○
5.5.4	EBR Gonadotrophins with the addition of metformin, could be used rather than gonadotrophin alone, in women with PCOS with anovulatory infertility, clomiphene citrate-resistance and no other infertility factors, to improve ovulation, pregnancy and live birth rates.	❖❖❖ ⊕⊕⊕○
5.5.5	EBR Either gonadotrophins or laparoscopic ovarian surgery could be used in women with PCOS with anovulatory infertility, clomiphene citrate-resistance and no other infertility factors, following counselling on benefits and risks of each therapy.	❖❖❖❖ ⊕⊕⊕○

NO.	CATE-	GORY RECOMMENDATION	QUALITY## AND GRADE
5.5.6	CPP	Where gonadotrophins are prescribed, considerations include:	
		<ul style="list-style-type: none"> ● cost and availability ● expertise required for use in ovulation induction ● degree of intensive ultrasound monitoring required ● lack of difference in clinical efficacy of available gonadotrophin preparations ● low dose gonadotrophin protocols optimise monofollicular development ● risk and implications of potential multiple pregnancy 	
5.5.7	CPP	Gonadotrophin induced ovulation is only triggered when there are fewer than three mature follicles and needs to be cancelled if there are more than two mature follicles with the patient advised to avoid unprotected intercourse.	
5.6	Anti-obesity agents		
5.6.1	CCR	Pharmacological anti-obesity agents should be considered an experimental therapy in women with PCOS for the purpose of improving fertility, with risk to benefit ratios currently too uncertain to advocate this as fertility therapy.	❖
5.7	Laparoscopic surgery		
5.7.1	EBR	Laparoscopic ovarian surgery could be second line therapy for women with PCOS, who are clomiphene citrate resistant, with anovulatory infertility and no other infertility factors.	❖❖❖ ⊕⊕○○
5.7.2	CCR	Laparoscopic ovarian surgery could potentially be offered as first line treatment if laparoscopy is indicated for another reason in women with PCOS with anovulatory infertility and no other infertility factors.	❖❖❖
5.7.3	CPP	Risks need to be explained to all women with PCOS considering laparoscopic ovarian surgery.	
5.7.4	CPP	Where laparoscopic ovarian surgery is to be recommended, the following need to be considered:	
		<ul style="list-style-type: none"> ● comparative cost ● expertise required for use in ovulation induction ● intra-operative and post-operative risks are higher in women who are overweight and obese ● there may be a small associated risk of lower ovarian reserve or loss of ovarian function ● periadnexal adhesion formation may be an associated risk. 	

CATE- NO.	GORY RECOMMENDATION	QUALITY## AND GRADE
5.8	Bariatric surgery	
5.8.1 CCR	Bariatric surgery should be considered an experimental therapy in women with PCOS, for the purpose of having a healthy baby, with risk to benefit ratios currently too uncertain to advocate this as fertility therapy.	❖
5.8.2 CPP	<p>If bariatric surgery is to be prescribed, the following need to be considered:</p> <ul style="list-style-type: none"> ● comparative cost ● the need for a structured weight management program involving diet, physical activity and interventions to improve psychological, musculoskeletal and cardiovascular health to continue post-operatively ● perinatal risks such as small for gestational age, premature delivery, possibly increased infant mortality ● potential benefits such as reduced incidence of large for gestational age fetus and gestational diabetes ● recommendations for pregnancy avoidance during periods of rapid weight loss and for at least 12 months after bariatric surgery with appropriate contraception. <p>If pregnancy occurs, the following need to be considered:</p> <ul style="list-style-type: none"> ● awareness and preventative management of pre-and post-operative nutritional deficiencies is important, ideally in a specialist interdisciplinary care setting ● monitoring of fetal growth during pregnancy. 	
5.9	In-vitro fertilisation (IVF)	
5.9.1 CCR	In the absence of an absolute indication for IVF ± intracytoplasmic sperm injection (ICSI), women with PCOS and anovulatory infertility could be offered IVF as third line therapy where first or second line ovulation induction therapies have failed.	❖❖❖
5.9.2 CPP	In women with anovulatory PCOS, the use of IVF is effective and when elective single embryo transfer is used multiple pregnancies can be minimised.	
5.9.3 CPP	Women with PCOS undergoing IVF ± ICSI therapy need to be counselled prior to starting treatment including on:	
	<ul style="list-style-type: none"> ● availability, cost and convenience ● increased risk of ovarian hyperstimulation syndrome ● options to reduce the risk of ovarian hyperstimulation. 	
5.9.4 CCR	Urinary or recombinant follicle stimulation hormone can be used in women with PCOS undergoing controlled ovarian hyperstimulation for IVF ± ICSI, with insufficient evidence to recommend specific follicle stimulating hormone (FSH) preparations.	❖❖❖
5.9.5 CCR	Exogenous recombinant luteinising hormone treatment should not be routinely used in combination with follicle stimulating hormone therapy in women with PCOS undergoing controlled ovarian hyperstimulation for IVF ± ICSI.	❖❖❖

CATE- NO.	GORY	RECOMMENDATION	QUALITY## AND GRADE
5.9.6	EBR	A gonadotrophin releasing hormone antagonist protocol is preferred in women with PCOS undergoing an IVF ± ICSI cycle, over a gonadotrophin releasing hormone agonist long protocol, to reduce the duration of stimulation, total gonadotrophin dose and incidence of ovarian hyperstimulation syndrome (OHSS).	❖❖❖ ⊕⊕○○
5.9.7	CPP	Human chorionic gonadotrophins is best used at the lowest doses to trigger final oocyte maturation in women with PCOS undergoing an IVF ± ICSI cycle to reduce the incidence of OHSS.	
5.9.8	CPP	Triggering final oocyte maturation with a gonadotropin-releasing hormone (GnRH) agonist and freezing all suitable embryos could be considered in women with PCOS having an IVF/ICSI cycle with a GnRH antagonist protocol and at an increased risk of developing OHSS or where fresh embryo transfer is not planned.	
5.9.9	CPP	In IVF ± ICSI cycles in women with PCOS, consideration needs to be given to an elective freeze of all embryos.	
5.9.10	EBR	Adjunct metformin therapy could be used before and/or during follicle stimulating hormone ovarian stimulation in women with PCOS undergoing a IVF ± ICSI therapy with a GnRH agonist protocol, to improve the clinical pregnancy rate and reduce the risk of OHSS.	❖❖❖ ⊕⊕○○
5.9.11	CCR	In a GnRH agonist protocol with adjunct metformin therapy, in women with PCOS undergoing IVF ± ICSI treatment, the following could be considered: <ul style="list-style-type: none"> ● metformin commencement at the start of GnRH agonist treatment ● metformin use at a dose of between 1000mg to 2550mg daily ● metformin cessation at the time of the pregnancy test or menses (unless the metformin therapy is otherwise indicated) ● metformin side-effects (see above metformin section) 	❖❖❖
5.9.12	CPP	In IVF ± ICSI cycles, women with PCOS could be counselled on potential benefits of adjunct metformin in a GnRH antagonist protocol to reduce risk of ovarian hyperstimulation syndrome (see above for metformin therapy considerations).	
5.9.13	CPP	The term in vitro maturation (IVM) treatment cycle is applied to “the maturation in vitro of immature cumulus oocyte complexes collected from antral follicles” (encompassing both stimulated and unstimulated cycles, but without the use of a human gonadotrophin trigger).	
5.9.14	CCR	In units with sufficient expertise, IVM could be offered to achieve pregnancy and livebirth rates approaching those of standard IVF ± ICSI treatment without the risk of OHSS for women with PCOS, where an embryo is generated, then vitrified and thawed and transferred in a subsequent cycle.	❖❖❖

Off-label' prescribing occurs when a drug is prescribed for an indication, a route of administration, or a patient group that is not included in the approved product information document for that drug by the regulatory body. Prescribing off label is often unavoidable and common and does not mean that the regulatory body has rejected the indication, more commonly there has not been a submission to request evaluation of the indication or that patient group for any given drug.

Chapter One

Screening, diagnostic assessment, risk assessment and life-stage

Diagnosis and treatment of polycystic ovary syndrome (PCOS) remain controversial with challenges defining individual components within the diagnostic criteria and significant clinical heterogeneity across the phenotypes, which is further varied by ethnic differences and changes in clinical features across the life course. The guideline addresses issues for all those affected with PCOS across the lifespan. Where recommendations differ by life stages or body mass index (BMI) status, this is clarified.

1.1 Irregular cycles and ovulatory dysfunction

In adolescents, at what time point after onset of menarche do irregular cycles indicate ongoing menstrual dysfunction?

Clinical need for the question

Ovulatory dysfunction is a key diagnostic feature of PCOS with irregular menstrual cycles reflecting ovulatory dysfunction, as reflected in the Rotterdam criteria. Ovulatory dysfunction can occur with regular cycles. When anovulation needs to be confirmed, hormonal assessment is relevant if PCOS is clinically suspected and cycles are regular.

Irregular cycles and ovulatory dysfunction are also a normal component of the pubertal and menopausal transitions and defining abnormality at these life stages remains challenging. Indeed, the greatest controversy in this diagnostic criteria is during the pubertal transition. Physiological maturation of the hypothalamic, pituitary ovarian axis occurs over years and ovulation and cycles in adolescents do not match those of reproductive-aged women. When irregular cycles reflect reproductive maturity and when they may indicate PCOS is unclear, challenging accurate diagnosis with potential concerns about over-diagnosis. Likewise, women internationally report under diagnosis and delayed diagnosis, dissatisfaction in diagnosis experience, with related anxiety and limited opportunity for education, prevention of complications and treatment of symptoms [13]. Young women may also be commenced on the combined oral contraceptive pill (COPC) prior to assessment and diagnosis, potentially delaying diagnosis. Hence this clinical question was prioritised.

Summary of systematic review evidence

We did not identify any evidence in our patient population to answer the question.

Summary of narrative review evidence

Given the limited evidence identified on systematic review, a narrative review was completed (see supplementary Technical report) and is summarised here. Physiologically, during the first year post-menarche, hormonal responses do not match adult patterns. During the second year about one half of the menstrual cycles range from 21 - 45 days in length, however progesterone levels are low [17]. The average adult menstrual cycle is 28 days, ranging from 24 - 35 days [18]. The majority of irregular cycles may be ovulatory two years post-menarche [18-21], with 80% of cycles being within 21 - 45 days [19, 21-23]. By the third post-menarcheal year, 95% of cycles fall into this range, however cycles can remain irregular until the fifth year [24, 25]. Regular ovulatory cycle onset is also related to age at menarche [26]. In those who begin menses before 12 years, between 12 - 13 years, and after 13 years of age, 50% of cycles are ovulatory by one year, three years, and 4.5 years, respectively [26]. At age 15, more than 50% of girls who are oligo-amenorrhoeic remain so at age 18 [27]. Overall, irregular cycles (> 35 or < 21 days) that continue for more than two years post-menarche are likely to have oligo-anovulation, based on general population data, with consideration needed for age of menarche. With increasing gynaecologic age, fewer females experience cycles exceeding 45 days [28].

It is recognised that irregular menstrual cycles and other features of PCOS can overlap with those observed in the normal pubertal transition and it is important to define where these features are more likely to reflect PCOS. Overall the greatest controversy here relates to the past approaches of identifying the 95th centile of cycle duration as abnormal. If this percentile is used to define a single diagnostic feature (e.g. menstrual cycles) in a condition with a prevalence of around 10%, this is a simplistic and poorly informed approach. In fields such as diabetes and other conditions where diagnostic features represent a continuum, considerable refinement has occurred with alignment with other clinical features and health outcomes. This approach was applied here and the body of literature on normal menstrual cycles reviewed to identify the 85th to 90th percentile, pending more appropriate cluster analysis and longitudinal follow-up data.

This approach was approved by the Paediatric guideline development group (GDG) panel ([Appendix III](#)).

Recommendations

1.1.1 CCR Irregular menstrual cycles are defined as:

- normal in the first year post menarche as part of the pubertal transition
- > 1 to < 3 years post menarche: < 21 or > 45 days
- > 3 years post menarche to perimenopause: < 21 or > 35 days or < 8 cycles per year
- > 1 year post menarche > 90 days for any one cycle
- Primary amenorrhea by age 15 or > 3 years post thelarche (breast development)

When irregular menstrual cycles are present a diagnosis of PCOS should be considered and assessed according to the guidelines.

1.1.2 CCR In an adolescent with irregular menstrual cycles, the value and optimal timing of assessment and diagnosis of PCOS should be discussed with the patient, taking into account diagnostic challenges at this life stage and psychosocial and cultural factors.

1.1.3 CPP For adolescents who have features of PCOS but do not meet diagnostic criteria, an “increased risk” could be considered and reassessment advised at or before full reproductive maturity, 8 years post menarche. This includes those with PCOS features before combined oral contraceptive pill (COCP) commencement, those with persisting features and those with significant weight gain in adolescence.

1.1.4 CPP Ovulatory dysfunction can still occur with regular cycles and if anovulation needs to be confirmed serum progesterone levels can be measured.

Justification

Whilst limited evidence was found to specifically address this question in PCOS, recommendations are informed by the best available evidence on normal adolescent menstrual patterns and ovulatory function and by previous available guidelines, multidisciplinary expertise and consumer perspectives. The GDG and the paediatric endocrine and gynecology expert panel from across the GDGs, carefully considered the available literature, the international feedback and the potential for both over diagnosis and delayed diagnosis when assessing this diagnostic feature in PCOS. They also considered the need for individual consideration around timing and value of diagnosis and the potential desirable and undesirable impacts of making a diagnosis. It was also recognised that many adolescents may be commenced on pharmacological therapy for irregular cycles without a diagnostic assessment for PCOS and this was addressed in the recommendations and practice points highlighting the need to identify those “at risk” and to emphasise reassessment. It is recognised these recommendations will change practice and deviate from past guidelines stipulating > 45 days for all adolescents. Here more specific cut-offs were provided aligned with gynaecological maturity.

1.2 Biochemical hyperandrogenism

In women with suspected PCOS, what is the most effective measure to diagnose PCOS-related biochemical hyperandrogenism?

Clinical need for the question

Hyperandrogenism is a key diagnostic feature of PCOS affecting between 60% - 100% with the condition with both clinical (hirsutism, alopecia and acne) and biochemical hyperandrogenism. Both features of hyperandrogenism are challenging to assess and vary by methods of assessment, ethnicity and confounding factors including excess weight and life stage. Assessment of biochemical hyperandrogenism is hampered by a lack of clarity on which androgens to measure, what assays to use, how to define normal ranges, overlaps between values obtained in controls and PCOS, and access and cost issues for high quality assays. Calculated bioavailable testosterone and calculated free testosterone using the formula of Vermeulen et al is commonly used [29], as is free androgen index (FAI = 100 x (total testosterone/SHBG)). Direct testosterone assays are widely used, however deficiencies in the accuracy of these assays limit their use. Moving forward standardised testosterone measurements that are accurate, reliable and comparable over time are essential [30, 31]. Given the controversy, methodological challenges, options, uncertainty in clinical practice and role of biochemical hyperandrogenism in the diagnosis of PCOS, this question was prioritised.

Summary of systematic review evidence

Seven studies of moderate to high risk of bias reported the diagnostic accuracy of different hormone markers to detect PCOS [32-38]; and another study of moderate risk of bias compared the diagnostic accuracy of different types of assays to detect PCOS [39]. There was insufficient evidence to make definitive recommendations on the optimal hormone and method to measure biochemical diagnosis hyperandrogenism in PCOS, although data indicates that, as a single measure, free testosterone measures provide the most optimal accuracy to detect biochemical hyperandrogenism followed, in no specific order by total testosterone, dehydroepiandrosterone sulfate (DHEAS), and androstenedione.

Summary of narrative review evidence

Given the limited evidence identified on systematic review, a narrative review was completed (see supplementary Technical Report). In summary, with few exceptions, methods for directly assessing total circulating testosterone levels (e.g. direct radioimmunoassays or chemiluminescence immunoassays) are of insufficient precision, sensitivity and specificity to be used for the accurate assessment of total testosterone levels in women and female adolescents, including those with PCOS. There are also currently no reliable direct assays for total or free testosterone. However, laboratories can provide calculated bioavailable testosterone, calculated free testosterone, or free androgen index (FAI). Androstenedione and DHEAS have a more limited role and can increase the probability of detecting hyperandrogenemia, yet they are arguably more useful in exclusion of other causes of hyperandrogenism. DHEAS is predominantly an adrenal androgen and mild elevation may be seen with PCOS, with significant elevations and/or virilisation requiring investigation for possible androgen secreting adrenal tumour. Androstenedione, is elevated in 21-hydroxylase deficient non-classical congenital adrenal hyperplasia. Testosterone secretion may be increased during mid-cycle and assessment of androgen status should preferably be during the early follicular phase in cycling women, whilst diurnal variation means morning levels may be most predictive. Current studies focus on different assays in women already diagnosed with PCOS. This approach has inherent bias as the diagnosis includes hyperandrogenism and further studies are needed to explore relationships between androgen levels and the various immediate and long term clinical features of PCOS.

Recommendations

1.2.1	EBR	Calculated free testosterone, free androgen index or calculated bioavailable testosterone should be used to assess biochemical hyperandrogenism in the diagnosis of PCOS.	❖❖❖ ⊕⊕○○
1.2.2	EBR	High quality assays such as liquid chromatography–mass spectrometry (LCMS)/mass spectrometry and extraction/chromatography immunoassays, should be used for the most accurate assessment of total or free testosterone in PCOS.	❖❖❖ ⊕⊕○○
1.2.3	EBR	Androstenedione and dehydroepiandrosterone sulfate (DHEAS) could be considered if total or free testosterone are not elevated; however, these provide limited additional information in the diagnosis of PCOS.	❖❖❖ ⊕⊕○○
1.2.4	CCR	Direct free testosterone assays, such as radiometric or enzyme-linked assays, preferably should not be used in assessment of biochemical hyperandrogenism in PCOS, as they demonstrate poor sensitivity, accuracy and precision.	❖❖❖
1.2.5	CPP	Reliable assessment of biochemical hyperandrogenism is not possible in women on hormonal contraception, due to effects on sex hormone-binding globulin and altered gonadotrophin-dependent androgen production.	
1.2.6	CPP	Where assessment of biochemical hyperandrogenism is important in women on hormonal contraception, drug withdrawal is recommended for three months or longer before measurement, and contraception management with a non-hormonal alternative is needed during this time.	
1.2.7	CPP	Assessment of biochemical hyperandrogenism is most useful in establishing the diagnosis of PCOS and/or phenotype where clinical signs of hyperandrogenism (in particular hirsutism) are unclear or absent.	
1.2.8	CPP	Interpretation of androgen levels needs to be guided by the reference ranges of the laboratory used, acknowledging that ranges for different methods and laboratories vary widely. Normal values are ideally based on levels from a well phenotyped healthy control population or by cluster analysis of a large general population considering age and pubertal specific stages.	
1.2.9	CPP	Where androgen levels are markedly above laboratory reference ranges, other causes of biochemical hyperandrogenism need to be considered. History of symptom onset and progression is critical in assessing for neoplasia, however, some androgen-secreting neoplasms may only induce mild to moderate increases in biochemical hyperandrogenism.	

Justification

Total testosterone alone can identify 20 - 30% of women with PCOS as having biochemical hyperandrogenism, while measures of unbound or free testosterone will identify 50 - 60%. Laboratory calculated values are recommended. High quality assays provide a more accurate diagnosis and the additional associated cost was deemed important and justified after considering all elements of the Grading of Recommendations, Assessment, Development, and Evaluation (GRADE) framework. Access issues were also acknowledged. Given the challenges in assessing biochemical hyperandrogenism, whilst androgen measures are useful to detect biochemical hyperandrogenism where PCOS is suspected, these are likely to be most useful in diagnosis of PCOS in adolescents and women who demonstrate minimal to no features of clinical hyperandrogenism (e.g. hirsutism). Clarity around standardised assessment for biochemical hyperandrogenism provided by the guideline is likely to be valued.

1.3 Clinical hyperandrogenism

In women with suspected PCOS, what is the most effective measure to clinically diagnose PCOS-related hyperandrogenism?

Clinical need for the question

Signs and symptoms of severe androgen excess can result in virilisation (e.g. male pattern balding, severe hirsutism, and clitoromegaly) and masculinisation. Virilisation is rare. Clinical evidence of mild to moderate androgen excess is more common including hirsutism, acne, and androgen-related alopecia. The interrelationships of these clinical features remains unclear, varies by ethnicity, and requires clinician training, vigilance and skill to assess. These features impact considerably on quality of life in women with PCOS and treatment burden including cosmetic therapies can be significant. Given the fundamental role of hyperandrogenism in diagnosis, and the adverse impact on quality of life, this question was prioritised.

Summary of systematic review evidence

We did not identify any evidence in our patient population to answer the question.

Summary of narrative review evidence

A narrative review provided in the technical report, notes the most recognisable clinical sign of hyperandrogenism as terminal hairs in a male-like pattern in women or “hirsutism”. Elevated androgens are detected in the vast majority (> 70%) of women with hirsutism and few do not demonstrate other features of PCOS (< 5%) [40]. The most common visual assessment tool is the modified Ferriman-Gallwey (mFG) [41, 42] to assess terminal hairs (hairs that would grow > 5mm in length if left unmolested, are usually pigmented, and are medullated). mFG assesses nine primarily masculine body areas for terminal hair: upper lip, chin and neck, upper chest (excluding the nipples), upper abdomen (above the umbilicus), lower abdomen (also known as male escutcheon), thighs (front and/or back), upper back, lower back, and upper arms [42, 43]. Each area is visually scored from zero (no terminal hair visible) to four (terminal hair consistent with a well-developed male). A photographic atlas assists scoring [42].

Comedonal acne is common in adolescent girls, moderate or severe comedonal acne (i.e. 10 or more facial lesions) in early puberty or moderate inflammatory acne through the perimenarcheal years is uncommon (< 5% prevalence) [44, 45]. There are no studies evaluating alopecia in adolescents. For these reasons, mild acne and alopecia are not recommended as considerations in the diagnostic criteria for adolescents.

Defining ‘abnormal’ in hirsutism is controversial. The mFG cut-off score can be based on percentile with a score > 6 - 8 consistent with the 95th percentile of unselected women [41, 43, 46]. It can also be defined by a lower percentile 85 - 90th percentile or by cluster analysis where the score is analysed in relation to other features of PCOS. These approaches suggest that an mFG scores of > 3 in White and Black women [47], and > 5 in Mongoloid Asian (Han Chinese) women [48] represents true abnormality. As outlined above under irregular menstrual cycles, a simplistic cut off at the 95th centile is not appropriate and for this reason the GDG, after reviewing all available evidence, recommended the cut offs of $\geq 4 - 6$ on mFG.

The prevalence of hirsutism is the same across ethnicities, yet the mFG cut-off scores for defining hirsutism and the severity of hirsutism varies by ethnicity. Overall, >50% of women with mFG scores of 3-5 have elevated androgens and/or PCOS [49], and >70-90% of women with scores >5 [42, 46]. Referral bias needs to be considered in reported populations [50, 51]. Hirsutism adversely impacts quality of life [52] and most women readily treat hirsutism complicating assessment, hence health professionals should be prepared to assess any woman who complains of excess hair [49, 53].

Acne is associated with biochemical hyperandrogenism [54, 55], yet the predictive value of acne alone is unclear [40, 54] and there is no accepted assessment tool [40]. Most studies of women with alopecia reveal a relatively low prevalence of hyperandrogenemia [40, 56] and the predictive value of alopecia alone remains unclear, in part as there are many causes that can contribute to alopecia aside from hyperandrogenism. Hair loss on the scalp is usually assessed visually using the Ludwig scale [40].

Recommendations

-
- 1.3.1 CCR A comprehensive history and physical examination should be completed for symptoms and signs of clinical hyperandrogenism, including acne, alopecia and hirsutism and, in adolescents, severe acne and hirsutism. 
- 1.3.2 CCR Health professionals should be aware of the potential negative psychosocial impact of clinical hyperandrogenism. Reported unwanted excess hair growth and/or alopecia should be considered important, regardless of apparent clinical severity. 
- 1.3.3 CCR Standardised visual scales are preferred when assessing hirsutism, such as the modified Ferriman Gallwey score (mFG) with a level ≥ 4 - 6 indicating hirsutism, depending on ethnicity, acknowledging that self-treatment is common and can limit clinical assessment. (See recommendations on ethnic variation). 
- 1.3.4 CCR The Ludwig visual score is preferred for assessing the degree and distribution of alopecia. 
- 1.3.5 CPP There are no universally accepted visual assessments for evaluating acne.
- 1.3.6 CPP The prevalence of hirsutism is the same across ethnicities, yet the mFG cut-off scores for defining hirsutism and the severity of hirsutism varies by ethnicity.
- 1.3.7 CPP As ethnic variation in vellus hair density is notable, over-estimation of hirsutism may occur if vellus hair is confused with terminal hair; only terminal hairs need to be considered in pathological hirsutism, with terminal hairs clinically growing $> 5\text{mm}$ in length if untreated, varying in shape and texture and generally being pigmented.
-

Justification

Both patients and clinicians value an accurate diagnosis of PCOS, clinical hyperandrogenism is an important determinant of quality of life and simple treatments are readily available. While subjective and visual, the mFG score for facial and terminal hair growth is the principal instrument for clinical assessment of hirsutism. Hirsutism can be over-estimated if vellus and terminal hairs are not distinguished. The desirable effects (an accurate and sensitive diagnosis) outweigh the undesirable effects (over-estimation of hirsutism). Assessing for clinical hyperandrogenism is low cost, relative to biochemical assessments for hyperandrogenism, and a standardised assessment for clinical hyperandrogenism is likely to be valued.

1.4 Ultrasound and polycystic ovarian morphology

When is ultrasound indicated to diagnose PCOS?

What are the most effective ultrasound criteria to diagnose PCOS?

Clinical need for the questions

Polycystic ovarian morphology (PCOM) was incorporated into the diagnosis of PCOS in 2003 in the Rotterdam criteria, as a common feature associated with clinical and endocrine features of the condition [57]. This introduced arguably milder phenotypes into PCOS with limited data on natural history, prompting calls for phenotype identification and more research [16]. The definition of PCOM in the Rotterdam criteria is 12 or more follicles measuring 2 - 9mm throughout the entire ovary or an ovarian volume $\geq 10\text{cm}^3$. This was based on a single report on sensitivity and specificity in PCOS compared to controls. Factors that mandate revision of this diagnostic criteria include inadequate initial evidence, advances in ultrasound technology with greater resolution, variable operator skill level, lack of standard reporting, ill-defined cut-offs between normal ovaries and PCOM, the impact of approach (e.g. transvaginal), body habits and age. Natural changes occur in antral follicle count during the pubertal and menopausal transitions and up to 70% of adolescents have PCOM on original criteria [58]. The term "cystic" is a misnomer referring to arrested follicles (not cysts) and identification of PCOM alone can lead to over diagnosis. Diagnosis of PCOS mandates not only PCOM, but associated features of hyperandrogenism and/or ovulatory dysfunction. Independent of diagnosis, if clinically indicated, ultrasound is useful to screen for other pathology. This clinical question was prioritised, with recognition that a reproducible technique and standard reporting to reliably estimate follicle number per ovary and define PCOM, is critical in the accurate diagnosis of PCOS.

Summary of systematic review evidence

A systematic review was completed to address the second clinical question on the most effective ultrasound criteria to diagnose PCOS. Fifteen studies of moderate to high risk of bias, reported the diagnostic accuracy of different ovarian morphology parameters to detect PCOS [32, 37, 59-71]. Two of the fifteen studies were in adolescents [64, 71]. The index tests addressed in these studies included various measures and thresholds of ovarian volume and follicle number. None of the studies pre-specified thresholds. Some studies have reported diagnostic accuracy data using multiple thresholds. Due to the heterogeneity in threshold/cut off values for each index test, meta-analyses (for pooled sensitivity and specificity estimates) could not be performed. However, forest plots were created and imputation of sensitivity and specificity data performed to derive true and false positives and true and false negatives to provide greater detail on accuracy outlined in the technical report. This approach enabled a rigorous evaluation of available evidence, acknowledging the overall poor quality of the studies. For follicle number per ovary (FNPO) there were 11 studies with 2961 adult participants suggesting optimal sensitivity and specificity at > 19 per ovary. Other key challenges with the literature in this area included the variable populations (with and without women with PCOS) used to define cut off values and the use of the 95th percentile cut offs to define abnormality. For ovarian volume, 12 studies with 2096 participants showed significant heterogeneity with a lack of clarity on the optimal size with both 5 - 8 cm^3 and 9 - 10 cm^3 emerging. There is insufficient evidence to suggest use of other ultrasound parameters including ovarian area; maximum number follicles in a single sonographic plane (FSSP); peripheral distribution of ovarian follicles; bright ovarian stroma; combination of age, follicle number, log ovarian volume, and testosterone; or combination of follicular size and ovarian volume for diagnosis of PCOS.

Summary of narrative review evidence

A narrative review was completed to address the first question, supplemented with additional relevant evidence from the above systematic search. The ovary has a full complement of follicles and oocytes, arrested at meiosis, during fetal life. These mature in childhood with ovulation noted after puberty and continuing until menopause [72]. Ovarian volumes change over time with increased antral follicles and stroma. There are no large studies across the lifespan to validate normal ovarian development. Ovarian size increases from age 9 - 11 and maximum volume is reached at age 20 [73-77]. The correlation between menstrual function and ovarian morphology is not straightforward in adolescence with the majority of adolescents having PCOM consistent with Rotterdam criteria, and the few longitudinal studies suggest that 2 - 4 years postmenarche, PCOM is common and not associated with reproductive dysfunction [58, 78]. Therefore, adult PCOM criteria are likely inaccurate for ultrasound diagnosis of PCOS in adolescence with substantive overlap between follicle numbers per ovary in normal adolescents and those with other features of PCOS.

Recommendations

- | | | | |
|-------|-----|---|--|
| 1.4.1 | CCR | Ultrasound should not be used for the diagnosis of PCOS in those with a gynaecological age of < 8 years (< 8 years after menarche), due to the high incidence of multi-follicular ovaries in this life stage. |  |
| 1.4.2 | CCR | The threshold for PCOM should be revised regularly with advancing ultrasound technology, and age-specific cut off values for PCOM should be defined. |  |
| 1.4.3 | CCR | The transvaginal ultrasound approach is preferred in the diagnosis of PCOS, if sexually active and if acceptable to the individual being assessed. |  |
| 1.4.4 | CCR | Using endovaginal ultrasound transducers with a frequency bandwidth that includes 8MHz, the threshold for PCOM should be on either ovary, a follicle number per ovary of ≥ 20 and/or an ovarian volume $\geq 10\text{ml}$, ensuring no corpora lutea, cysts or dominant follicles are present. |  |
| 1.4.5 | CPP | If using older technology, the threshold for PCOM could be an ovarian volume $\geq 10\text{ml}$ on either ovary. | |
| 1.4.6 | CPP | In patients with irregular menstrual cycles and hyperandrogenism, an ovarian ultrasound is not necessary for PCOS diagnosis; however, ultrasound will identify the complete PCOS phenotype. | |
| 1.4.7 | CPP | In transabdominal ultrasound reporting is best focussed on ovarian volume with a threshold of $\geq 10\text{ml}$, given the difficulty of reliably assessing follicle number with this approach. | |
| 1.4.8 | CPP | Clear protocols are recommended for reporting follicle number per ovary and ovarian volume on ultrasound. Recommended minimum reporting standards include: <ul style="list-style-type: none">● last menstrual period● transducer bandwidth frequency● approach/route assessed● total follicle number per ovary measuring 2-9mm● three dimensions and volume of each ovary● Reporting of endometrial thickness and appearance is preferred – 3-layer endometrial assessment may be useful to screen for endometrial pathology● other ovarian and uterine pathology, as well as ovarian cysts, corpus luteum, dominant follicles \geq equal 10mm | |
| 1.4.9 | CPP | There is a need for training in careful and meticulous follicle counting per ovary, to improve reporting. | |

Justification

It was recognised that the data in young women with a gynaecological age of < 8 years (< 8 years after menarche) is inadequate, that peak ovarian maturity has not yet been reached and that defining PCOM at this life stage is not currently possible with the high incidence of multi-follicular ovaries. There was recognition of the risk of over diagnosis in adolescents if ultrasound criteria were included in this age group. Limitations in performing transvaginal ultrasounds in those not yet sexually active was also recognised. These factors were deemed to make the use of ultrasound inappropriate for diagnosis of PCOS in those with a gynaecological age < 8 years at this time. Ultrasound may be indicated for other reasons at this life stage, hence this recommendation is limited to the role of ultrasound in PCOS diagnosis.

Ultrasound is not required for diagnosis in adults with features of hyperandrogenism and ovulatory dysfunction, who already meet PCOS diagnostic criteria. It is recognised that omission of ultrasound does limit full phenotyping. The recommendation to use FNPO as the key diagnostic criteria for PCOM in adults was reconfirmed by the updated evidence review and expert deliberation. Technology advancements in the last decade support an increase in FNPO in diagnosis. Rigorous evaluation of the evidence and multidisciplinary expertise informed modified FNPO recommendations and reaffirmed secondary ovarian volume assessment in diagnosis. Limitations in the evidence were recognised, however significant advances were noted since the original Rotterdam recommendations. All relevant limitations of the evidence were considered by the GDG and co-opted experts, especially the limited relevance of the 95th centile cut offs in determining abnormal FNPO. These factors resulted in a FNPO recommendation between the original Rotterdam and more recent Androgen Excess and PCOS Society (AEPCOS) recommendations. These recommendations also recognise the optimal ultrasound approach, technological ultrasound advances and variability in availability of newer technologies and aim to improve training and standardise reporting. They are likely to improve the reliability of assessing and reporting FNPO, provide for more accurate reporting of PCOM in the diagnosis of PCOS. Importantly, they also limit use and costs of a somewhat invasive test, where it is not appropriate.

1.5 Anti-Müllerian Hormone (AMH)

Is Anti-Müllerian Hormone effective for diagnosis of PCOS?

Is Anti-Müllerian Hormone effective for diagnosis of PCOM?

Clinical need for the questions

Given the challenges with ultrasound in diagnosis of PCOS, including in the years after menarche, serum Anti-Müllerian Hormone (AMH) has been proposed as an alternative marker of ovulatory dysfunction in PCOS. AMH is a polypeptide of the transforming growth factor beta (TGF- β) family solely secreted by granulosa cells of the preantral and small antral ovarian follicles. Serum AMH levels are significantly higher in women with PCOS compared with normal ovulatory women [79, 80]. Strong correlations have been demonstrated between circulating AMH levels and antral follicle count on ultrasound in PCOS. AMH may also provide insight into the pathogenesis of PCOS and the different phenotypes. However, current literature reveals significant heterogeneity and the diagnostic value of serum AMH remains far from clear.

Summary of systematic review evidence

Twenty-nine studies of moderate to high risk of bias were identified by our search to address diagnostic accuracy of AMH for PCOS and/or PCOM [62, 65, 81-107]. One of these was a systematic review [88] and included nine of the studies identified here, however it also included studies that did not meet the inclusion criteria for this evidence review and it was missing additional more recently studies identified by the search: therefore it cannot be used. Four of the 28 primary studies addressed the diagnostic accuracy of AMH for PCOS and PCOM [85, 86, 92, 98]; and one for PCOM only [103]. Six studies included adolescents and one of these addressed PCOS and PCOM [86]. The remaining 21 studies included adult participants for diagnosis of PCOS, with three addressing PCOS and PCOM [85, 92, 98], and the remaining 18 addressing PCOS [62, 65, 81-84, 87, 91, 93-97, 99, 102, 104, 105, 107]. In adolescents, one was in overweight and obese participants [89] and one had unclear BMI [106]. In adults, one [82] included lean and obese participants; and five [62, 81, 85, 91, 107] included overweight and obese participants. Here we generated receiver operating characteristic (ROC) curves by plotting the true positive rate against the false positive rate at various threshold settings, based on published literature. The area under the ROC curve in adolescents for PCOS was around 0.5 - 0.88 and the threshold from 25 - 44pmol/L. In adults, the area under the ROC curve was about 0.66 - 0.994 and the threshold from 10-57pmol/L. In PCOM detection, in adolescents, one study showed an area under the ROC curve of about 0.87 and the threshold 50pmol/L. In adults, the ROC was about 0.67 - 0.92 and the threshold 20 - 30pmol/L.

Although serum AMH levels in adolescent and adult women with both PCOM and PCOS are significantly higher than those without these features in all studies, there is considerable overlap. A specific threshold of AMH in PCOS and PCOM is therefore very challenging. Heterogeneity between studies relates to assays, life stage and phenotypes studied. Another key contributor is the lack of well-defined populations including variable ultrasound criteria to establish PCOM and the criteria used to define controls.

Recommendations

1.5.1 EBR Serum AMH levels should not yet be used as an alternative for the detection of PCOM or as a single test for the diagnosis of PCOS.

1.5.2 CPP There is emerging evidence that with improved standardisation of assays and established cut off levels or thresholds based on large scale validation in populations of different ages and ethnicities, AMH may become a more accurate assay in the detection of PCOM.

Justification

Whilst an AMH assay to reflect ovarian morphology and diagnose PCOS offers convenience and lower costs, current assays and available evidence do not adequately support these roles for AMH at the current time. It is acknowledged that both ultrasound and AMH levels present challenges in PCOS diagnosis. It is also acknowledged that assays are improving and this recommendation may evolve over time.

1.6 Ethnic variation

In women with suspected PCOS is there evidence of ethnic and geographic variations in prevalence and presentation?

Clinical need for the question

PCOS was originally described in Caucasians and subsequently has shown to be prevalent across the world. Whilst there are many studies that explore PCOS within different ethnic groups, few compare across groups. Some studies consider within country populations by ethnicity, yet do not consider differences in diet, lifestyle and occupation. None the less, studies suggest differences in prevalence and clinical features across ethnic groups and greater clarity is needed to inform considerations and adaptation of guideline recommendations in the diagnosis and treatment of PCOS.

Summary of narrative review evidence

A systematic review was not conducted to answer this question which was reviewed narratively based on clinical expertise. In summary, an identified systematic review on prevalence and phenotypic features revealed some differences internationally [4] between ethnic and geographic regions. The highest prevalence has been reported among Australian Aboriginal women and South Asians migrating to developed countries, both populations with increased BMI [4, 108]. Ovulation appears not to differ, whilst androgen levels appear similar. Ultrasound ovarian features are difficult to compare, compromised by the differences in technology, diagnostic features and operator skill, yet no clear differences have emerged. For hirsutism there are clear ethnic differences in the cut off scores, with Middle Eastern and South Asian women having higher cut off scores for hirsutism than those of Eastern Asian origin. Acanthosis is more common in women of South East Asian background, reflecting increased insulin resistance. For metabolic features, BMI differs between ethnic groups, primarily dependent on lifestyle and environmental factors. Insulin resistance, diabetes risk and lipid profiles do appear to vary, potentially influenced by genetic factors and visceral adiposity. Genetic data shows both similarities and differences. Psychological features have not been well studied, however on quality of life studies, cultural rather than ethnic factors appear to impact, including cultural perspectives on infertility [109]. In terms of treatment responses, IVF may be less successful in women with of Asian ethnicity, but there is no similar data for ovulation induction.

Recommendations

- 1.6.1 CCR Health professionals should consider ethnic variation in the presentation and manifestations of PCOS, including:
- a relatively mild phenotype in Caucasians
 - higher BMI in Caucasian women, especially in North America and Australia
 - more severe hirsutism in Middle Eastern, Hispanic and Mediterranean women
 - increased central adiposity, insulin resistance, diabetes, metabolic risks and acanthosis nigricans in South East Asians and Indigenous Australians
 - lower BMI and milder hirsutism in East Asians
 - higher BMI and metabolic features in Africans

Justification

Ethnic differences appear to relate primarily to skin manifestations and metabolic features of PCOS. These may affect interpretation and application of relevant guideline recommendations and need to be considered by health professionals when assessing the individual woman. In response to peer review feedback specific ethnic differences have been noted in the guideline to inform practice.

1.7 Menopause life-stage

What is the post-menopausal phenotype of PCOS and how elevated should androgens be to indicate PCOS?

Clinical need for the question

Menopause is a natural life stage occurring generally around the age of 51 years. The diagnosis of PCOS by Rotterdam criteria requires two of three criteria in women, including oligo- and/or anovulation, clinical or biochemical hyperandrogenism and polycystic ovaries by ultrasound [57]. However, these three criteria for diagnosis change naturally with age impacting on phenotype and presenting challenges in diagnosis. Overall it is acknowledged that there is inadequate evidence of the natural history of PCOS and the concept of whether PCOS resolves and/or persists remains unclear pending better longitudinal studies. Postmenopausal phenotypes of PCOS are poorly defined, with limited longitudinal natural history studies. Uncertainty in assessment and diagnosis at this life stage leads to confusion for health professionals and women on long term health risks and screening recommendations.

Summary of narrative review evidence

A systematic review was not conducted to answer this question, which was reviewed narratively based on clinical expertise. With aging, changes occur in all three diagnostic criteria. Menstrual cycles become more regular in PCOS [110-112]. Ovarian volume and follicle number decrease longitudinally in PCOS and control women. Using cross-sectional data, ovarian volume and follicle number decrease in both groups, but the decrease in ovarian volume is less pronounced in women with PCOS than in controls. Age-based criteria to define PCOM have been proposed using a combination of age, log ovarian volume, follicle number, and testosterone to distinguish PCOS from non-PCOS [60]. Androgens decline with age in women generally including those with PCOS [113-115] in longitudinal and cross-sectional studies [116]. Testosterone free androgen index (FAI), and calculated free testosterone are higher in women with PCOS aged 18–44 years compared to controls [116]. Regarding menstrual cycles, the average age of menopause in PCOS is not known. A two-year delay in the age of menopause has been estimated using AMH levels [117] and PCOS has been independently associated with later menopause [118]. There is no established phenotype for PCOS after menopause. In postmenopausal women, ovulation ceases. Hirsutism is greater in PCOS than in controls in postmenopausal women [119] but little is known about acne and alopecia in these women. Postmenopausal women with PCOS have higher 17-hydroxyprogesterone, androstenedione, DHEAS, total Testosterone and FAI than women without PCOS [116, 119, 120]. However, androgen assays are unreliable in women especially with the lower levels generally observed postmenopause [121]. Postmenopausal women with PCOS have abnormal glucose metabolism [122] and higher triglycerides than controls [119]. Other methods to identify PCOS in postmenopausal women have been proposed. For PCOS diagnosis in menopause, previous history of oligo-ovulation, PCOM and current features of hyperandrogenism [123, 124] have been considered, as have insulin resistance [125].

Recommendations

- | | | | |
|-------|-----|--|---|
| 1.7.1 | CCR | Postmenopausal persistence of PCOS could be considered likely with continuing evidence of hyperandrogenism. |  |
| 1.7.2 | CCR | A diagnosis of PCOS postmenopause could be considered if there is a past diagnosis of PCOS, a long-term history of irregular menstrual cycles and hyperandrogenism and/or PCOM, during the reproductive years. |  |
| 1.7.3 | CPP | Postmenopausal women presenting with new-onset, severe or worsening hyperandrogenism including hirsutism, require further investigation to rule out androgen-secreting tumours and ovarian hyperthecosis. | |

Justification

A consensus recommendation was made around assessment of persistence of PCOS in those with a past diagnosis of PCOS or the relevant diagnostic features, or in women with persistent hyperandrogenism. The importance of excluding other diagnoses in cases of significant hyperandrogenism was recognised. These recommendations align with past guidelines with a key emphasis placed on research to provide clarity on postmenopausal PCOS phenotypes and persistence of PCOS postmenopause. Undesirable effects are unclear and it is important to note that reliance on history may overestimate the presence of oligo/amenorrhoea. Labelling of patients with a diagnosis may also have adverse consequences (psychological etc), whilst making a diagnosis may prompt risk recognition and screening such as for glycaemic abnormalities.

1.8 Cardiovascular disease

Are women with PCOS at increased risk for cardiovascular disease?

In women with PCOS, what is the most effective tool/method to assess risk of cardiovascular disease?

Clinical need for the questions

Cardiovascular disease (CVD) remains one of the leading causes of death in women and any condition further increasing CVD risk, will have significant public health impact. CVD primarily affects postmenopausal women in the later decades of life, however CVD development and risk factors are present in early adulthood. Longitudinal studies of well-defined cohorts with and without PCOS are limited. Existing cohorts have poorly defined PCOS status and focus on younger women, or on CVD risk factors rather than clinical events. This makes the determination of CVD risk in PCOS very challenging. It is acknowledged that metabolic syndrome and CVD risk factors are clearly increased in PCOS and that cardiovascular health overall needs to be considered, however given the limited current data on clinical events, overall CVD risk and optimal screening for additional risk factors remains highly controversial.

Summary of systematic review evidence

Two systematic reviews [126, 127] and eight observational studies [128-135] were identified by the search to address risk of CVD in women with PCOS. Seven of the observational studies were addressed across the two systematic reviews, however the systematic reviews included studies in the analysis that do not meet the PICO for this evidence review, therefore the data from the systematic reviews cannot be used here. The risk of bias/methodological quality assessments from the systematic reviews have been used. Studies were retrospective (6) and prospective cohort (1) studies reporting CVD-related event rates in women with and without PCOS over time.

Meta-analysis was conducted for outcomes with two or more studies. There was no statistical difference between PCOS and non-PCOS groups in terms of myocardial infarction (3 studies, 1633 participants, I² 0%); stroke (4 studies, 3012 participants, I² 14%; CVD-related death (2 studies, 779 participants, I² 0%); and coronary artery/heart disease (2 studies, 2152 participants, I² 80%). One study each addressed angina (no difference), large vessel disease (p value not reported), coronary artery calcification (p value not reported). One study presented odds ratios and suggest that when a group of women with PCOS are compared to a UK-wide population, the risk of myocardial infarction (but not angina) was increased in women with PCOS over 45 years (stratified into 15 - 44, 45 - 54, 55 - 64 and > 65). When they compared the same women with PCOS to a local community population, the risk of myocardial infarction and angina was increased in women with PCOS. However, when all age groups were combined, there was no difference in risk between women with and without PCOS, for either myocardial infarction or angina, regardless of where the control population was sourced. Given the methodological and reporting limitations and small sample sizes of these observational studies, all findings should be interpreted with caution. Furthermore the relatively young age of women included in most studies limits the interpretation of the available data.

On screening tools/methods for CVD, we did not identify any evidence in women with PCOS to answer the question regarding the most effective method/tool to assess risk of CVD. The summary of the narrative review evidence is provided here including an international position statement on CVD risk assessment in PCOS [136] and existing guidelines on absolute or global CVD risk assessment [137], obesity [138], lipids [139, 140] and hypertension [141] for the general population. The concept of overall or global CVD risk was also considered important and relevant in women with PCOS.

Recommendations

- 1.8.1 CCR All those with PCOS should be offered regular monitoring for weight changes and excess weight, in consultation with and where acceptable to the individual woman. Monitoring could be at each visit or at a minimum 6 - 12 monthly, with frequency planned and agreed between the health professional and the individual (see 3.5). 
- 1.8.2 CCR Weight, height and ideally waist circumference should be measured and BMI calculated with the following considered:
- BMI categories and waist circumference should follow World Health Organisation guidelines, also noting ethnic and adolescent ranges.
 - Consideration should be given for Asian and high-risk ethnic groups including recommended monitoring of waist circumference.
- 1.8.3 CCR All women with PCOS should be assessed for cardiovascular risk factors and global CVD risk. 
- 1.8.4 CCR If screening reveals CVD risk factors including obesity, cigarette smoking, dyslipidemia, hypertension, impaired glucose tolerance and lack of physical activity, women with PCOS should be considered at increased risk of CVD. 
- 1.8.5 CCR Overweight and obese women with PCOS, regardless of age, should have a fasting lipid profile (cholesterol, low density lipoprotein cholesterol, high density lipoprotein cholesterol and triglyceride level at diagnosis). Thereafter, frequency of measurement should be based on the presence of hyperlipidemia and global CVD risk. 
- 1.8.6 CCR All women with PCOS should have blood pressure measured annually, or more frequently based on global CVD risk. 
- 1.8.7 CPP Health professionals need to be aware that CVD risk in women with PCOS, remains unclear pending high quality studies, however prevalence of CVD risk factors is increased, warranting consideration of screening.
- 1.8.8 CPP Consideration needs to be given to the significant differences in CVD risk across ethnicities (see 1.6.1) when determining frequency of risk assessment.

Justification

Whilst it remains unclear as to whether women with PCOS have a higher risk of CVD, data remains limited and women have generally been studied at a relatively young age. The guidelines therefore emphasise the increase in CVD risk factors, rather than making a recommendation about CVD risk. Assessment of CVD risk in PCOS needs to encompass assessment of well-established risk factors, including those specifically increased in PCOS: weight, BMI, waist circumference, lipid profiles, blood pressure, glucose levels and physical activity. The presence of PCOS as an independent CVD risk factor is yet to be confirmed pending quality studies to determine whether these elevated CVD risk factors convert to the anticipated risk of CVD in the longer term. However, in the presence of well-established CVD risk factors and inadequate longitudinal CVD data, it was deemed that women with PCOS require screening.

1.9 Gestational diabetes, impaired glucose tolerance and type 2 diabetes

Are women with PCOS at increased risk for impaired glucose tolerance, gestational diabetes and type 2 diabetes mellitus?

In women with PCOS, what is the most effective tool/method to assess risk of type 2 diabetes?

Clinical need for the questions

Glucose is a continuous variable. Cut off levels for gestational diabetes (GDM), impaired glucose tolerance (IGT) and type II diabetes (DM2) remain controversial and somewhat arbitrary. Clinical sequelae inform the arbitrary cut offs for these conditions; in pregnancy any elevation of blood glucose increases morbidity for mother and baby; in IGT long-term health risks including CVD are increased and in DM2, both micro and macrovascular risks are increased. In the general population, optimal screening protocols for these conditions vary and the most reliable tests for screening and diagnosis [oral glucose tolerance tests (OGTT), fasting glucose or HbA1c] remain controversial. These controversies extend to PCOS, where increased risks of GDM, IGT and DM2 [9] and underlying insulin resistance [142] have been demonstrated on meta-analyses, independent of BMI. Controversy around the optimal screening test is significant in PCOS, with proposed benefits of identifying IGT on an OGTT, requiring balance with increased inconvenience, cost and poor implementation, despite recommendations in past guidelines. Ethnicity, BMI and other risk factors also influence risk of glycaemic abnormalities and as per the general populations, these need to be considered when determining screening type and frequency.

Hyperglycaemic conditions

Summary of narrative review evidence

A systematic review was not conducted to answer the first question and was reviewed narratively based on clinical expertise and prior systematic reviews and meta-analyses. In summary, meta-analyses indicate increased IGT, GDM and DM2 risks, independent of obesity. Women with PCOS had increased prevalence of IGT (OR 2.48, 95% CI 1.63, 3.77; BMI-matched studies OR 2.54, 95% CI 1.44, 4.47), DM2 (OR 4.43, 95% CI 4.06, 4.82; BMI-matched studies OR 4.00, 95% CI 1.97, 8.10) [143]. Consistently, DM2 was four times higher in a recent Danish registry study and was diagnosed four years earlier in PCOS [144]. The prevalence differs by ethnicity and is higher in more obese study populations [144]. HbA1c, fasting glucose, 2h glucose, measures of insulin resistance, triglycerides, sex hormone binding globulin and BMI at baseline may be the best predictors for development of DM2 [144]. When models were corrected for age and BMI, fasting glucose, 2h glucose on OGTT and triglycerides were the best predictors.

Screening

Summary of systematic review evidence

One low quality systematic review with high risk of bias was identified by our search [145] that asked the question: How can women with PCOS be identified for risk of DM2 screening? The authors of the systematic review found no studies addressing the question and in the absence of evidence, the authors suggest that oligomenorrhoea, along with clinical or biochemical hyperandrogenism, obesity or a family history of risk of DM2 may be indicators of risk of DM2. The systematic review was deemed insufficient evidence on which to base a recommendation. Therefore clinical consensus recommendations have been made based on the systematic review, an international position statement on CVD risk assessment in PCOS [136] and guidelines for case detection and diagnosis of DM2 [146].

Summary of narrative review evidence

Whilst guidelines consistently recommend screening for DM2 in PCOS, whether to target subgroups, which test to use (fasting glucose, OGTT or HbA1c) and optimal frequency, vary between guidelines [147] and remain controversial. Some recommend screening all women with PCOS [148], whereas others consider additional risk factors including ethnicity, BMI, previous GDM or a family history of DM2. Most recommend the OGTT, whilst frequency of testing is variable. The specific impact of ethnicity (65% of the world's population are of high-risk Asian ethnicity) and of excess weight on DM2 risk in PCOS, presents challenges. In a low risk northern European ethnic group, lean women did not develop DM2 by 46 years, with risk increased in the majority who were overweight or obese [149]. Yet, in a recent abstract, 47% of Asian women with PCOS had IGT or DM2 by 41 years, despite limited obesity. The concept of absolute versus relative risk is also important as in low risk populations (Caucasian, healthy weight), a four-fold increased risk from PCOS equates to a low incidence of DM2, yet in high-risk South East Asians or obese women, PCOS significantly impacts on DM2 incidence [150].

General guidelines recommend testing for prediabetes and DM2 in adolescents and adults at any age who are overweight or obese (BMI over 25 kg/m² or 23 kg/m² in Asians), with additional risk factors (e.g. PCOS) [151]. Given the increased risks associated with hyperglycaemia in reproductive aged women (outlined below), the high prevalence of additional risk factors in PCOS and the increased risks with PCOS, screening was considered in all adults with PCOS, and adolescents who are overweight or from a high-risk ethnic group.

The optimal screening test remains unclear in the general population and in PCOS, with fasting glucose, OGTT or HbA1c now acceptable for diagnosis of DM2. The OGTT has higher cost and greater inconvenience, yet can define IGT and influence practice around lifestyle intervention and metformin use, with clear evidence of DM2 prevention in general populations [152], not yet demonstrated based on fasting glucose or HbA1c criteria [151]. HbA1c also brings cost, interference with other conditions and variation across ethnicities. The GDG deemed that on balance, the type of screening should be influenced by clinical judgement on overall risk, resources, access, preference and consideration of where results for IGT will influence practice on prevention of DM2. The high background risk of GDM and the increase in PCOS were considered, along with morbidity in pregnancy based on OGTT (fasting, one hour and two hour levels are all independently associated with adverse outcomes) [153]. Population recommendations are to screen at antenatal booking and at 24 - 28 weeks in women with risk factors for DM2 [151], with many guidelines recommending universal screening at 24 - 28 weeks. In this context the GDG recommended an OGTT preconception or at booking and at 24 - 28 weeks, acknowledging the need for further research.

In terms of frequency of screening, a minimum of three yearly is recommended in the general population, considering other risk factors. This was considered reasonable in PCOS, with increased frequency with other risk factors.

Recommendations

-
- 1.9.1 CCR Health professionals and women with PCOS should be aware that, regardless of age, the prevalence of gestational diabetes, impaired glucose tolerance and type 2 diabetes (5 fold in Asia, 4 fold in the Americas and 3 fold in Europe) are significantly increased in PCOS, with risk independent of, yet exacerbated by, obesity. 
- 1.9.2 CCR Glycaemic status should be assessed at baseline in all women with PCOS. Thereafter, assessment should be every one to three years, influenced by the presence of other diabetes risk factors. 
- 1.9.3 CCR An oral glucose tolerance test (OGTT), fasting plasma glucose or HbA1c should be performed to assess glycaemic status. In high-risk women with PCOS (including a BMI > 25kg/m² or in Asians > 23kg/m², history of impaired fasting glucose, impaired glucose tolerance or gestational diabetes, family history of diabetes mellitus type 2, hypertension or high-risk ethnicity), an OGTT is recommended. 
- 1.9.4 CCR A 75-g OGTT should be offered in all women with PCOS preconception when planning pregnancy or seeking fertility treatment, given the high risk of hyperglycaemia and the associated comorbidities in pregnancy. If not performed preconception, an OGTT should be offered at < 20 weeks gestation, and all women with PCOS should be offered the test at 24-28 weeks gestation. 
-

Justification

DM2 risk factors significantly increase background population risk and prevalence of GDM and DM2, which are further increased in PCOS, independent of BMI, age and ethnicity, representing a significant health and cost burden. The GDG unanimously agreed that screening was warranted in all adults with PCOS and in adolescents with additional risk factors at baseline. Optimal tests remain unclear and fasting glucose, HbA1c or OGTT can be used. An OGTT brings higher cost and inconvenience, yet where background risk is high, or where diagnosis of IGT will change practice (lifestyle intervention or metformin use) an OGTT is recommended, at minimum at baseline. Frequency of testing should be a minimum of three yearly informed by additional risk factors. These recommendations are less intensive than many prior guidelines. Where past guidelines were followed costs and inconvenience may now be reduced. The majority of GDG members voted in favour of the final recommendations, however support for these recommendations were not unanimous (see supplementary Technical Report).

1.10 Obstructive sleep apnea

Are women with PCOS at increased risk for sleep apnea and what is the method/tool most effective to screen for sleep apnea in PCOS?

Clinical need for the question

Obstructive sleep apnea (OSA) is characterised by repetitive occlusions of the upper airway during sleep with futile ventilatory efforts, oxygen desaturations, sleep arousal and the resumption of ventilation, fragmenting sleep and causing daytime sleepiness. OSA appears more common in PCOS and in obesity, a common corollary of PCOS. OSA prevalence among general adult populations varies across cohorts and is between 9 - 38% [154], with half being minimally symptomatic. Unlike conditions such as hypertension and diabetes where clinical sequelae are measurable at a particular cut off point that inform treatment decisions, there is no established cut off point at which OSA warrants treatment. Treatment process describes a personalised care plan that factors in symptomatology and disruptive impact of associated snoring. Although not well quantified, the potential long term health sequelae still remain an important consideration in the treatment decision and treatment is usually offered routinely to severe cases [155]. Addressing the public health implications of OSA are challenged by the magnitude of its prevalence, the complexity of the diagnostic process as well as the suboptimal effectiveness of device-based treatments such as continuous positive airway pressure (CPAP).

Summary of narrative review evidence

A systematic review was not conducted to answer this question and this was reviewed narratively based on clinical expertise. Randomised controlled trials (RCTs) demonstrate benefits for symptoms, quality of life, mood and productivity [156]. Observational trials link OSA to adverse cardiovascular outcomes and death [157] and surrogate outcomes may improve with treatment [158]. Relationships to diabetes and glycaemic response to treatment remain controversial [159-163], whilst large RCTs have failed to show CVD benefits of OSA treatment [156, 164, 165]. Clinically, OSA screening is currently warranted in those with symptoms, where treatment benefit has been demonstrated in the general population [166]. In PCOS, several studies demonstrate high rates of OSA [167-170] and with matched controls [167], the high prevalence of OSA was not explained by obesity. Hyperandrogenism may contribute to OSA [171] and there are links to metabolic syndrome [172, 173], although treatment studies in PCOS are very limited [172].

Despite poor quality evidence and the current lack of rationale for screening and treatment of OSA based on metabolic risk, screening for OSA has been advocated in PCOS [174]. In the setting of current evidence, clinical screening for those women with symptoms is justified consistent with recommendations in the general population, with validated tools available [175, 176] including the **Berlin Questionnaire** which does not include age criteria and may be more applicable here (**Appendix IV**), although none of these are validated in young women with and without PCOS. A positive screen cannot guide treatment and further experiences assessment is required through a detailed history. Overall the most compelling case for treating OSA relates to the improving symptoms of non-restorative sleep, daytime fatigue and sleepiness.

Recommendations

- 1.10.1 CCR Screening should only be considered for OSA in PCOS to identify and alleviate related symptoms, such as snoring, waking unrefreshed from sleep, daytime sleepiness, and the potential for fatigue to contribute to mood disorders. Screening should not be considered with the intention of improving cardiometabolic risk, with inadequate evidence for metabolic benefits of OSA treatment in PCOS and in general populations. 
- 1.10.2 CCR A simple screening questionnaire, preferably the Berlin tool, could be applied and if positive, referral to a specialist considered. 
- 1.10.3 CPP A positive screen raises the likelihood of OSA, however it does not quantify symptom burden and alone does not justify treatment. If women with PCOS have OSA symptoms and a positive screen, consideration can be given to referral to a specialist centre for further evaluation.

Justification

Screening and identification of women with symptomatic OSA who may benefit from treatment appears warranted. Wide scale screening on the basis of unproven metabolic benefits of OSA treatment is not currently warranted. The resource implications of selective screening in symptomatic women may both reduce or increase resources (clinician time) depending on current practice. Availability of ambulatory or in laboratory polysomnography in conjunction with clinical follow-up of the results and treatment planning may not be universal.

1.11 Endometrial cancer

Are women with PCOS at increased risk of endometrial cancer and what is the method/tool most effective to screen for endometrial cancer in PCOS?

Clinical need for the question

PCOS has been associated with increased risk of endometrial cancer, yet the interplay is complex with inter-related comorbidities including obesity, and with potential influence from PCOS treatments. Pathophysiology is related to unopposed estrogen in the setting of anovulation and prevention is feasible. Overall given the prevalence and interrelated comorbidities between endometrial cancer and PCOS, this question was prioritised.

Summary of narrative review evidence

A systematic review was not conducted to answer this question and it was reviewed narratively based on clinical expertise and is summarised here. The risk of endometrial cancer has been shown to be between 2 - 6 times higher in women with PCOS [177], with most adenocarcinomas (> 95%) including Type I and Type II cancers [178, 179], with type I increased in PCOS [180, 181]. The increased prevalence of endometrial cancer in PCOS [182], is related to prolonged endometrial exposure to unopposed estrogen in anovulation. Additionally, endometrium in PCOS may exhibit progesterone resistance [183]. Associations between PCOS and endometrial cancer are complex and co-morbid conditions such as obesity, infertility, DM2 and metabolic syndrome are relevant, whilst PCOS treatment options may influence cancer risk [181, 183].

Three meta-analyses, with overlapping studies, report increased risk of endometrial cancer in PCOS [184-186]. All include estimates from analyses that did not take into account BMI, relevant in both PCOS and endometrial cancer [177] with studies limited by few exposed cases. Where BMI was considered, associations with PCOS and endometrial cancer are less consistent [181]. A cohort study reported an increased risk of endometrial cancer in PCOS compared to age-matched controls with OR of 5.3 (95% CI=?1.5–18.6) without adjustment for BMI and 6.1 (95% CI=?1.0–36.9) with adjustment [187], yet others report contrasting results on BMI [180]. Another group reported a higher OR in premenopausal women [188]. Differences relate to variable adjustment for confounders and study population [181], with endometrial thickness and age significant predictors [189, 190].

Regarding PCOS treatments, metformin has no association or a protective association with endometrial cancer [181]. Clomiphene studies are limited by power, but a small non-significant increased risk of endometrial cancer has been shown [191]. Letrozole, yet to be explored in relation to endometrial cancer, is used as an adjuvant treatment for hormone receptor positive postmenopausal breast cancer and may decrease hormonal related cancer risk [181]. Oral contraceptives reduce risk for endometrial cancer in general populations and effects may be enduring.

Routine screening for endometrial hyperplasia or cancer in PCOS is not warranted although endometrial surveillance by transvaginal ultrasound or endometrial biopsy is indicated for those women with PCOS who have thickened endometrium, prolonged amenorrhea, unopposed estrogen exposure or abnormal vaginal bleeding, based upon clinical suspicion [183].

Recommendations

- 1.11.1 CCR Health professionals and women with PCOS should be aware of a two to six-fold increased risk of endometrial cancer, which often presents before menopause; however absolute risk of endometrial cancer remains relatively low. 
- 1.11.2 CPP Health professionals require a low threshold for investigation of endometrial cancer in women with PCOS or a history of PCOS, with investigation by transvaginal ultrasound and/or endometrial biopsy recommended with persistent thickened endometrium and/or risk factors including prolonged amenorrhea, abnormal vaginal bleeding or excess weight. However, routine ultrasound screening of endometrial thickness in PCOS is not recommended.
- 1.11.3 CPP Optimal prevention for endometrial hyperplasia and endometrial cancer is not known. A pragmatic approach could include COCP or progestin therapy in those with cycles longer than 90 days.

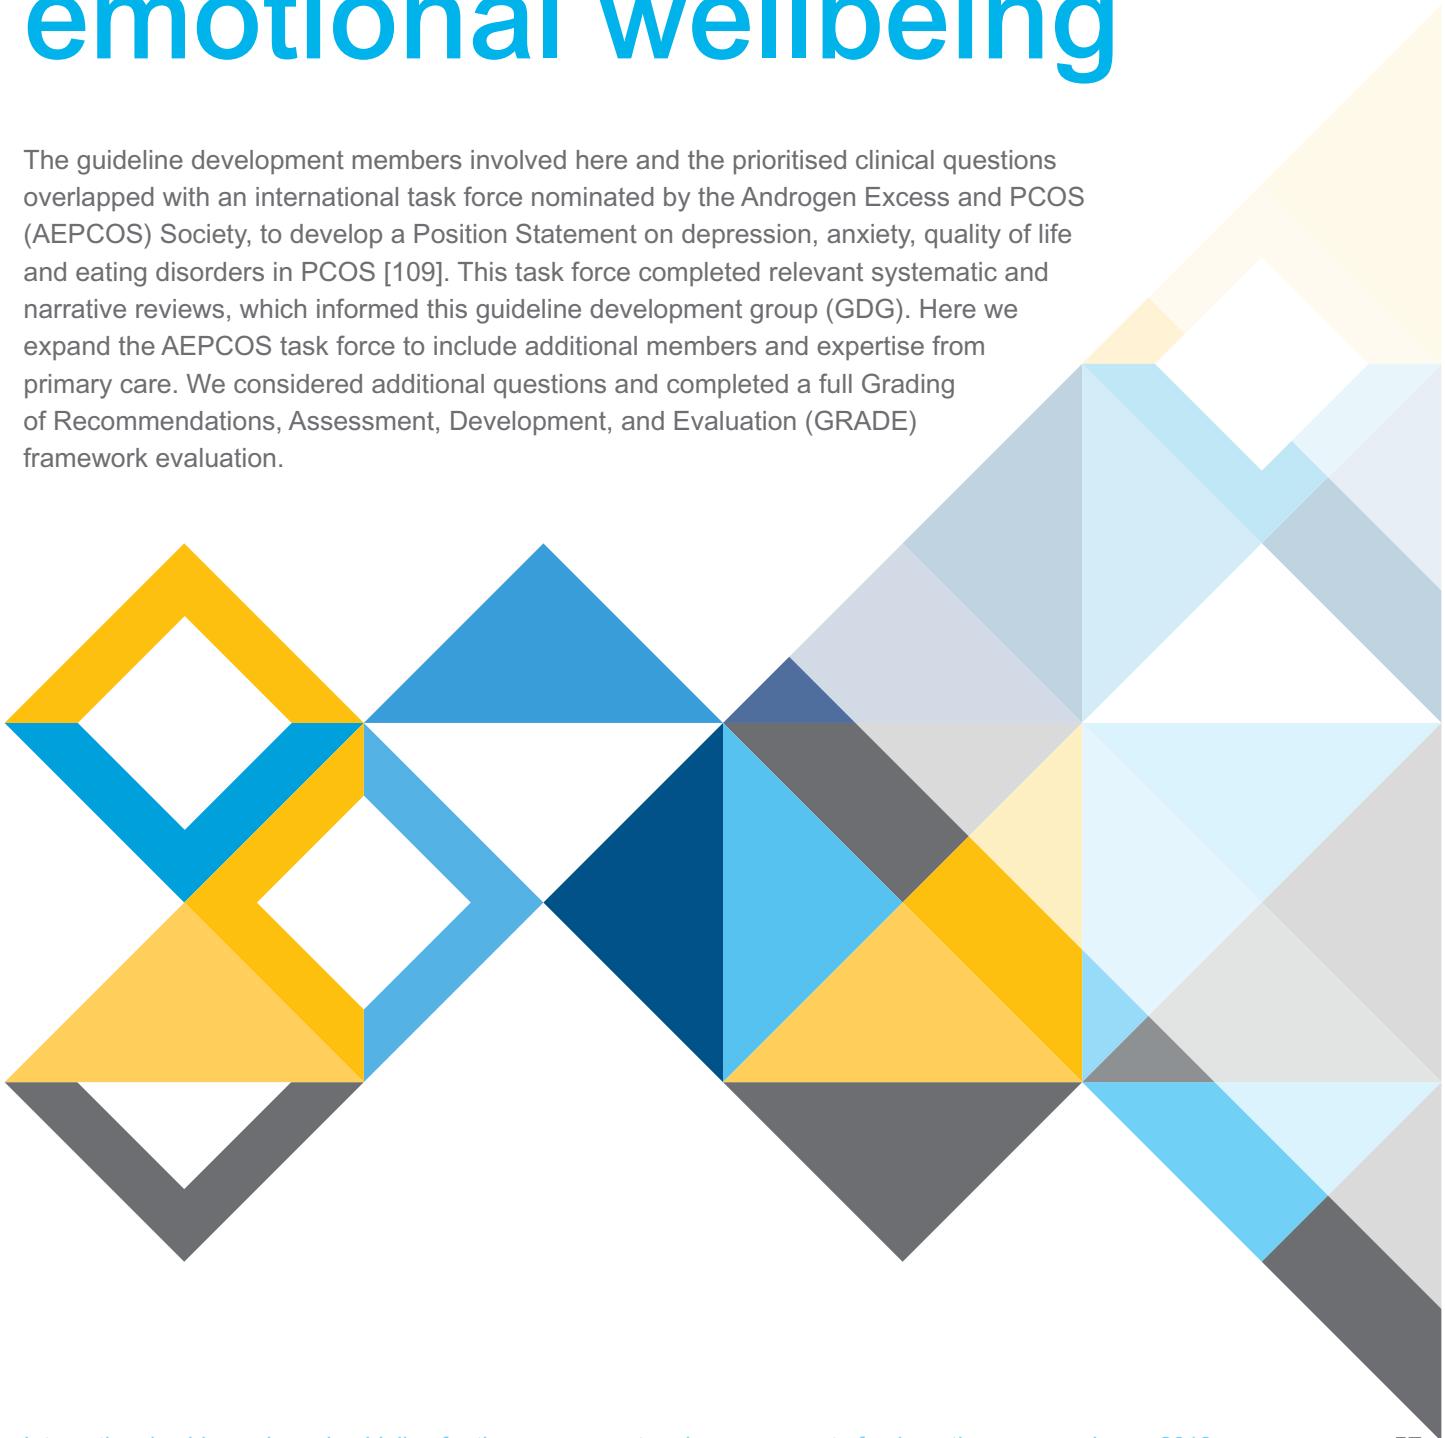

Justification

Associations between PCOS and endometrial cancer are complex, with many potential confounders. Women with PCOS appear to have an increased risk of endometrial cancer consistent with anovulation and increased prevalence of obesity. Routine screening for endometrial cancer in PCOS is not recommended, however vigilance and awareness of increased risk is important.

Chapter Two

Prevalence, screening, diagnostic assessment and treatment of emotional wellbeing

The guideline development members involved here and the prioritised clinical questions overlapped with an international task force nominated by the Androgen Excess and PCOS (AEPCOS) Society, to develop a Position Statement on depression, anxiety, quality of life and eating disorders in PCOS [109]. This task force completed relevant systematic and narrative reviews, which informed this guideline development group (GDG). Here we expand the AEPCOS task force to include additional members and expertise from primary care. We considered additional questions and completed a full Grading of Recommendations, Assessment, Development, and Evaluation (GRADE) framework evaluation.

2.1 Quality of life

In women with PCOS, what is the prevalence and severity of reduced quality of life and should quality of life be assessed as part of standard care?

In women with PCOS, what dimensions of quality of life are most affected?

In women with PCOS, what is the most effective tool/method to assess quality of life?

Clinical need for the questions

Health related quality of life (HRQoL) is a well-recognised and important health outcome, especially in chronic disease and relates to patient reported physical, social and emotional effects of a condition and its associated treatments [109]. Assessment is self-reported and can be measured through a variety of tools. Generic tools include the Short Form -36 (SF-36) and World Health Organisation (WHO) tools, yet these are not ideal for PCOS with a significant focus on mobility, impact on work, pain, environment and propensity to infective illnesses. They do not consider key dimensions of PCOS such as infertility and hirsutism and PCOS specific tools are now available. The polycystic ovary syndrome questionnaire (PCOSQ) has 26 items across emotions, body hair, weight, infertility and menstrual abnormalities and the modified polycystic ovary syndrome questionnaire (MPCOSQ) adds acne [109, 192]. These tools have been adapted and tested in different ethnic populations. The role of these tools in clinical care remains unclear and the key dimensions affecting quality of life (QoL) are controversial.

Summary of systematic review evidence

Meta-analysis of five studies using SF-36 and three studies using the WHO tool in adult women, all of which were low quality and low certainty, suggest that women with PCOS have lower quality of life compared to women without PCOS. Statistical heterogeneity was present in meta-analysis for six out of the ten domains in SF-36 and in one out of four domains in the WHO tool. These generic QoL tools are poorly tailored and include features unrelated to PCOS such as immobility, pain, risk of infections and environment with limited relevance in PCOS. However they are the only tools that can compare HRQoL across women with and without PCOS, with studies demonstrating reduced HRQoL scores in PCOS, compared to controls and normative population data, as summarised in the AEPCOS position statement [109].

Summary of narrative review evidence

PCOS specific tools have been developed, validated and applied across ethnic groups. The commonly used tools for screening women with PCOS are the PCOSQ scale with domains to assess emotions, body hair, weight, infertility difficulties and menstrual problems and the MPCOSQ which includes an acne domain [193, 194]. In PCOS, HRQoL occurs in the context of the multitude of clinical features and is affected by anxiety, poor body image and low self-esteem, depressive symptoms, delayed diagnosis and inadequate education and information provision by health professionals [7, 195]. A meta-analysis and recent update have showed that key domains were hirsutism, menstruation and infertility [196], yet this varied by population studied, life stage and cultural factors [109] and heterogeneity is to be expected.

In clinical care, the key consideration was determined by the GDG to be the self-reported priority of specific PCOS dimensions in an individual woman at a given life stage. Addressing patient-reported and prioritised outcomes is important in improving QoL and optimising health in chronic conditions. If patient-reported priorities and outcomes were recognised as fundamental in care, this was seen as a substantive step forward in addressing key gaps in care and dissatisfaction expressed by women with PCOS. It is important to consider QoL in PCOS research and may be useful to consider applying relevant tools in clinical care to highlight patient priorities, with the caveat that clinically meaningful differences in scores need to be determined.

Recommendations

- 2.1.1 CCR Health professionals and women should be aware of the adverse impact of PCOS on quality of life. 
- 2.1.2 CCR Health professionals should capture and consider perceptions of symptoms, impact on quality of life and personal priorities for care to improve patient outcomes. 
- 2.1.3 CPP The PCOS quality of life tool (PCOSQ), or the modified PCOSQ, may be useful clinically to highlight PCOS features causing greatest distress, and to evaluate treatment outcomes on women's subjective PCOS health concerns.
-

Justification

HRQoL is reduced in PCOS. This diverse condition varies across the lifespan, phenotypes and is influenced by cultural factors which all impact on HRQoL. Key gaps in patient satisfaction have been demonstrated along with limited capture of patient priorities to guide management. There is a need to determine clinical meaningful differences in QoL scores and to validate the tools for change over time, based on a range of evidence sources. However, the expert group including patient perspectives considered it important to formally measure QoL with condition-specific tools in research settings. In the clinical setting, the role of formal screening is less clear, however it may highlight clinical priorities for women. Primarily, health professionals should be armed with awareness of the impact of PCOS on QoL and should capture patient priorities to deliver meaningful outcomes when partnering with women with PCOS in their care.

2.2 Depressive and anxiety symptoms, screening and treatment

In women with PCOS, what is the prevalence and severity of depressive and anxiety symptoms and should they be screened?

In women with PCOS, what is the most effective tool/method to assess depression and/or anxiety?

Clinical need for the questions

The prevalence and severity of depressive and anxiety symptoms are increased in PCOS. Psychological conditions impact on QoL and are likely to influence engagement in lifestyle interventions and self-management in PCOS. Hormonal medications can influence mood in the general population, although literature in PCOS is limited [197]. Effective, readily available screening tools are available for clinical practice, yet uptake and recognition of psychological symptoms in PCOS appears limited internationally. A large international survey has shown that most women report psychological issues are under-recognised [13] and less than 5% are satisfied with emotional support and counselling. Given the prevalence and severity of depressive and anxiety symptoms and the dissatisfaction expressed by women in this area, these clinical questions were prioritised.

Summary of systematic review evidence

A systematic review was not completed for the first question and the review for the second question did not identify any evidence in women with PCOS to answer this question.

Summary of narrative review evidence

These areas were reviewed narratively, based on clinical expertise.

Depression: Depressive symptoms and depression are more common in PCOS [109], with daily fatigue, sleep disturbances and diminished interest prominent [195]. A meta-analysis of 10 studies reported increased depressive symptom scores in 44% with PCOS versus 17% in controls (OR: 4.03, 95% CI: 2.96-5.5, p<0.01) [198], which persisted in BMI matched studies. A meta-analysis of 910 women with PCOS and 1347 controls reported higher depression scores in PCOS [199], although these may not have been clinically significant. A meta-analysis of 26 studies including 4716 participants from 14 countries [200], noted scores were not in a clinically significant range in half of studies, and others were consistent with mild depression. A recent meta-analysis of 23 studies with rigorous inclusion criteria including physician diagnosis of PCOS [201], showed increased moderate/severe depressive symptoms (OR4.18, 95% CI: 2.68-6.52) with a prevalence of depression of 36.6% in PCOS (IQR: 22.3, 50.0%) and 14.2% in controls (IQR: 10.7, 22.2%), independent of obesity and seen in both clinic and community recruits. Limitations included relatively small sample sizes and limited formal diagnosis of depression on clinical assessment. Also, a large population-based registry study [202] showing an increased adjusted risk of depression in PCOS and a large hospital database study documented depression in PCOS (9.8%), compared to those without a recorded diagnosis of PCOS (4.6%) [203]. Overall, women with PCOS have a higher prevalence of depressive symptoms and depression, independent of obesity.

Anxiety: Anxiety symptoms are increased in PCOS [109]. Meta-analyses of six studies and another of eleven studies reported higher anxiety scores in PCOS compared to controls [199, 200]. Another of four studies reported a sevenfold increase in abnormal anxiety scores in PCOS [204], however, heterogeneity existed in all meta-analysis. A recent rigorous meta-analysis of ten studies [201] showed increased moderate/severe anxiety symptoms in PCOS (OR: 5.38; 95% CI: 2.28, 12.67), with a prevalence of 41.9% (IQR: 13.6, 52.0%) in PCOS and 8.5% (IQR: 3.3, 12.0%) in controls. A large population-based study of 24385 women with PCOS matched for sex, age and country of birth to ten controls, showed increased anxiety disorder (OR 1.37, CI: 1.32, 1.43) [202]. A large hospital database showed anxiety in PCOS at 14%, compared to 5.9% of those without a diagnosis of PCOS [203]. Collectively, these studies indicate increased anxiety symptoms and anxiety disorders in women with PCOS, across diverse ethnic groups.

The cause of depressive and anxiety symptoms in PCOS are not fully elucidated [109] as are the effects of PCOS treatments. While acne, hirsutism, infertility and increased BMI have been linked to increased mood and distress, the evidence is inconsistent [205-208]. Further potential contributors to depression and anxiety in PCOS include the chronic [209-213], complex and frustrating nature of PCOS [214, 215]. Chronic conditions can cause related emotional distress, and treatment of the underlying condition may improve these, although few PCOS studies have explored this. In PCOS, consideration should be given to the individual underlying concerns for each woman to optimise impact on emotional wellbeing.

Screening for depressive and anxiety symptoms:

Given the lack of evidence to address this question in PCOS on systematic review, key relevant sources of evidence-based information were sourced for the general population, and with multidisciplinary GDG expertise and consumer perspectives, informed the recommendations. These included:

- The treatment of depression in adults with chronic physical health problems, NICE, 2009 [216].
- Common mental health problems: identification and pathways to care, NICE, 2011 [217].
- Antenatal and postnatal mental health: clinical management and service guidance, NICE, 2014 [218].
- Screening for Depression in Adults: US Preventive Services Task Force Recommendations, 2016 [219].
- Screening for Depression in Children and Adolescents: US Preventive Services Task Force Recommendations 2016 [220].
- Screening for and Treatment of Suicide Risk Relevant to Primary Care: A Systematic Review for the US Preventive Services Task Force, 2014 [221].
- Royal Australian NZ College of Psychiatrists Clinical Practice Guidelines for Mood Disorders 2015 [222].
- Principles of Practice in Mental Health Assessment with Aboriginal Australians. In Working Together: Aboriginal and Torres Strait Islander mental health and wellbeing principles and practice, 2014 [223].

National US and UK guidelines recommend routine screening for common mental health disorders for all adults and adolescents, particularly with chronic physical health problems and in the perinatal period [216-220]. US guidelines conclude moderate benefit of depression screening in the general adult population [219]. Australian guidelines for the general population do not recommend routine screening, except during the perinatal period [222, 224].

Overall in PCOS, where prevalence and severity is higher, the GDG deemed that it was the responsibility of all health professionals partnering with women with PCOS to understand the increased prevalence of depressive and anxiety symptoms and the impact of PCOS on psychological health, and routine screening for depressive and anxiety symptoms was recommended. Reciprocally, screening may increase distress with another potentially stigmatising diagnosis. Evidence in diabetes suggests that depression and anxiety are over-estimated by screening questionnaires and that diabetes-specific distress explains considerable variance in these symptom scores. This would suggest a need to be sensitive to the distress associated with PCOS and emphasises the need to avoid over-diagnosis of anxiety and depression. While the optimal timing and interval for screening is unknown, a pragmatic approach may be to screen all women and adolescents at the time of PCOS diagnosis. Frequency of screening is unclear and some assessment at the time of regular physical health checks for PCOS may be warranted. Use of clinical judgement considering an individual woman's risk factors, can inform if additional screening appears warranted. Screening during the antenatal and postnatal periods in PCOS is aligned with recommendations in the general population.

Recommendations

2.2.1	CCR	Health professionals should be aware that in PCOS, there is a high prevalence of moderate to severe anxiety and depressive symptoms in adults; and a likely increased prevalence in adolescents.	
2.2.2	CCR	Anxiety and depressive symptoms should be routinely screened in all adolescents and women with PCOS at diagnosis. If the screen for these symptoms and/or other aspects of emotional wellbeing is positive, further assessment and/or referral for assessment and treatment should be completed by suitably qualified health professionals, informed by regional guidelines.	
2.2.3	CCR	If treatment is warranted, psychological therapy and/or pharmacological treatment should be offered in PCOS, informed by regional clinical practice guidelines.	
2.2.4	CPP	The optimal interval for anxiety and depressive symptom screening is not known. A pragmatic approach could include repeat screening using clinical judgment, considering risk factors, comorbidities and life events.	
2.2.5	CPP	Assessment of anxiety and or depressive symptoms involves assessment of risk factors, symptoms and severity. Symptoms can be screened according to regional guidelines, or by using the following stepped approach: Step 1: Initial questions could include: <ul style="list-style-type: none">● Over the last 2 weeks, how often have you been bothered by the following problems?● feeling down, depressed, or hopeless?● little interest or pleasure in doing things?● feeling nervous, anxious or on edge?● not being able to stop or control worrying? Step 2: If any of the responses are positive, further screening should involve: <ul style="list-style-type: none">● assessment of risk factors and symptoms using age, culturally and regionally appropriate tools, such as the Patient Health Questionnaire (PHQ) or the Generalised Anxiety Disorder Scale (GAD7) and/or refer to an appropriate professional for further assessment.	
2.2.6	CPP	Where pharmacological treatment for anxiety and depression is offered in PCOS, the following need consideration: <ul style="list-style-type: none">● Caution is needed to avoid inappropriate treatment with antidepressants or anxiolytics. Where mental health disorders are clearly documented and persistent, or if suicidal symptoms are present, treatment of depression or anxiety need to be informed by clinical regional practice guidelines.● Use of agents that exacerbate PCOS symptoms, including weight gain, need careful consideration.	
2.2.7	CPP	Factors including obesity, infertility, hirsutism need consideration along with use of hormonal medications in PCOS, as they may independently exacerbate depressive and anxiety symptoms and other aspects of emotional wellbeing.	

Justification

Women with PCOS are at increased risk of depressive and anxiety symptoms compared to women without PCOS. Moderate to severe symptoms and clinically diagnosed disorders are increased. These symptoms may be related to the distress associated with PCOS. In the context of PCOS, identification of psychological features and mental health disorders is crucial to address gaps in care identified by affected women, to improve wellbeing and QoL, facilitate appropriate referral and care and optimise engagement with lifestyle and preventive strategies. However, over-diagnosis of depression and anxiety should also be avoided. Life stage, culture and preferred language should be considered. It is not always usual practice to screen women with PCOS for depressive and/or anxiety symptoms and this will change practice. Time, resources and access issues were considered, yet on balance screening is recommended, aligned with international, broadly validated screening approaches in general populations.

2.3 Psychosexual function

In women with PCOS, what is the prevalence and severity of psychosexual dysfunction and should they be screened?

In women with PCOS, what is the most effective tool/method to assess psychosexual dysfunction?

Clinical need for the questions

Psychosexual dysfunction refers to sexual problems or difficulties that have a psychological origin based in cognitions and/or emotions such as depression, low self-esteem and negative body image [225] and both risk factors for and prevalence of psychosexual dysfunction appear increased in PCOS. This may be an important issue for the individual woman and may impact on QoL and relationships. Therapies used in PCOS, including hormonal contraceptives and ovulation induction agents, can affect psychosexual function in the general population although data in PCOS is limited [226]. Hence, clinicians should be aware of potential psychosexual dysfunction in PCOS and screening and assessment should be considered. In this setting, guidance on the most effective way to assess psychosexual dysfunction is needed.

Summary of narrative review evidence

A systematic review was not conducted to answer these questions and they were reviewed narratively based on clinical expertise. The prevalence of psychosexual dysfunction varies from 13.3% to 62.5% in PCOS [227-230]. It appears that women with PCOS suffer from greater psychosexual dysfunction than women in the general population in most studies [207, 231-237]. Whilst there is limited quality research in this area, studies [207, 233, 234] do show a correlation between PCOS and reduced QoL, sexual satisfaction and feminine identity. A recent systematic review on psychosexual dysfunction in PCOS found that a satisfying sex life is important for women with PCOS, however, in women with PCOS sexual function, as well as feelings of sexual attractiveness, are compromised [238]. Women with PCOS judge their appearance and body hair to negatively impact on their sexuality and their ability to engage in relationships. This remains controversial with some studies suggesting the prevalence of psychosexual dysfunction in PCOS group is similar to the general population [229, 230]. A recent systematic review by GDG members identified 18 relevant studies using validated sexual function questionnaires and Visual Analogue Scales (VASs). Small, yet significant differences were detected in sexual function subscales, arousal, lubrication, satisfaction and orgasm were all impaired in PCOS compared to women without PCOS. Large effect sizes were evident for body hair impact, social impact of appearance, sexual attractiveness and satisfaction with sex life was impaired, whereas the importance of sex was similar to that of non-PCOS women. Physical PCOS symptoms such as hirsutism, obesity, menstrual irregularity and infertility may cause loss of feminine identity and a feeling of being unattractive which may impact on sexuality [207, 233, 235]. Women with PCOS also report less sexual satisfaction and lower sexual self-worth than women without PCOS and sexual dysfunction impacts more on relationships in women with PCOS [232]. In considering screening tools the [Female Sexual Function Index](#) (FSFI) [229] and [Arizona Sexual Experience Scale](#) (ASEX) [230] are commonly used to evaluate psychosexual dysfunction.

Recommendations

- 2.3.1 CCR All health professionals should be aware of the increased prevalence of psychosexual dysfunction and should consider exploring how features of PCOS, including hirsutism and body image, impact on sex life and relationships in PCOS. 
- 2.3.2 CCR If psychosexual dysfunction is suspected, tools such as the Female Sexual Function Index can be considered. 
-

Justification

As prevalence and severity of psychosexual dysfunction appears increased in women with PCOS, screening and assessment should be considered in sexually active women to facilitate appropriate intervention aiming to optimise sexual function, limit the social impact of PCOS and improve QoL. It is not usual practice to screen and assess women with PCOS for psychosexual dysfunction. Sensitivities and cultural challenges around psychosexual dysfunction from the woman's and health professional perspectives may present barriers to implementation. However, the international, multi-disciplinary GDG, including consumers, agreed that despite implementation challenges, the recommendation was warranted on the basis of prevalence data from a recent systematic review and on potential impact.

2.4 Body image

In women with PCOS, what is the prevalence and severity of body image distress and should they be screened?

In women with PCOS, what is the most effective tool/method to assess body image distress?

Clinical need for the questions

Body image is complex and is influenced by many factors. Body image is defined here as the way a woman may feel, think about and view their body including their appearance. Relevant physical (excess weight and hirsutism), psychological (self-esteem) and sociocultural factors influence body image. Assessment of body image considers body dissatisfaction, disordered eating, body size estimation and weight. Most women from the general population are dissatisfied with their body, yet negative body image appears more prevalent in PCOS and impacts on thoughts and feelings of health, appearance, QoL, mood and physical fitness. In this context, body image should be considered in PCOS. Recommendations for screening and assessment that are easy to use and widely applicable are needed and if identified, addressing negative body and associated mood disorders is important to improve emotional wellbeing and QoL in PCOS.

Summary of narrative review evidence

A systematic review was not conducted to answer these questions; therefore, the literature was reviewed narratively based on clinical expertise. Women with PCOS, compared with controls, had a negative body image on the validated Multidimensional Body-Self Relations Questionnaire (MBSRQ) [7]. Evidence is conflicting however, with some case-control studies not finding differences in body image satisfaction and self-esteem compared to women without PCOS [237, 239, 240]. Women with PCOS feel less physically attractive, healthy or physically fit and are less satisfied with their body size and appearance [241], and this negative body image predicts both depression and anxiety [242]. Infertile women with PCOS have lower body satisfaction than non-infertile women with PCOS [243]. Hirsute women experienced lower self-esteem than non-hirsute women [243]. Overall, PCOS features, in particular hirsutism and increased weight, impact negatively on body image and QoL [242, 244], and negative body image is strongly associated with depression in women with PCOS [245, 246], even after controlling for weight [8, 246].

We did not identify any evidence in women with PCOS to address the question on screening tools and therefore, a clinical consensus recommendation has been made based on the expertise of the multidisciplinary GDG and key relevant sources of evidence-based information for the general population. Assessment of body image includes measures of body dissatisfaction and disordered eating [247], body size estimation [248] and weight [249, 250]. The National Institute for Health and Care Excellence (NICE) Guideline 31 – Obsessive Compulsive Disorder: Core interventions in the treatment of obsessive compulsive disorder and body dysmorphic disorder [251] and the Australian Medical Association Position Statement: Body Image and Health 2002 [252] informed the recommendations provided. The Female Sexual Function Index tool is the most commonly used in PCOS studies of psychosexual dysfunction.

Recommendations

2.4.1 CCR Health professionals and women should be aware that features of PCOS can impact on body image.

2.4.2 CPP Negative body image, can be screened according to regional guidelines or by using the following stepped approach:

Step 1: Initial questions could include:

- Do you worry a lot about the way you look and wish you could think about it less?
- On a typical day, do you spend more than 1 hour per day worrying about your appearance? (More than 1 hour a day is considered excessive)
- What specific concerns do you have about your appearance?
- What effect does it have on your life?
- Does it make it hard to do your work or be with your friends and family?

Step 2: If an issue is identified, health professionals could further assess by:

- Identifying any focus of concern of the patient and respond appropriately
- Assessing the level of depression and/or anxiety
- Identifying distortion of body image or disordered eating

Justification

Given that negative body image in PCOS appears to be increased and may result in increased depression and poorer HRQoL, body image in women with PCOS should be considered as part of a comprehensive assessment and management plan. Approaches for screening and assessment that are easy to use and widely applicable are needed. Detection of negative body image provides the opportunity to address both psychological aspects such as self-esteem and self-acceptance as well as working on the physical aspects of the condition such as hirsutism, overweight and acne, if appropriate. It was acknowledged that it is not usual practice to screen PCOS women for negative body image, and an individualised approach focusing on individual priorities is needed. Screening may have resource implications, including length of consultation. Available body image scales can reduce time required in assessment and should also be considered in all clinical, health services and population health research in PCOS.

2.5 Eating disorders and disordered eating

In women with PCOS, what is the prevalence and severity of disordered eating, and should they be screened?

In women with PCOS, what is the most effective tool/method to assess disordered eating?

Clinical need for the questions

Diagnosable eating disorders include anorexia nervosa; bulimia nervosa, binge-eating disorder, other specified feeding or eating disorders, and unspecified feeding or eating disorders that do not meet the full criteria for any of the eating disorder diagnoses. Disordered eating refers to eating and weight related symptoms and can include behavioural (e.g. bingeing, excessive restriction), cognitive (e.g. excessive dietary restraint, negative body image) and emotional factors. Disordered eating affects health and wellbeing and capacity to participate in and contribute to society. Many of those affected are not identified in primary care. Risk factors and prevalence appears increased in PCOS [109]. Increased awareness of these conditions, and effective assessment when clinically suspected, is important as it should increase recognition and management of eating disorders and disordered eating, thereby improving the psychological functioning and overall QoL in women with PCOS and reducing associated health risks.

Summary of narrative review evidence

A systematic review was not conducted to answer these questions, which were reviewed narratively based on clinical expertise. The prevalence of disordered eating is far higher than the prevalence of eating disorders; many women who do not meet full criteria for an eating disorder experience disordered eating and associated distress [253], including binge eating, purging, and strict dieting or fasting. There is a lack of good evidence regarding the prevalence of eating disorders and disordered eating in women with PCOS, although available data suggests a higher prevalence than in the general community, on clinical interview [254] of any eating disorder (21% vs 4%) but not bulimia nervosa (12% vs 4%). A registry study of women with PCOS (n=24 385) and matched controls reported increased bulimia nervosa, but not anorexia nervosa [202]. Surveys in PCOS show mixed results across the different disorders [195, 255, 256], but overall suggest an increased prevalence of eating disorders and disordered eating. Women with PCOS also have more identified risk factors for eating disorders [257] across obesity, depression, anxiety, self-esteem and poor body image [195, 240, 256].

The apparent higher prevalence of eating disorders and disordered eating in women with PCOS, and the negative biopsychosocial consequences of eating disorders and disordered eating, highlight the need to raise awareness of these conditions. The NICE recommendations for Eating Disorders: Recognition and Treatment [258] suggest clinicians think about the possibility of an eating disorder in individuals with a range of symptoms relevant to PCOS. Many women with eating disorders are undiagnosed and unaware that they have an eating disorder, or that their eating and weight-related thoughts and behaviours are unusual and/or cause distress. Unfortunately, there are not standardised, widely implemented processes for screening and assessment and the breadth and complexity of these conditions makes simple screening and assessment difficult. This review highlighted the limited, and low-quality evidence regarding eating disorder screening tools and it was concluded that none of the tools are effective for identifying eating disorders when used in isolation. Instead, the clinician should use their judgement based on a full diagnostic interview. The SCOFF tool is the most commonly used screening tool in adults, takes only a few minutes to administer [258] and is an option. Along with more sensitive tools it is outlined in translation resources (under development). The risk of false positives (and hence inappropriate treatment) was noted with these tools [258] and they cannot replace clinical interview.

Recommendations

- 2.5.1 CCR All health professionals and women should be aware of the increased prevalence of eating disorders and disordered eating associated with PCOS. 
- 2.5.2 CCR If eating disorders and disordered eating are suspected, further assessment, referral and treatment, including psychological therapy, could be offered by appropriately trained health professionals, informed by regional clinical practice guidelines. 
- 2.5.3 CPP Eating disorders and disordered eating can be screened using the following stepped approach.
- Step 1:** The SCOFF (Sick, Control, One stone, Fat, Food) screening tool can be used or initial screening questions can include:
- Does your weight affect the way you feel about yourself?
 - Are you satisfied with your eating patterns?
- Step 2:** If the SCOFF tool or any of these questions are positive, further screening should involve:
- assessment of risk factors and symptoms using age, culturally and regionally appropriate tools;
 - referral to an appropriate health professional for further mental health assessment and diagnostic interview. If this is not the patient's usual healthcare provider, inform the primary care physician.
-

Justification

The increased risk factors for and apparent increased prevalence of eating disorders and disordered eating in women with PCOS, and the negative biopsychosocial consequences of these disorders, highlight the need for greater awareness in women with PCOS. Many women with eating disorders are undiagnosed and unaware of the presence of an eating disorder. Likewise, many women with disordered eating are unaware that their eating and weight-related thoughts and behaviours are unusual and/or causing distress. Therefore, raised awareness and consideration of assessment and diagnosis are important. It was acknowledged that screening is challenging given the breadth and complexity of these conditions and false positives with current tools are noted. Resource and time implications were also considered.

2.6 Information resources, models of care, cultural and linguistic considerations

What is the effectiveness of different models of care compared to usual care?

What are the information, resource and education needs of women and healthcare providers regarding PCOS?

Access to culturally and linguistically diverse appropriate care.

Clinical need for the questions

PCOS can involve diverse clinical features that change across the life course. For models of care, women affected by PCOS may consult multiple health professionals such as a general practitioner/primary care physician, gynaecologist, endocrinologist, infertility specialist, dietitian, dermatologist, psychologist and/or an exercise physiologist. Multidisciplinary care is increasingly required in chronic disease management, with improvements in health related outcomes [259], yet presenting increased complexity, compartmentalisation and communication challenges. An interdisciplinary care model involves “the collaboration between a woman with PCOS and a care team who have shared goals for total wellbeing” and is founded on patient-centred care principles and is well suited to the PCOS context.

In PCOS, there is a well-demonstrated gap and compelling need for improved information provision [13, 260, 261]. Women internationally report inadequate information, delayed diagnosis and variation in care. Provision of information also improves satisfaction with care and patient experience. Culturally and linguistically appropriate care and information are also a key consideration in PCOS. PCOS is a common disorder worldwide and given the significant psychosocial impacts of PCOS, and the cultural differences in perception of features such as hirsutism, infertility and other complications, cultural awareness is important. The majority of consumer information is in English, presenting language barriers for immigrant populations and for women living in countries where English is not the first language. Given current dissatisfaction in care and information provision noted by women internationally, the evidence that health professionals do not adequately address the diverse features of PCOS and the cultural and linguistic considerations in PCOS care, these clinical questions were prioritised.

Summary of systematic review evidence

We did not identify any evidence in our patient population to answer the question about models of care.

Summary of narrative review evidence

Narrative reviews were completed to address all three questions. Four studies described models of care across barriers, enablers and satisfaction of patients and health professionals and benefits of information and socio-emotional support. Evaluation of a multidisciplinary PCOS service showed successful evidence-based care, emotional screening and lifestyle management [262] and was greatly valued by patients and health professionals. Barriers included staffing limitations and turnover, funding challenges and system issues [262]. Support groups have been explored [263, 264] including online peer-support in the UK [263]. Connecting with people who understand, access to information and advice, building confidence in interaction with health care professionals, help with treatment-related decision-making and improvement in adjustment and management were reported. Disempowering experiences included “reading about the negative experiences of others” and “feeling like an outsider”. A nurse-led UK peer support group increased participation, reduced isolation and improved empowerment, provided relevant information and positively affected self-management [264]. A Canadian educational program [265] increased motivation to implement preventive strategies, enhanced satisfaction with health care professional engagement and empowered women to participate in self-management.

A systematic search was completed on i) women’s experiences of PCOS care and PCOS information ii) women’s perceived needs for PCOS care and information, iii) health care providers’ delivery of PCOS care and information, iv) health care providers’ perceived needs for PCOS information, education programs, or professional development. Comprehensive, accurate, personalised information is important in PCOS as a chronic condition requiring self-management [261], enables informed decisions, optimises prevention and is associated with better quality of life [13, 266]. Women often see multiple health professionals before diagnosis [13, 260, 267, 268], flag symptoms multiple times [214, 269] and experience delays in diagnosis [13, 214, 260, 267]. Receiving a diagnosis is important to women [214]; yet may lead to anxiety and frustration without adequate information [267-269]. Reproductive and metabolic features are concerns [13, 270], psychological features are under-appreciated [269], and women report that primary concerns go unrecognised [267]. Specific and practical information is needed, yet often not provided, or does not meet needs [13, 214, 260, 268, 269, 271, 272]. Women’s initial source of information is their healthcare provider [214, 269, 270], yet if inadequate, inaccurate or conflicting, frustration is reported [13, 271]. The internet is accessed yet quality is often poor [214, 269, 271] or conflicted by commercial interests [271], impacting patient experience [267]. Overall, PCOS information needs to be comprehensive, evidence-based and inclusive of the bio-psycho-social dimensions of the condition and care needs to prioritise women’s personal concerns [13, 260, 267, 268, 273]. Women with PCOS are best supported by a range of information resources: respectful and empathetic healthcare providers, websites, leaflets and support groups [214, 264, 265]. Health professional research suggests variation in care by specialty including across rates of undiagnosed PCOS [274] and investigations [275]. Women with PCOS infrequently report seeing a dietitian or receiving dietary advice [276]. Educational programs improve knowledge and confidence in PCOS among doctors [277], with greater activity needed to address gaps identified by women with PCOS.

Regarding culturally and linguistically competent medical care in PCOS, there are few relevant studies. Adaptation of educational resources and longer consultation times may be required [278] and family rather than individual consultations may be relevant. Cultural barriers can include low health literacy, high level of tolerance to problems and unwillingness to see a male physician [278]. Many of the studies in information and care needs and preferences in PCOS are limited to English-speaking women and do not explore cultural issues.

Recommendations

-
- 2.6.1 CCR Information and education resources for women with PCOS should be culturally appropriate, tailored and high-quality, should use a respectful and empathetic approach, and promote self-care and highlight peer support groups. 
- 2.6.2 CCR Information and education resources for healthcare professionals should promote the recommended diagnostic criteria, appropriate screening for comorbidities and effective lifestyle and pharmacological management. 
- 2.6.3 CCR PCOS information should be comprehensive, evidence-based and inclusive of the biopsychosocial dimensions of PCOS across the life-span. 
- 2.6.4 CCR Women's needs, communication preferences, beliefs and culture should be considered and addressed through provision of culturally and linguistically appropriate co-designed resources and care. 
- 2.6.5 CCR Interdisciplinary care needs to be considered for those with PCOS where appropriate and available. Primary care is generally well placed to diagnose, screen and coordinate interdisciplinary care. 
- 2.6.6 CCR Care needs to be person centred, address women's priorities and be provided in partnership with those with PCOS and where appropriate, their families. 
- 2.6.7 CPP Guideline dissemination and translation including multimodal education tools and resources is important, with consultation and engagement with stakeholders internationally.
-

Justification

Evidence specific to PCOS models of care remains limited, especially for adolescents transitioning from paediatric to adult care. However, existing evidence suggests integrated multidisciplinary services, support groups and nurse-led education can address identified gaps, increase understanding of PCOS and improve lifestyle change whether online, or nurse-led. New models of care should follow best practice and be co-designed with both women and health professionals. Key gaps in information provision need to be addressed through multi-faceted resources: health professionals, websites, written information and support groups with more comprehensive, evidence-based information that covers diverse PCOS features and prioritises women's personal concerns. Needs differ by individual and life stage and diagnosis is a time of greater need. Cultural influences need to be considered in PCOS in the context of both care and information needs. Culturally appropriate care involves more than linguistic considerations and is just as important for women who speak English but are not of the cultural majority.

Chapter Three

Lifestyle

3.1 Effectiveness of lifestyle interventions

In women with PCOS, are lifestyle interventions (combined compared to minimal or nothing) effective for improving weight loss, metabolic, reproductive, fertility, quality of life and emotional wellbeing outcomes?

Clinical need for the question

Rates of weight gain and prevalence of excess weight are increased in adolescents and women with PCOS. The potent combination of excess weight and PCOS is adversely affecting reproductive, metabolic and psychological health, presenting a major public health challenge mandating both prevention and treatment. Insulin resistance affects 75% of lean women and 95% of overweight women [279]. It is independently exacerbated by excess weight [142, 280], increasing prevalence and severity of metabolic, reproductive and psychological features of PCOS [11, 281-283]. Benefits from lifestyle intervention and weight loss have been demonstrated in women with PCOS [284-287] and healthy lifestyle is important in preventing excess weight gain in PCOS and can offer benefits even without weight loss [288-292]. Women with PCOS internationally report that excess weight causes significant distress and concern and that there is inadequate information and support around lifestyle change [13]. Weight was also a highly ranked, prioritised outcome by both health professionals and women during the guideline development process. Overall, in women with PCOS and excess weight, lifestyle interventions which reduced weight by as little as 5% of total body weight have been shown to have health metabolic, reproductive and psychological benefits [284-287, 293-312]. Given the uncertainty on effectiveness and optimal components of lifestyle intervention in PCOS, underpinned by the generally small and uncontrolled trials, variable outcomes and populations, this clinical question was prioritised.

Summary of systematic review evidence

One high quality systematic review with a low risk of bias was identified to answer this question. The systematic review appraised six randomised controlled trials (RCTs) (low to moderate quality and moderate to high risk of bias) for the effectiveness of lifestyle treatment compared to minimal treatment in improving reproductive, metabolic, anthropometric and quality of life (QoL) factors in women with PCOS [313]. Due to the inconsistencies and methodological weaknesses of included studies, caution is recommended when interpreting the combined meta-analyses and results of the systematic review. There were three studies that used exercise and three that used combined lifestyle modification programmes (including diet, exercise and behaviour), with the outcome measurements reported at various times (12, 16, 24, and 48 weeks). Lifestyle intervention was better than minimal treatment for total testosterone (mean difference (MD) -0.27 nmol/L [-0.46 to -0.09] p=0.004), hirsutism by Ferriman-Gallwey score (MD -1.19 [-2.35 to -0.03] p=0.04), weight (MD -3.47 kg [-4.94 to -2.00] p<0.00001), waist circumference (MD -1.95 cm [-3.34 to -0.57] p=0.006), waist-hip-ratio (MD -0.04 [-0.07 to -0.00] p=0.02), fasting insulin (MD -2.02 µU/mL [-3.28 to -0.77] p=0.002) and oral glucose tolerance test insulin (standardised mean difference -1.32 [-1.73 to -0.92] p<0.00001) and percent weight change (MD -7.00% [-10.1 to -3.90] p<0.00001). There was no difference between the two interventions for body mass index (BMI), free androgen index (FAI), sex hormone-binding globulin (SHBG), glucose or lipids. QoL, patient satisfaction and acne were not reported. None of the studies addressed fertility outcomes such as pregnancy, live birth and miscarriage. While some studies reported on menstrual regularity and ovulation, the findings were reported in a variety of ways and it was not possible to estimate the overall effects of lifestyle on these outcomes.

Recommendations

-
- 3.1.1 CCR Healthy lifestyle behaviours encompassing healthy eating and regular physical activity should be recommended in all those with PCOS to achieve and/or maintain healthy weight and to optimise hormonal outcomes, general health, and QoL across the life course. 
- 3.1.2 EBR Lifestyle intervention (preferably multicomponent including diet, exercise and behavioural strategies) should be recommended in all those with PCOS and excess weight, for reductions in weight, central obesity and insulin resistance. 
- 3.1.3 CPP Achievable goals such as 5% to 10% weight loss in those with excess weight yields significant clinical improvements and is considered successful weight reduction within six months. Ongoing assessment and monitoring is important during weight loss and maintenance in all women with PCOS.
- 3.1.4 CPP SMART (Specific Measurable, Achievable, Realistic and Timely) goal setting and self-monitoring can enable achievement of realistic lifestyle goals.
- 3.1.5 CPP Psychological factors such as anxiety and depressive symptoms, body image concerns and disordered eating, need consideration and management to optimise engagement and adherence to lifestyle interventions.
- 3.1.6 CPP Health professional interactions around healthy lifestyle, including diet and exercise, need to be respectful, patient-centred and to value women's individualised healthy lifestyle preferences and cultural, socioeconomic and ethnic differences. Health professionals need to also consider personal sensitivities, marginalisation and potential weight-related stigma.
- 3.1.7 CPP Adolescent and ethnic-specific BMI and waist circumference categories need to be considered when optimising lifestyle and weight.
- 3.1.8 CPP Healthy lifestyle may contribute to health and QoL benefits in the absence of weight loss.
- 3.1.9 CPP Healthy lifestyle and optimal weight management appears equally effective in PCOS as in the general population and is the joint responsibility of all health professionals, partnering with women with PCOS. Where complex issues arise, referral to suitably trained allied health professionals needs to be considered.
- 3.1.10 CPP Ethnic groups with PCOS who are at high cardiometabolic risk as per 1.6.1 require greater consideration in terms of healthy lifestyle and lifestyle intervention.
-

Justification

Given the high prevalence and important adverse impact of excess weight in PCOS and the apparent efficacy in PCOS and in general populations, lifestyle management was deemed important in this high-risk group. Women with PCOS prioritised weight management and also emphasised the need to optimise healthy lifestyle in lean women and in all women with PCOS, independent of weight loss goals. The recommendations and practice points were informed by general population guidelines, the evidence identified in PCOS and by multidisciplinary health professional and consumer input. They are intended to reduce variation in practice, improve lifestyle advice and support for women with PCOS, and target both prevention of weight gain and where appropriate weight loss. The recommendations also consider important psychosocial, cultural and ethnic aspects in relation to lifestyle interventions and were informed by evidence generated for other clinical questions under emotional wellbeing and under specific lifestyle interventions. These recommendations may increase consultation times, referral to allied health professionals and associated healthcare costs, however long-term benefits are anticipated to reduce the health and economic burden of PCOS. Engagement of health practitioners and financial barriers for patients may present implementation issues.

3.2 Behavioural interventions

In women with PCOS, are behavioural interventions (compared to different types of behavioural interventions) effective for improving anthropometric, metabolic, reproductive, fertility, quality of life and emotional wellbeing outcomes?

Clinical need for the question

With weight gain increasing in women, and even higher rates of weight gain shown in PCOS, preventive strategies area needed [314, 315]. Previous lifestyle intervention studies in PCOS have involved short-term dietary interventions with or without an exercise component. Dietary intervention studies have shown benefit with weight loss [314], however retention and sustainability prove challenging, suggesting a need for additional strategies. Behavioural and cognitive behavioural intervention approaches target behaviours, their antecedents and consequences and cognitions that maintain positive energy balance and promote weight gain [316] and are common in weight management. Behaviour therapy results in significantly greater weight loss than placebo, and behaviour/cognitive behaviour therapy combined with diet and exercise has efficacy. Given the need to improve adherence and impact of lifestyle interventions in PCOS, this question was prioritised.

Summary of systematic review evidence

We did not identify any evidence in women with PCOS to answer the question and therefore the literature has been reviewed narratively.

Summary of narrative review evidence

A multidisciplinary model of care with a dietitian, health psychologist, gynaecologist and endocrinologist, in adolescents with PCOS, showed that a ‘behavioural intervention’ enhanced weight loss when combined with dietary consultation, compared to receiving neither or dietary advice only [317]. The intervention was not well defined or replicable and metabolic, reproductive and psychosocial outcomes were not assessed. Two RCT's included behavioural lifestyle components yet had minimal detail on the theoretical framework or behavioural components. These compared comprehensive lifestyle intervention (diet, behaviour and physical activity) over 24 weeks with placebo [318, 319] with variable but limited benefits.

In this context, recommendations on behavioural lifestyle interventions in women with PCOS are informed by data from general populations. A comprehensive systematic review of lifestyle interventions in populations at risk of type 2 diabetes (DM2) or cardiovascular disease (CVD), summarised key success factors in lifestyle interventions [320]. Behavioural change techniques in combination with diet and exercise interventions, increased weight loss over diet and/or physical activity alone [320]. Self-management has positive impacts [320] and family support improves outcomes, [320]. Mode of delivery and trained intervention facilitator, setting and intensity didn't impact outcomes [320]. Overall, this underpins international guidelines recommending integration of: 1/ established behaviour change techniques 2/ self-management/self-monitoring and 3/ social support to preventative and treatment lifestyle interventions [320, e.g., 321]. Combining behavioural/cognitive behavioural weight loss components with intensive interventions, including very low calorie diets and weight loss medications, also improves weight loss than these interventions alone [322-325].

Guidelines highlight the need for resources (e.g., written, audio-visual) and the potential for e-health to supplement face to face support with strategies including; goal-setting, self-monitoring, stimulus control, problem solving, assertiveness training, slowing the rate of eating, reinforcing changes, and relapse prevention. Continued contact after treatment (face-to-face or telephone) also improves weight-loss maintenance. More intensive behavioural interventions induce greater weight loss [326]. In the general population, behavioural and cognitive behavioural interventions have strong empirical support and are recommended in international guidelines on the treatment of excess weight [e.g., 321, 327].

Recommendations

- 3.2.1 CCR Lifestyle interventions could include behavioural strategies such as goal-setting, self-monitoring, stimulus control, problem solving, assertiveness training, slower eating, reinforcing changes and relapse prevention, to optimise weight management, healthy lifestyle and emotional wellbeing in women with PCOS. 
- 3.2.2 CPP Comprehensive health behavioural or cognitive behavioural interventions could be considered to increase support, engagement, retention, adherence and maintenance of healthy lifestyle and improve health outcomes in women with PCOS.
-

Justification

In other high cardiometabolic risk populations, behavioural change strategies and/or behavioural/cognitive interventions in combination with diet and exercise, improves weight loss over diet and/or physical activity alone. Emphasis on self-management components enhances weight loss and healthy lifestyle behaviour change and are incorporated into advice on lifestyle interventions for the general population. Skill levels among health professionals may vary, presenting implementation challenges.

3.3 Dietary interventions

In women with PCOS, are diet interventions (compared to no diet or different diets) effective for improving weight loss, metabolic, fertility, and emotional wellbeing outcomes?

Clinical need for the question

Specific dietary composition in lifestyle interventions remains controversial. Given the general recommendations to reduce caloric (energy) intake, rather than modifying macronutrient composition, the widespread promotion of specific dietary composition in PCOS and the limited comparative research on efficacy of specific dietary macronutrient approaches in PCOS, this clinical question was prioritised.

Summary of systematic review evidence

Four articles reporting three studies were identified to answer this question. One RCT with a moderate risk of bias investigated the changes in anthropometric, metabolic and non-fertility outcomes by comparing a high protein diet to a high carbohydrate diet [308]; one RCT with a low risk of bias investigating the changes in anthropometric and metabolic outcomes by comparing a DASH (dietary approaches to stop hypertension) diet with a control diet [328, 329]; and one RCT with a high risk of bias investigating the changes in anthropometric and metabolic outcomes by comparing a high protein diet with a normal protein diet [330]. There was no difference for the majority of the anthropometric, metabolic, fertility, non-fertility, QoL and emotional wellbeing outcomes, however, regardless of the type of diet, the overall finding was that a diet aimed at reducing weight was of benefit to women with PCOS.

Summary of narrative review evidence

Given the limitations in evidence in PCOS, evidence was also sought from the general population. A systematic review [331] and more recent large scale studies [332] show that in the general population, there is no benefit of any one diet type and that hormone levels including insulin do not predict responses. Given the above evidence and other systematic reviews in the general population that reported similar or less weight loss and compliance for a low fat diet compared to other approaches [333, 334], and a large RCT reported similar changes in weight for a range of reduced energy diets with different macronutrient content over two years [335], the assertions that specific dietary composition has selective long term advantages at this stage appears to be unjustified.

Recommendations

- 3.3.1 CCR A variety of balanced dietary approaches could be recommended to reduce dietary energy intake and induce weight loss in women with PCOS and overweight and obesity, as per general population recommendations. 
- 3.3.2 CCR General healthy eating principles should be followed for all women with PCOS across the life course, as per general population recommendations. 
- 3.3.3 CPP To achieve weight loss in those with excess weight, an energy deficit of 30% or 500 - 750 kcal/day (1,200 to 1,500 kcal/day) could be prescribed for women, also considering individual energy requirements, body weight and physical activity levels.
- 3.3.4 CPP In women with PCOS, there is no or limited evidence that any specific energy equivalent diet type is better than another, or that there is any differential response to weight management intervention, compared to women without PCOS.
- 3.3.5 CPP Tailoring of dietary changes to food preferences, allowing for a flexible and individual approach to reducing energy intake and avoiding unduly restrictive and nutritionally unbalanced diets, are important, as per general population recommendations.
-

Justification

Given that consumer targeted information about PCOS purport the benefit of specific macronutrient composition, this recommendation is important to ensure that women and health professionals are informed on the evidence on dietary composition and efficacy. Emphasis should be on individual preferences and cultural needs of each woman and on an overall balanced and healthy dietary composition to achieve energy intake reduction for weight loss. Education for both women and health professionals is needed in this area. Specific cost and resource implications were considered but recommendations were approved on balance, informed by recommendations in the general population and benefits in PCOS.

3.4 Exercise interventions

In women with PCOS, are exercise interventions (compared to different exercises) effective for improving anthropometric, metabolic, reproductive, fertility, quality of life and emotional wellbeing outcomes?

Clinical need for the question

Whilst not formally included in the diagnostic criteria, insulin resistance, is involved in the aetiology and clinical features of PCOS [336, 337]. Exercise ameliorates insulin resistance and offers a potentially effective intervention in PCOS, with some evidence of clinical benefit. In general populations, physical activity (any bodily movement produced by skeletal muscles that requires energy expenditure) and structured exercise (activity requiring physical effort, carried out to sustain or improve health and fitness), deliver clear health benefits, whilst sedentary behaviours (activities during waking hours in a seated or reclined position with energy expenditure less than 1.5 times resting metabolic rate) have adverse health impacts. Despite the potential for benefit, women with PCOS report receiving limited lifestyle advice and specific efficacy of different types and intensity of exercise is unclear and was prioritised in PCOS and its associated co-morbidities.

Summary of systematic review evidence

We did not identify any evidence in women with PCOS to answer the question and therefore the literature has been reviewed narratively.

Summary of narrative review evidence

Physical activity and formal exercise interventions are classified as aerobic/endurance (focusing on aerobic capacity/fitness), resistance activities (targeting muscle mass and strength) or a combination, further sub-grouped by exercise intensity into light, moderate, vigorous or high-intensity [338] ([Table 5](#)). Two small RCTs are relevant in PCOS. Regular moderate intensity cycle exercise had greater metabolic benefit over 24 compared to 12 weeks, without impact on reproductive biomarkers [148, 339, 340]. Whilst 20 weeks of aerobic compared to combined exercise, superimposed on a high protein diet, showed similarly improved PCOS features [148, 287, 339, 341]. Small RCTs and high quality mechanistic studies (cohort and case control studies) show physical activity, including formal exercise (aerobic and muscle strengthening), improves body composition and clinical features [148, 206, 287, 290, 339, 341-349], compared to minimum or no interventions. These benefits occur independent of significant weight loss [290] and can occur with exercise alone [290, 350].

The mechanistic impacts of exercise and physical activity on cardiometabolic and reproductive features of PCOS are well described [339, 351-353]. While acknowledging the limitations in quality of evidence (sample size, study type, heterogeneity of interventions), improved glycaemic and reproductive outcomes, QoL and functional capacities have been shown [148, 287, 339, 349, 351-354]. Psychologically, limited community based/epidemiological studies show positive associations between self-reported physical activity and mental health status [206, 342] and vigorous exercise and better health outcomes in women with PCOS [355]. Conversely, there is an increase in sedentary behaviour documented in PCOS [356]. Mechanistically, insulin resistance, underpinned by insulin signalling pathway defects, is involved in the aetiology [336, 337] and clinical features of PCOS [336, 337, 357-359]. Moderate aerobic exercise improves insulin sensitivity short-term in PCOS [360].

Insulin resistance is also ameliorated in groups where exercise reduces DM2 risk [152, 361] and CVD factors [362, 363]. Similarly, resistance or weight-bearing exercise either alone or in combination with aerobic exercise improves health outcomes in groups [364-367]. In general populations, physical activity and structured exercise deliver metabolic, cardiovascular, and psychosocial benefits, whether alone or combined with diet changes [368-370]. Sedentary behaviours link to all-cause mortality and adverse health impacts [371, 372], whilst aerobic and resistance exercise reduce cardiometabolic risk factors [373]. Health impacts of exercise therapy may also reduce long-term healthcare costs [374]. Overall, current guidelines for the general population recommend 150 minutes of exercise per week, with 90 minutes at moderate to high intensity [338, 375-382] ([Table 5](#)).

Recommendations

- 3.4.1 CCR Health professionals should encourage and advise the following for prevention of weight gain and maintenance of health: ♦♦♦
- in adults from 18 – 64 years, a minimum of 150 min/week of moderate intensity physical activity or 75 min/week of vigorous intensities or an equivalent combination of both, including muscle strengthening activities on 2 non-consecutive days/week
 - in adolescents, at least 60 minutes of moderate to vigorous intensity physical activity/day, including those that strengthen muscle and bone at least 3 times weekly
 - activity be performed in at least 10-minute bouts or around 1000 steps, aiming to achieve at least 30 minutes daily on most days.
- 3.4.2 CCR Health professionals should encourage and advise the following for modest weight-loss, prevention of weight-regain and greater health benefits: ♦♦♦
- a minimum of 250 min/week of moderate intensity activities or 150 min/week of vigorous intensity or an equivalent combination of both, and muscle strengthening activities involving major muscle groups on 2 non-consecutive days/week
 - minimised sedentary, screen or sitting time.
- 3.4.3 CPP Physical activity includes leisure time physical activity, transportation such as walking or cycling, occupational work, household chores, games, sports or planned exercise, in the context of daily, family and community activities. Daily, 10000 steps is ideal, including activities of daily living and 30 minutes of structured physical activity or around 3000 steps. Structuring of recommended activities need to consider women's and family routines as well as cultural preferences
- 3.4.4 CPP Realistic physical activity SMART goals could include 10-minute bouts, progressively increasing physical activity 5% weekly, up to and above recommendations.
- 3.4.5 CPP Self-monitoring including with fitness tracking devices and technologies for step count and exercise intensity, could be used as an adjunct to support and promote active lifestyles and minimise sedentary behaviours.
-

Justification

Exercise should be encouraged and advised in PCOS based on evidence in the general population and in PCOS. It was considered that exercise interventions and physical activity do not require clinical centres, expensive gyms and fitness centres. They can be delivered in community centres, sporting grounds/facilities, in groups and with minimal equipment. Low cost e-health (electronic health) and m-health (mobile health) options may also be used. As such, costs and resources need not be prohibitive. Where available and affordable, and where there is risk from injury, barriers to exercise or additional motivation required, due consideration should be given to involvement of exercise physiologists/specialists in structured exercise intervention, as captured in [Section 3.1 Lifestyle interventions](#).

Table 5: Physical activity intensity and examples.

INTENSITY AND MEASURE	DESCRIPTION	EXAMPLES OF ACTIVITIES AND ADL'S (ACTIVITIES OF DAILY LIVING)
LIGHT 1.6 - 3 [†] METs 40 - 55% *HRmax	<ul style="list-style-type: none"> Aerobic activity that does not cause noticeable changes in breathing rate. An intensity that can be sustained for at least 60 minutes. 	Casual walking, cycling < 8km/hr (5mph), stretching, light weight training, dancing slowly, leisurely sports (playing catch) golf (using cart), light yard/house work.
MODERATE 3 - 6 [†] METs 55 - 70% *HRmax	<ul style="list-style-type: none"> Aerobic activity that can be conducted whilst having an uninterrupted conversation. An intensity that may last between 30 to 60 minutes. 	Brisk walking (5 - 7km/hr, 3 - 4.5mph), walking uphill, hiking, cycling (8 - 15km/hr, 5 - 9mph), low impact or aqua aerobics, yoga gymnastics, weight training, moderate dancing, aerobic machines (stair climber, elliptical, stationary bike) — most competitive tennis, volleyball, badminton, recreational swimming, golf — carrying clubs, intense house/yard work or occupations with extended standing or walking.
VIGOROUS 6 - 9 [†] METs 70 - 90% *HRmax	<ul style="list-style-type: none"> Aerobic activity where an uninterrupted conversation generally can't be maintained Intensity that may last up to 30 minutes 	Race walking, jogging/running, mountain climbing, cycling (> 16km/hr, 10mph), high impact aerobics, karate or similar, circuit weight training, vigorous dancing and aerobic machines, competitive basketball, netball, soccer, football, rugby, hockey, swimming, water jogging, downhill or cross country skiing, non-motorised lawn mowing, occupations with heavy lifting or rapid movement.

* Predicted maximal heart rate (HRmax) = 208 – (0.7 X AGE[years]);

† metabolic equivalent (MET) where 1 MET is the O₂/kg body weight/min required to sustain ones resting metabolic rate [3.5 mL/kg/min])[338] and [383].

3.5 Obesity and weight assessment

Are women with PCOS at increased risk of obesity?

In women with PCOS, does obesity impact on prevalence and severity of hormonal and clinical features?

Clinical need for the questions

Obesity affects the majority of women recruited from clinic populations and is common in community-based studies. The complex pathophysiology and clinical heterogeneity of PCOS has contributed to the lack of a clear understanding of interactions between PCOS, excess body weight and body fat distribution. Obesity, particularly central obesity, increases insulin resistance and hyperandrogenism, may increase PCOS prevalence and exacerbates the clinical features of PCOS. It is also of significant concern to women with PCOS and a key target for prevention and management in this condition. The degree of increased risk of excess weight and the impact on prevalence and severity of features of PCOS remain unclear.

Summary of narrative review evidence

A systematic review was not conducted to answer these questions, which were reviewed narratively based on clinical expertise. This review informs both the recommendations for assessment and screening in chapter 1 and the recommendations in chapter 3. In terms of prevalence of excess weight in PCOS, the great majority of women seeking treatment for PCOS are overweight or obese [384]. Rates of weight gain appear higher in PCOS, and BMI increases of one, are associated with a 9% higher prevalence of PCOS [315]. Women with PCOS also appear to have higher genetic susceptibility to obesity [385]. The temporal trends of obesity prevalence in PCOS show an increase from 51% in the 90s to 74% in the following decades [386]. There is general recognition that women with PCOS who present for diagnosis and care may be more likely to have excess weight than those who do not, however longitudinal community-based data supports higher weight gain and excess body weight in PCOS. Weight gain over 10 years among women with PCOS is significantly greater than in unaffected women in a longitudinal community-based study (mean difference 2.6kg 95% CI 1.2-4.0) [387]. Weight gain escalates from adolescence and early vigilance and intervention is important. Central obesity increases over time with a progressive increase in waist hip ratio between 20 - 25 years and 40 - 45 years [115]. This is consistent with reports from a prospective birth cohort of increased weight gain in early adulthood in women with symptoms of or a diagnosis of PCOS compared with controls [388]. Overall rates of weight gain and excess weight are increased in PCOS.

Obesity influences the phenotypic expression of PCOS, exacerbating metabolic, reproductive, and psychological features [279, 389]. Lipid abnormalities are increased independently in PCOS and are exacerbated by excess weight [386, 389, 390]. Central obesity is associated with more severe metabolic disturbance [389]. The prevalence of impaired glucose tolerance (IGT) and DM2 is further increased in women with PCOS with excess weight, especially in high-risk ethnic groups [391]. Conversely, weight loss reduces abdominal fat and insulin resistance and improves clinical features of PCOS ([see Chapter 3](#)) [294, 392].

Obesity impacts on ovulatory dysfunction, irregular menstrual cycles, time to conception, infertility and response to ovulation induction and is associated with increased miscarriage, hyperglycaemia, pre-eclampsia, perinatal morbidity, fetal macrosomia and greater potential for trans-generational transmission of obesity and adverse metabolic features [294, 386, 390, 393]. When combined with insulin resistance, DM2 and PCOS, the adverse outcomes can be more than additive [386, 390]. Expert opinion recommends that obese women with PCOS delay infertility therapy and pursue lifestyle modification, where possible [384, 387].

Psychological comorbidities of PCOS with overweight/obesity include anxiety, depression, low health-related QoL, sexual dissatisfaction, poor self-esteem and psychological distress [384, 390, 392]. Psychological health also requires consideration when assessing and managing excess weight, especially in PCOS. When assessing weight, related stigma, negative body image and/or low self-esteem should be considered and assessment should be respectful. Consistent with population recommendations, explanations on the purpose, how the information will be used and opportunity for questions and preferences should be provided and permission sought. Implications of results should be explained and support provided as needed.

Overall, healthy lifestyle is recommended in all women with PCOS to maintain healthy weight and prevent excess weight gain and lifestyle intervention is recommended to induce weight loss in women with excess weight. Monitoring of weight is a component of behavioural interventions and self-management associated with better short and long-term weight outcomes. General population guidelines recommend monitoring weight, BMI and where appropriate (especially in high-risk ethnic groups) waist circumference.

Recommendations

-
- 3.5.1 CCR Health professionals and women should be aware that women with PCOS have a higher prevalence of weight gain and obesity, presenting significant concerns for women, impacting on health and emotional wellbeing, with a clear need for prevention. 
- 3.5.2 CCR All those with PCOS should be offered regular monitoring for weight changes and excess weight as per 1.8.1 and 1.8.2. 
- 3.5.3 CPP When assessing weight, related stigma, negative body image and/or low self-esteem need to be considered and assessment needs to be respectful and considerate. Beforehand, explanations on the purpose and how the information will be used and the opportunity for questions and preferences needs to be provided, permission sought and scales and tape measures adequate. Implications of results need to be explained and where this impacts on emotional wellbeing, support provided. 
- 3.5.4 CPP Prevention of weight gain, monitoring of weight and encouraging evidence-based and socio-culturally appropriate healthy lifestyle is important in PCOS, particularly from adolescence. 
-

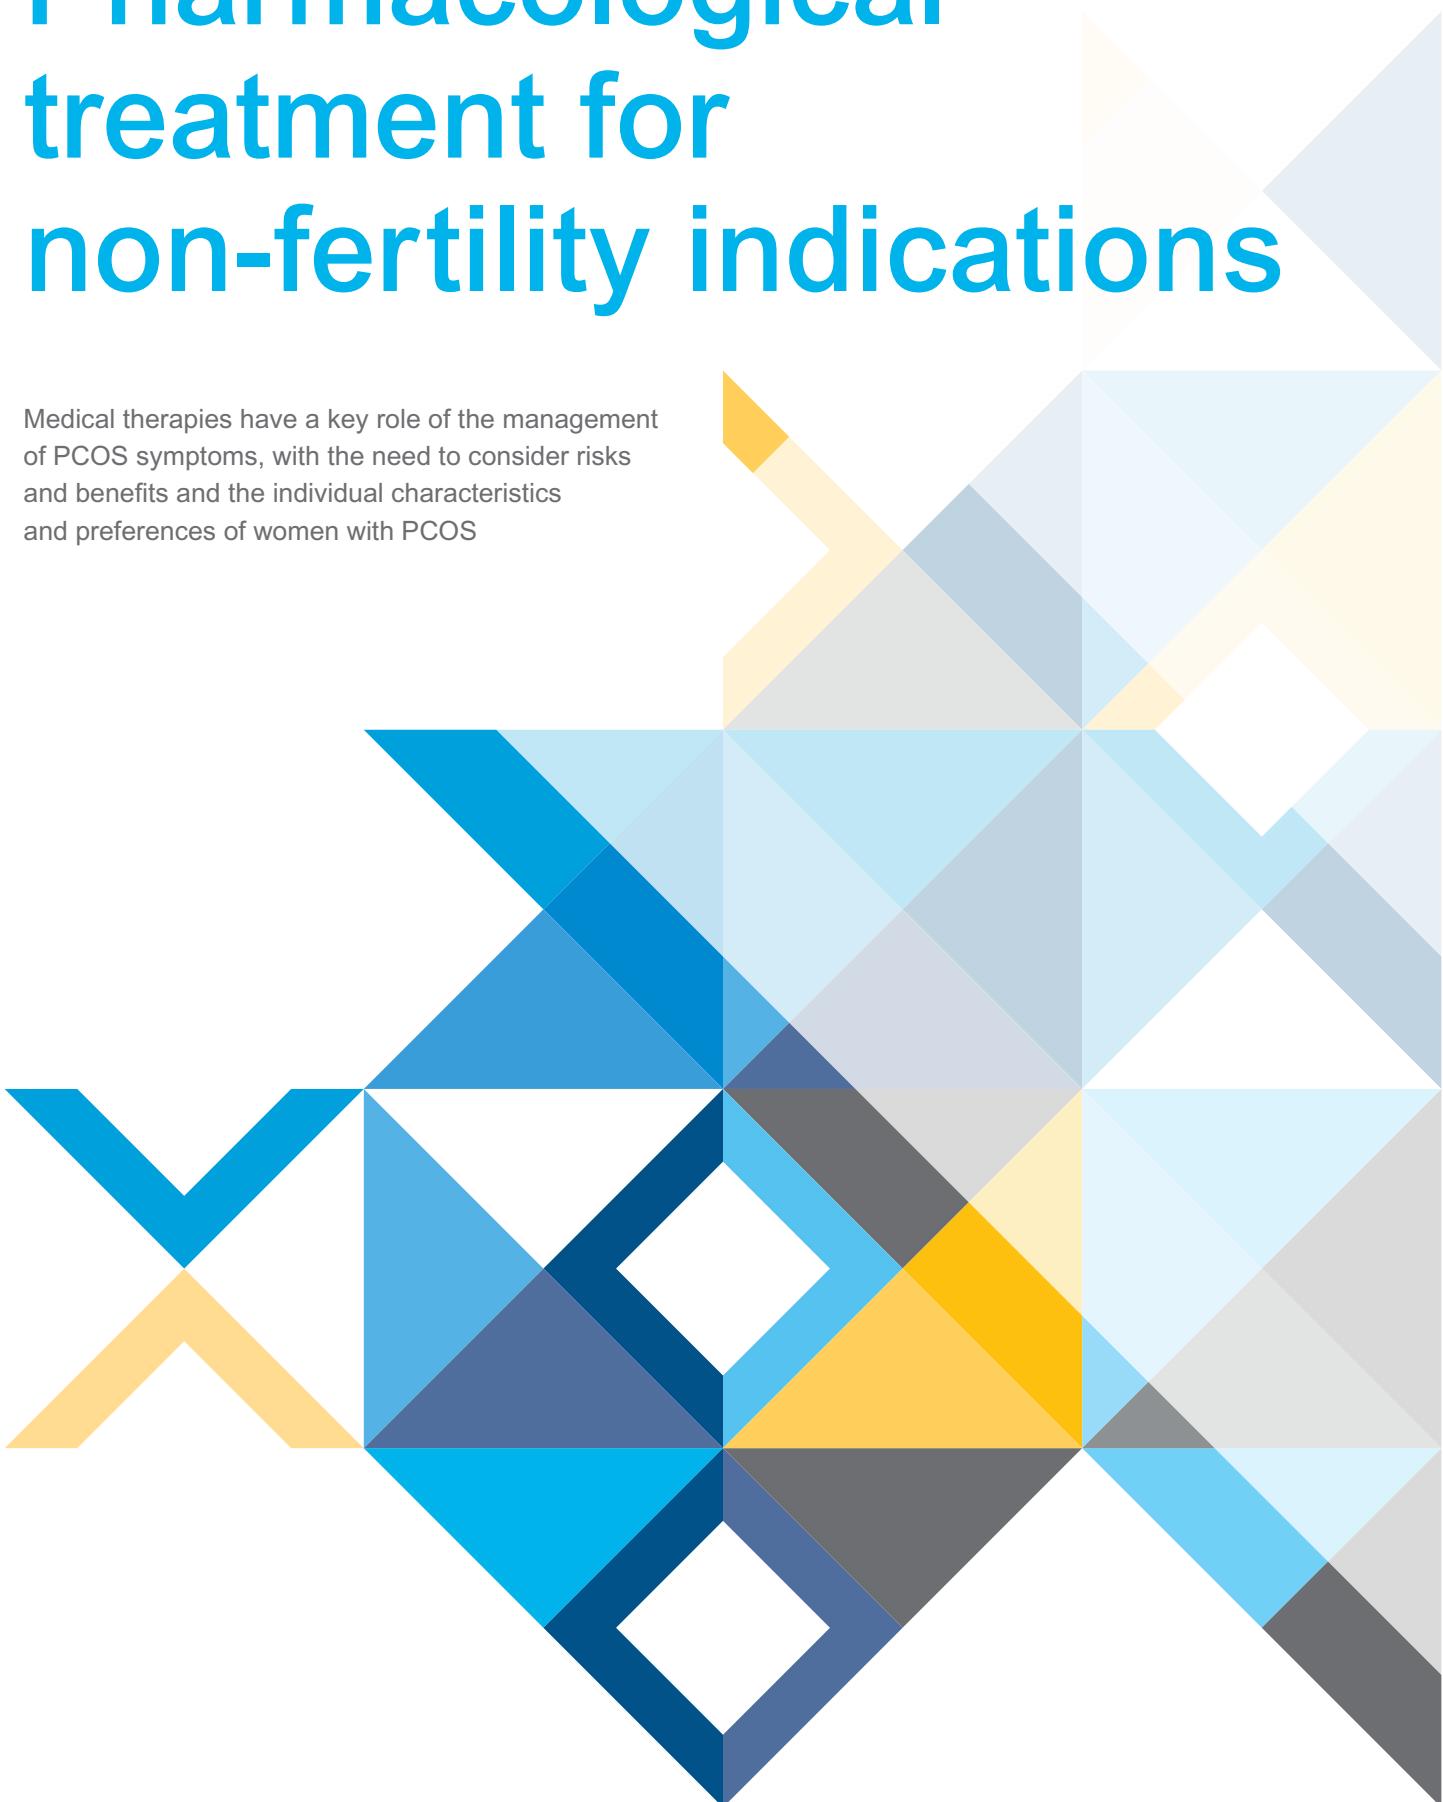

Justification

Rate of weight gain and excess weight/obesity is more prevalent in women with PCOS, compared to women without PCOS, and causes considerable concern for affected women. Obesity exacerbates the clinical features of PCOS and given the significant burden, low adherence rates and challenges with weight loss and maintenance, prevention of weight gain through healthy lifestyle is vital, consistent with international public health recommendations. Awareness, respectful monitoring and early intervention are important considerations from adolescence. The GDG recognised the need for adequate training of health professionals in the empathetic partnering with women to enable weight management.

Chapter Four

Pharmacological treatment for non-fertility indications

Medical therapies have a key role of the management of PCOS symptoms, with the need to consider risks and benefits and the individual characteristics and preferences of women with PCOS

4.1 Pharmacological treatment principles in PCOS

In reviewing the literature on pharmacological treatments, general principles emerged that apply across all pharmacological therapies. These have been extracted into a set of clinical practice points to inform women and guide health professionals when considering or recommending pharmacological therapy in PCOS. These practice points apply to all pharmacological treatments prioritised and addressed in the guideline.

Recommendations

-
- 4.1.1 CPP Consideration of the individual's personal characteristics, preferences and values is important in recommending pharmacological treatment.
 - 4.1.2 CPP When prescribing pharmacological therapy in PCOS, benefits, adverse effects and contraindications in PCOS and general populations need to be considered and discussed before commencement.
 - 4.1.3 CPP COCPs, metformin and other pharmacological treatments are generally off label# in PCOS. However off label use is predominantly evidence-based and is allowed in many countries. Where it is allowed, health professionals need to inform women and discuss the evidence, possible concerns and side effects of treatment.
 - 4.1.4 CPP Holistic approaches are required and pharmacological therapy in PCOS needs to be considered alongside education, lifestyle and other options including cosmetic therapy and counselling.
-

'Off label' prescribing occurs when a drug is prescribed for an indication, a route of administration, or a patient group that is not included in the approved product information document for that drug by the relevant regulatory body. Prescribing off label is often unavoidable and common and does not mean that the regulatory body has rejected the indication; more commonly there has not been a submission to request evaluation of the indication or that patient group for any given drug.

4.2 and 4.3 Combined Oral Contraceptive Pills and combined oral contraceptive pills in combination with other agents

Is the combined oral contraceptive pill (COCP) alone or in combination effective for management of hormonal and clinical PCOS features in adolescents and adults with PCOS?

Clinical need for the question

Combined contraceptives, including oral contraceptive pills, are commonly prescribed for adults and adolescents with PCOS to ameliorate the clinical symptoms and associated hormonal disturbances. The effects of COCPs on menstrual cycle, hirsutism, weight loss, waist/hip ratio, testosterone concentrations, lipid profile and blood sugar levels are variably reported and depend on type of COCP used, duration of use, severity of presentation/phenotype, adherence to the regimen, among other factors. Different combinations of COCPs are available with heterogeneous estrogen and progestin preparations with varying pharmacological and clinical properties. Thus, the efficacy and consequences of COCPs in PCOS may vary. Some preparations also comprise natural estrogen instead of synthetic ethynodiol (EE) with benefits and contraindications considered similar.

Summary of systematic review evidence – COCP alone

Research evidence - ADOLESCENTS

COCP versus placebo

One randomised controlled trial (RCT) was identified to address this comparison in adolescents [319]. There was a statistically significant improvement with COCP (compared to placebo) for high-density lipoprotein (HDL) in this very low quality study with low certainty. No statistically significant differences were found for outcomes: body mass index (BMI) (kg/m^2); Waist (cm); Total testosterone (ng/dl); sex hormone-binding globulin (SHBG) (nmol/liter); free androgen index (FAI); Hirsutism (FG score); Total cholesterol (mg/dl); LDL (mg/dl); Triglycerides (mg/dl); Fasting insulin (IU/ml); Fasting blood sugar (mg/dl); CRP (mg/l); PAI-1. Side effects were not reported.

COCP versus lifestyle

One RCT was identified to address this comparison in adolescents [319]. There was a statistically significant improvement with lifestyle (compared to COCP) for low-density lipoprotein (LDL) in this very low quality study with very low certainty. No statistically significant differences were found for: BMI (kg/m^2); Total testosterone (ng/dl); SHBG (nmol/liter); FAI; Hirsutism (FG score); Total cholesterol (mg/dl); HDL (mg/dl); Triglycerides (mg/dl); Fasting insulin (IU/ml); Fasting blood sugar (mg/dl); CRP (mg/l); PAI-1. Side effects were not reported.

COCP versus metformin

A systematic review including four RCTs that address this comparison in adolescents was identified [394]. The evidence team conducted additional analysis of outcomes not addressed in the systematic review. While a statistically significant improvement was found in BMI and LDL with use of metformin over COCP; and a statistically significant improvement was found in menstrual regulation with use of COCP over metformin, we remain cautious due to very low certainty in effect estimates and the quality of evidence. A statistically significant improvement in dysglycemia (OGTT) was found with the use of metformin over COCP, however it should be noted that there is low certainty in the effect estimates and the quality of evidence. No statistically significant differences were found for: Hirsutism; Total Testosterone (nmol/L); Triglyceride (mg/dL); Total Cholesterol (mg/dL); HDL (mg/dL); Weight (kg); Fasting insulin; SHBG; FAI; Fasting blood sugar (mg/dL); CRP (mg/L); PAI-1. Side effects included weight gain with COCP; and side effects were not specified with metformin.

COCP versus metformin + anti-androgen

One RCT was identified to address this comparison in adolescents [395]. Due to the lack of direct comparisons between groups (no p values reported for between groups) it is uncertain whether there were any differences in this very low quality study with very low certainty for outcomes: BMI (kg/m²); Hirsutism (FG score); Glucose/insulin ratio; SHBG (ug/dl); Testosterone (ng/dl); Triglycerides (mg/dl); HDL (mg/dl); LDL (mg/dl); Cycle regularity; Weight. Side effects were not reported.

Research evidence - ADULTS

COCP versus metformin

Nine RCTs were identified to address this comparison [396-404]. There were statistically significant improvements with metformin (compared with COCP) for fasting insulin, including for both BMI subgroups. Metformin improved HDL in the BMI > 25 subgroup but not in the BMI < 25 subgroup or when all participants were combined; and improved triglycerides when all participants were combined, in the BMI > 25 subgroup and in the subgroup where BMI was not defined, but not in the BMI < 25 subgroup. There were statistically significant improvements with COCP (compared with metformin) for SHBG, FAI, total testosterone and irregular cycles, including for all BMI subgroups. COCP improved LDL in the BMI > 25 subgroup but not in the BMI < 25 subgroup or when all participants were combined. No statistically significant differences were found for: Weight; Clamp (M value); homeostatic model assessment (HOMA) (change from baseline); BMI (kg/m²); waist-hip-ratio (WHR); Hirsutism [FG score]; Fasting glucose [mmol/l], Total cholesterol [mmol/l]. Metformin use increased GI-related events, whereas the COCP group had none. While one of the included studies was of moderate quality and certainty, the majority of studies in these meta-analyses were of low to very low certainty in effect estimates and the quality of evidence and therefore all findings should be interpreted with caution.

COCP versus COCP + metformin

Six RCTs were identified to address this comparison [402, 404-408]. There was a statistically significant improvement with COCP alone (compared with COCP plus metformin) for triglycerides. COCP alone improved SHBG in the BMI < 25 subgroup but not in the BMI > 25 subgroup or when all participants were combined. There were statistically significant improvements with COCP plus metformin (compared with COCP alone) for FAI. COCP plus metformin improved testosterone when all participants were combined but not in BMI subgroups; improved hirsutism and fasting glucose when all participants were combined and in the BMI > 25 subgroup but not in the BMI < 25 subgroup; improved SHBG and fasting insulin in the BMI < 25 subgroup but not when all participants were combined or in the BMI > 25 subgroup; and improved total cholesterol in the BMI > 25 subgroup but not when all participants were combined or in the BMI < 25 subgroup. No statistically significant differences were found for: HOMA; Weight (kg); BMI (kg/m²); WHR; HDL [mmol/l]; LDL [mmol/l]. The addition of metformin to COCP increased GI-related events, whereas the COCP alone group had none. While one of the included studies was of moderate quality and certainty, the majority of studies in these meta-analyses were of low to very low certainty in effect estimates and the quality of evidence and therefore all findings should be interpreted with caution.

COCP versus COCP + metformin + anti-androgen

One RCT was identified to address this comparison in adults [395]. Due to the lack of direct comparisons between groups (no p values reported for between groups) it is uncertain whether there were any differences in this very low quality study with very low certainty for outcomes: BMI (kg/m²); Hirsutism (FG score); Glucose/insulin ratio; SHBG (ug/dl); Testosterone (ng/dl); Triglycerides (mg/dl); HDL (mg/dl); LDL (mg/dl); Cycle regularity; Weight. Side effects were not reported.

COCP versus anti-androgen

One RCT was identified to address this comparison in adults [409]. Due to the lack of direct comparisons between groups (no p values reported for between groups) it is uncertain whether there were any differences in this very low quality study with very low certainty for the outcome hirsutism (FG score).

Summary of systematic review evidence – COCP combined with other agents

Research evidence - ADOLESCENTS

COCP + metformin+ lifestyle versus COCP + lifestyle + placebo

One RCT was identified to address this comparison in adolescents [319]. There was a statistically significant improvement with the addition of metformin to COCP and lifestyle (compared to COCP and lifestyle plus placebo) for testosterone and HDL in this very low quality study with very low certainty. No statistically significant differences were found for: BMI (kg/m^2); Waist (cm); SHBG (nmol/l); FAI; Hirsutism (FG score); Total cholesterol (mg/dl); LDL (mg/dl); Triglycerides (mg/dl); Fasting insulin (IU/ml); Fasting blood sugar (mg/dl); CRP (mg/liter). One in each group stopped metformin or placebo due to GI effects.

COCP + anti-androgen versus COCP + anti-androgen + metformin

One RCT was identified to address this comparison in adolescents [410]. Due to the lack of direct comparisons between groups (no p values reported for between groups) it is uncertain whether there were any differences in this very low quality study with very low certainty for outcomes: BMI (kg/m^2); Fasting glucose/insulin ratio SHBG ($\mu\text{g}/\text{dl}$); Testosterone (ng/dl); LDL (mg/dl); HDL (mg/dl); Triglycerides (mg/dl). Side effects were not reported.

Research evidence - ADULTS

COCP versus COCP + metformin

Six RCTs were identified to address this comparison [402, 404-408]. There was a statistically significant improvement with COCP alone (compared with COCP plus metformin) for triglycerides. COCP alone improved SHBG in the BMI < 25 subgroup but not in the BMI > 25 subgroup or when all participants were combined. There were statistically significant improvements with COCP plus metformin (compared with COCP alone) for FAI. COCP plus metformin improved testosterone when all participants were combined but not in BMI subgroups; improved hirsutism and fasting glucose when all participants were combined and in the BMI > 25 subgroup but not in the BMI < 25 subgroup; improved SHBG and fasting insulin in the BMI < 25 subgroup but not when all participants were combined or in the BMI > 25 subgroup; and improved total cholesterol in the BMI > 25 subgroup but not when all participants were combined or in the BMI < 25 subgroup. No statistically significant differences were found for: HOMA; Weight (kg); BMI (kg/m^2); WHR; HDL [mmol/l]; LDL [mmol/l]. The addition of metformin to COCP increased GI-related events, whereas the COCP alone group had none. While one of the included studies was of moderate quality and certainty, the majority of studies in these meta-analyses were of low to very low certainty in effect estimates and the quality of evidence and therefore all findings should be interpreted with caution.

COCP versus COCP + metformin + anti-androgen

One RCT was identified to address this comparison in adults [395]. Due to the lack of direct comparisons between groups (no p values reported for between groups) it is uncertain whether there were any differences in this very low quality study with very low certainty for outcomes: BMI (kg/m^2); Hirsutism (FG score); Glucose/insulin ratio; SHBG ($\mu\text{g}/\text{dl}$); Testosterone (ng/dl); Triglycerides (mg/dl); HDL (mg/dl); LDL (mg/dl); Cycle regularity; Weight. Side effects were not reported.

COCP versus COCP + anti-androgen

Four RCTs were identified to address this comparison in adults [411-414]. There was a statistically significant improvement with COCP alone (compared with COCP plus anti-androgen) for BMI and LDL. No statistically significant differences were found for: Weight (kg); WHR; Hirsutism (FG score); FAI (%); Testosterone (nmol/L); SHBG [nmol/l]; Fasting insulin (uIU/ml); Fasting glucose [mmol/l]; Total cholesterol [mmol/l]; HDL [mmol/l]; Triglycerides (mg/dL); HOMA; CRP (mg/l); Headache; Breast-related side effects; Vomit/Nausea; Minor depressive state; Liver function. The majority of studies in these meta-analyses were of low to very low certainty in effect estimates and the quality of evidence and therefore all findings should be interpreted with caution.

COCP + metformin + lifestyle versus COCP + metformin + lifestyle

One study was identified to address this comparison in adults [415]. There were no statistically significant differences reported between the two interventions (differing by the combination in the COCP) in this very low quality study of very low certainty for outcomes: WHR; Fasting plasma glucose (mmol/L); HbA1c (%); Total cholesterol (mmol/L); LDL (mmol/L). Side effects were not reported.

Summary of narrative review evidence

Evidence on COCP use from the general population also informed recommendations. Consideration of adverse effects is needed before prescribing COCPs. Absolute contraindications for COCP use according to world health organisation (WHO) include a history of migraine with aura, deep vein thrombosis (DVT)/pulmonary emboli (PE), known thrombogenic mutations, multiple risk factors for arterial cardiovascular disease, history of ischemic heart disease or stroke, complicated valvular heart disease, breast cancer, neuropathy, severe cirrhosis and malignant liver tumours [416]. Other risk factors for DVT need consideration including postpartum immobility, transfusion at delivery, BMI > 30 kg/m², postpartum haemorrhage, immediately post-caesarean delivery, preeclampsia or smoking. Current evidence suggests that COCPs containing levonorgestrel, norethisterone and norgestimate are associated with the lowest relative risk of DVT. Also, WHO recommends that COCPs with 35 micrograms of EE and cyproterone acetate should only be used when treating moderate to severe hirsutism or acne due to higher DVT risk. For contraception, irregular menstrual cycles and mild to moderate hirsutism, other lower risk preparations are recommended first line [417].

Recommendations – COCP alone

4.2.1	EBR	The COCP alone should be recommended in adult women with PCOS for management of hyperandrogenism and/or irregular menstrual cycles.	❖❖❖❖ ⊕⊕○○
4.2.2	EBR	The COCP alone should be considered in adolescents with a clear diagnosis of PCOS for management of clinical hyperandrogenism and/or irregular menstrual cycles.	❖❖❖ ⊕⊕○○
4.2.3	EBR	The COCP could be considered in adolescents who are deemed “at risk” but not yet diagnosed with PCOS, for management of clinical hyperandrogenism and irregular menstrual cycles.	❖❖❖ ⊕⊕○○
4.2.4	EBR	Specific types or dose of progestins, estrogens or combinations of COCP cannot currently be recommended in adults and adolescents with PCOS and practice should be informed by general population guidelines.	❖❖❖ ⊕⊕○○
4.2.5	CCR	The 35 microgram ethinyloestradiol plus cyproterone acetate preparations should not be considered first line in PCOS as per general population guidelines, due to adverse effects including venous thromboembolic risks.	❖
4.2.6	CPP	When prescribing COCPs in adults and adolescents with PCOS: <ul style="list-style-type: none">• various COCP preparations have similar efficacy in treating hirsutism• the lowest effective estrogen doses (such as 20-30 micrograms of ethinyloestradiol or equivalent), and natural estrogen preparations need consideration, balancing efficacy, metabolic risk profile, side effects, cost and availability• the generally limited evidence on effects of COCPs in PCOS needs to be appreciated with practice informed by general population guidelines (WHO Guidelines)• the relative and absolute contraindications and side effects of COCPs need to be considered and to be the subject of individualised discussion• PCOS specific risk factors such as high BMI, hyperlipidemia and hypertension need to be considered.	

Recommendations – COCP in combination with other agents

4.3.1	EBR	In combination with the COCP, metformin should be considered in women with PCOS for management of metabolic features where COCP and lifestyle changes do not achieve desired goals.	
4.3.2	EBR	In combination with the COCP, metformin could be considered in adolescents with PCOS and BMI $\geq 25\text{kg}/\text{m}^2$ where COCP and lifestyle changes do not achieve desired goals.	
4.3.3	CPP	In combination with the COCP, metformin may be most beneficial in high metabolic risk groups including those with diabetes risk factors, impaired glucose tolerance or high-risk ethnic groups.	
4.3.4	EBR	In combination with the COCP, antiandrogens should only be considered in PCOS to treat hirsutism, after six months or more of COCP and cosmetic therapy have failed to adequately improve symptoms.	
4.3.5	CCR	In combination with the COCP, antiandrogens could be considered for the treatment of androgen-related alopecia in PCOS.	
4.3.6	CPP	In PCOS, antiandrogens must be used with effective contraception, to avoid male foetal undervirilisation. Variable availability and regulatory status of these agents is notable and for some agents, potential liver toxicity requires caution.	

Justification

Although relatively safe, COCPs have absolute and relative contraindications and risks and benefits in the general population that need consideration by health professionals and women. Although combined metformin and COCP offers additional benefits, these did not surpass the impact of COCP plus lifestyle intervention. Hence the combination is indicated where COCP and lifestyle have failed to meet goals. A combination regime may also lead to increased mild gastrointestinal side effects, which can impact on adherence. Strategies to reduce side effects are available (see metformin recommendations below). With metformin therapy in addition to COCP, women with PCOS and obesity may yield the greatest benefit. The PCOS phenotype, BMI, ethnicity and the informed preference of the individual with PCOS need to be considered when recommending pharmacological agents for the treatment of PCOS.

COCPs, metformin and anti-androgens are off label treatments specifically for treatment of PCOS. However, use is evidence-based for the treatment of clinical features of PCOS and is generally not restricted for use in PCOS. Women should be informed of the benefits and risks and the regulation status of relevant medications. The combination of off label treatments with the COCP is not routine practice and will require education and integration into algorithms. This is anticipated to significantly change practice. Due to subgroup differences in recommendations, the personal characteristics of all women need to be considered.

4.4 Metformin

Is metformin alone, or in combination, effective for management of hormonal and clinical PCOS features and weight in adolescents and adults with PCOS?

Clinical need for the question

Metformin is a low cost, readily available medication that has been extensively used as an insulin sensitiser for over seven decades in DM2 and for several decades in PCOS. Insulin resistance is documented on clamp studies in 75% of lean women and 95% of overweight women [279] and addressing this has underpinned the use of metformin in PCOS. Metformin is currently widely used by women with PCOS, yet there is variability in recommendations across health professional specialties, with endocrinologists familiar with metformin and more likely to prescribe this therapy. Also the efficacy of metformin in terms of improving clinical outcomes remains uncertain. Mild side effects do cause some concern, and metformin use in PCOS is generally off label. Yet metformin is a low cost, readily available medication and off label use in PCOS is allowed in many countries. A multitude of studies have been completed in PCOS for a range of clinical outcomes and synthesis of the literature and recommendations on metformin use was prioritised.

Summary of systematic review evidence

Metformin versus placebo

Twenty RCTs that address outcomes for this comparison were identified [318, 319, 418-435], of which 19 RCTs were in adults [318, 418-435], and 1 was in adolescents [319].

Weight: When 5 RCTs were combined in meta-analysis, there was no statistically significant difference between metformin and placebo [418, 424, 427, 433, 434]. When three of the studies in those with BMI > 25kg/m² were subgrouped [424, 427, 433], metformin was better than placebo.

BMI: When 15 RCTs were combined in meta-analysis [318, 319, 418-422, 424, 425, 428-432, 435], and when 11 of the RCTs in those with BMI > 25kg/m² was subgrouped [318, 319, 419-422, 424, 425, 429, 431, 432, 435], metformin was better than placebo.

WHR: When 8 RCTs were combined in meta-analysis, there was no statistically significant difference between metformin and placebo ($p=0.06$ in favour of metformin) [418, 419, 421, 424, 427, 429, 431, 434]. When 3 of the RCTs in those with BMI < 25kg/m² were subgrouped [418, 429, 431], metformin was better than placebo.

Hirsutism: When 6 RCTs were combined in meta-analysis, there was no statistically significant difference between metformin and placebo, regardless of BMI subgroups [319, 423, 425, 429-431].

SHBG: When 13 RCTs were combined in meta-analysis there was no statistically significant difference between metformin and placebo, regardless of BMI subgroups [318, 319, 418-421, 423-425, 428, 430, 431, 434]. In one very small RCT (n=20), where BMI was not reported, there was a statistically significant difference in favour of metformin [423].

FAI: When 6 RCTs were combined in meta-analysis there was no statistically significant difference between metformin and placebo, regardless of BMI subgroups [318, 319, 423, 424, 430, 431].

Testosterone: When 15 RCTs were combined in meta-analysis metformin was better than placebo, however there was no statistically significant difference for any of the BMI subgroups [318, 319, 418-421, 423-425, 428, 430, 431, 433-435].

Fasting insulin: When 9 RCTs were combined in meta-analysis there was no statistically significant difference between metformin and placebo [318, 419-421, 424, 425, 429, 433, 434]. In one small RCT (n=60) of those with BMI < or > 25kg/m², there was a statistically significant difference in favour of metformin [434].

Fasting glucose: When 13 RCTs were combined in meta-analysis there was no statistically significant difference between metformin and placebo [318, 319, 418-421, 424, 425, 428, 429, 433-435]. In one small RCT (n=58) of those with BMI <or> 25kg/m², there was a statistically significant difference in favour of metformin [434].

Cholesterol: When 10 RCTs were combined in meta-analysis [319, 419, 421, 422, 424, 425, 428, 429, 431, 434], and when 6 of the RCTs in those with BMI > 25kg/m² was subgrouped [319, 419, 421, 424, 425, 429], metformin was better than placebo.

HDL: When 9 RCTs were combined in meta-analysis, there was no statistically significant difference between metformin and placebo, regardless of BMI subgroups [319, 419, 424, 425, 429-431, 433, 434].

LDL: When 9 RCTs were combined in meta-analysis, there was no statistically significant difference between metformin and placebo (p=0.07 in favour of metformin) [319, 419, 423-425, 429-431, 434]. When 6 of the RCTs in those with BMI > 25kg/m² were subgrouped, metformin was better than placebo.

Triglycerides: When 13 RCTs were combined in meta-analysis, metformin was better than placebo, however there was no statistically significant difference for any of the BMI subgroups [319, 419, 421, 423-425, 428, 429, 431, 434].

There were no statistically significant differences between metformin and placebo for HOMA, menstrual cycles, CRP (C-reactive protein) or PAI-1 (plasminogen activator inhibitor-1).

It is important to remain cautious due to low to very low certainty in effect estimates and the quality of evidence across all outcomes.

Gastrointestinal side effects were more prevalent in the metformin groups, but only 5 out of 20 studies including in total 358 women and metformin doses of 1500 - 1700mg/day reported on side effects without specific details. 10 to 62% of women taking metformin reported side effects. The majority of gastrointestinal side effects were mild to moderate and were self-limiting. The side effects reported included nausea, vomiting, diarrhoea, abdominal pain or non-specified gastrointestinal disturbance. Only one study reported higher drop out in the metformin treated due to unacceptable gastrointestinal side effects and suggested lower start metformin dose (500 mg/day),

There were no reports on Vitamin B12 levels.

Metformin versus metformin + COCP

Three RCTs that address this comparison in adults were identified [402, 404, 436]. While a statistically significant improvement was found in WHR and triglycerides with use of metformin over metformin plus COCP, regardless of BMI, we remain cautious due to very low certainty in effect estimates and the quality of evidence.

No statistically significant differences were found for: Weight, BMI, FAI, testosterone, Fasting glucose (mg/dl), Fasting insulin [mIU/ml], fasting glucose-insulin ratio, HOMA, OGTT, Total cholesterol [mg/dl], HDL [mg/dl] and LDL [mg/dl].

Side effects were not reported.

Metformin versus lifestyle

Three RCTs that address this comparison in adolescents and adults were identified [318, 319, 437]. While a statistically significant improvement was found in testosterone with use of metformin over lifestyle; and in SHBG with the use of lifestyle over metformin, we remain cautious due to very low certainty in effect estimates and the quality of evidence. While not statistically significant, fasting glucose tended to favour metformin.

No statistically significant differences were found for: BMI, WHR, PAI-1, Hirsutism (FG score), Menstruation (cycle/mnth), FAI, Fasting glucose (mg/dl), Fasting insulin [mIU/ml], HOMA, Total cholesterol [mg/dl], HDL [mg/dl], LDL [mg/dl], Triglycerides [mg/dl], CRP [mg/dl].

Side effects were GI related with metformin and only reported in one study including adult women.

Metformin + lifestyle versus lifestyle ± placebo

A systematic review including seven relevant RCTs that address this comparison in adults and adolescents was identified [438]. The evidence team conducted additional analysis of outcomes not addressed in the systematic review. No statistically significant differences were found for any of the outcomes in this body of evidence of low to very low certainty and quality.

Side effects were not reported.

Metformin versus metformin (dose)

One study was identified to address this comparison [439]. Age was not reported. There was no difference in weight between the two interventions in this very low quality of very low certainty. Other relevant outcomes were mentioned in this study, however no useable data was reported.

The highest metformin dose used was 850mg twice a day.

Metformin versus anti-androgen + COCP

One study was identified to address this comparison in adults [440]. 500mg of metformin was better for fasting glucose; and 850mg was better for CRP; however, there was no difference for BMI, HDL or triglycerides in this moderate quality study with low certainty.

Metformin + lifestyle versus anti-androgen + lifestyle

Four RCTs that address this comparison in adults was identified [441-444]. While a statistically significant improvement was found in cycles per year and HOMA-IR (homeopathic model assessment of insulin resistance) with use of metformin plus lifestyle over anti-androgen plus lifestyle, and a statistically significant improvement found in hirsutism, SHBG, fasting insulin and fasting glucose-insulin ration with use of anti-androgen plus lifestyle over metformin plus lifestyle, we remain cautious due to low to very low certainty in effect estimates and the quality of evidence.

No statistically significant differences were found for: Weight (kg); BMI; WHR; Testosterone (nmol/L); Fasting glucose (mg/dL); QUICKI [mg/dl]; FAI (pg/ml); OGTT (mg/dl) and HOMA-IR (mIU · mmol/L²).

Side effects were only reported in one study and included vomiting, nausea and diarrhoea with metformin plus lifestyle; and abdominal pain, polyuria, menstrual irregularity and dryness of the mouth with anti-androgen plus lifestyle.

Three subjects in the metformin group and four in the spironolactone group withdrew due to side effects.

Total cholesterol, HDL and LDL were reported in two studies however units were unclear and there was missing data. Of the data presented, there were no differences between interventions for these outcomes in one study and in the other, p values were not reported for direct comparisons.

Metformin + diet versus metformin + anti-androgen + diet

Four RCTs that address this comparison in adults was identified [441, 442, 444, 445]. While a statistically significant improvement was found in testosterone and fasting glucose with use of metformin plus anti-androgen plus lifestyle over metformin plus lifestyle, we remain cautious due to very low certainty in effect estimates and the quality of evidence.

No statistically significant differences were found for: Weight; BMI; WHR; cycles; hirsutism, SHBG, FAI, fasting insulin; OGTT (mg/dl) and HOMA-IR, total cholesterol, HDL, LDL and triglycerides.

Side effects were only reported in one study and included vomiting, nausea, diarrhoea symptoms with metformin plus lifestyle; and nausea, diarrhoea, abdominal pain and metrorrhagia with metformin plus anti-androgen plus lifestyle.

There was stronger evidence in higher BMI groups for metabolic outcomes. Overall there was inadequate evidence to make a recommendation about the use of metformin for menstrual regulation. The maximum dose used in the included studies was 850bd and the optimum dose is not known.

Gastrointestinal side effects may be present. Side effects are usually mild, self-limiting and may be minimised with lower metformin starting dose. Extended release preparations and administration with food might also decrease gastrointestinal side effects.

Summary of narrative review evidence

Given the gaps in evidence in some areas in PCOS, the relevant literature on metformin in other populations was reviewed to inform recommendations. Metformin works by decreasing gluconeogenesis, lipogenesis and enhancing glucose uptake in the liver, skeletal muscle, adipose tissue and ovaries [446]. It is known in other populations to prevent weight gain and appears to assist with weight loss, to prevent and manage DM2, gestational diabetes (GDM), and to reduce microvascular and cardiovascular disease in DM2 [446, 447]. Side effects have are not uncommon, yet these are primarily gastrointestinal, appear mild and self-limiting, with more severe side effects rare and primarily affecting those with other comorbidities [446]. Concerns on Vitamin B12 deficiency with longer term metformin use have also emerged [448], however more research is needed. Data from other populations suggests that side effects can be minimised with lower metformin starting dose, extended release preparations and/or administration with food [449].

Recommendations

4.4.1	EBR	Metformin in addition to lifestyle, could be recommended in adult women with PCOS, for the treatment of weight, hormonal and metabolic outcomes.	❖❖❖ ⊕⊕○○
4.4.2	EBR	Metformin in addition to lifestyle, should be considered in adult women with PCOS with $BMI \geq 25\text{kg}/\text{m}^2$ for management of weight and metabolic outcomes.	❖❖❖ ⊕⊕○○
4.4.3	EBR	Metformin in additional to lifestyle, could be considered in adolescents with a clear diagnosis of PCOS or with symptoms of PCOS before the diagnosis is made.	❖❖❖ ⊕⊕○○
4.4.4	CPP	Metformin may offer greater benefit in high metabolic risk groups including those with diabetes risk factors, impaired glucose tolerance or high-risk ethnic groups (see 1.6.1).	
4.4.5	CPP	Where metformin is prescribed the following need to be considered:	
		<ul style="list-style-type: none">adverse effects, including gastrointestinal side-effects that are generally dose dependent and self-limiting, need to be the subject of individualised discussionstarting at a low dose, with 500mg increments 1-2 weekly and extended release preparations may minimise side effectsmetformin use appears safe long-term, based on use in other populations, however ongoing requirement needs to be considered and use may be associated with low vitamin B12 levelsuse is generally off label and health professionals need to inform women and discuss the evidence, possible concerns and side effects.	

Justification

Study numbers were considerable however, the quality and certainty of the evidence was limited. Metformin also has clear benefits in other relevant populations including those with DM2, which also informed GDG recommendations. In PCOS, evidence indicated that metformin is effective overall and /or in specified subgroups, in improving weight, BMI, WHR ratio, testosterone and TG in women with PCOS including those defined by Rotterdam criteria. In providing these recommendations, the GDG considered the very high rating that women with PCOS credited to BMI as an outcome of importance and value. Evidence of metabolic benefits was generally stronger in women with increased BMI. There was inadequate evidence to make a recommendation about the use of metformin for irregular menstrual cycles and efficacy for infertility is addressed later in this guideline. Gastrointestinal side effects were noted, but appear to be mild, self-limiting and could be minimised with lower metformin starting dose, extended release preparations or administration with food. Overall, the beneficial effects in PCOS favoured the use of metformin, the undesirable effects were generally mild and self-limiting and on balance, evidence was felt to probably favour metformin use in PCOS. Whilst use is off label, it is also generally allowed. Cost was relatively low and availability generally widespread and implementation of recommendations were judged to be feasible.

4.5 Anti-obesity pharmacological agents

Are anti-obesity pharmacological agents alone or in combination, effective for management of hormonal and clinical PCOS features and weight in adolescents and adults with PCOS?

Clinical need for the question

As previously outlined, excess weight is a significant concern for adolescents and women with PCOS and is more prevalent than in women without PCOS. Whilst lifestyle intervention has a first line role in the prevention and management of excess weight in PCOS, the role of anti-obesity pharmacological agents in achieving and maintaining weight loss and in delivering potential health benefits is being increasingly recognised in general and other high-risk populations. Challenges with adherence, efficacy and sustainability all appear to benefit from the addition of these agents to lifestyle interventions. Recent guidelines, systematic and Cochrane reviews have focused on the role of these agents in general and high-risk populations including in obese adolescents. A range of different agents are now approved as anti-obesity medications in adults, although approval status varies across countries, costs remain generally high and there are challenges in access and availability. Despite the challenges, these medications are increasingly being used in adults for assistance with weight loss and weight maintenance in obesity management in other populations [450]. However, in PCOS and in reproductive-aged women generally, the role of anti-obesity pharmacological agents remains unclear. Anti-obesity agents reviewed here were sibutramine and orlistat.

Summary of systematic review evidence

We did not identify any evidence in adolescents with PCOS and below is a summary of the evidence identified in adults.

Anti-obesity versus placebo

One study was identified to address this comparison [451]. Due to the lack of direct comparisons between groups (no p values reported for between groups for end of treatment data), it is uncertain whether there were any differences in this low quality study with low certainty for outcomes: Weight loss (kg); WHR (cm); Menstrual periods (n/6 months); Triglycerides (mmol/L); Fasting glucose (mmol/L); Fasting insulin (mU/L); Fasting glucose/insulin ratio; HOMA-IR; Hs-CRP (mg/L); Testosterone (nmol/L); SHBG (nmol/L); FAI. Side effects were not reported.

Anti-obesity versus anti-obesity

One study was identified to address this comparison [452]. Due to the lack of direct comparisons between groups (no p values reported for between groups for end of treatment data), it is uncertain whether there were any differences in this low quality study with low certainty for outcomes: BMI (kg/m²); WHR (cm); Testosterone (ng/dl); Δ4- Androstenedione (ng/ml); DHEA-S (ng/ml); FAI; SHBG (nmol/l); Fasting glucose (mg/dl); Fasting insulin (μIU/ml); Fasting glucose/insulin; AUC OGTT; HOMA-IR; QUICKI; PAI-1 (ng/ml). Side effects were not reported.

Summary of narrative review evidence

Given the gaps in evidence in some areas in PCOS, the relevant literature on anti-obesity agents in other populations was reviewed to inform recommendations. Recent US Endocrine Society guidelines [450], systematic and Cochrane reviews [453] have focused on the role of these agents in general and high-risk populations including in obese adolescents. A range of different agents are now approved as anti-obesity medications in adults, although approval status varies across countries, costs remain generally high and there are challenges in access, efficacy and availability. Despite the challenges, these medications are increasingly being used and recommended in adults for assistance with weight loss and weight maintenance in obesity management in other populations [450]. It was noted that cost effectiveness of these agents is yet to be established [454].

Recommendations

-
- 4.5.1 CCR Anti-obesity medications in addition to lifestyle, could be considered for the management of obesity in adults with PCOS after lifestyle intervention, as per general population recommendations. 
- 4.5.2 CPP For anti-obesity medications, cost, contraindications, side effects, variable availability and regulatory status need to be considered and pregnancy needs to be avoided whilst taking these medications.
-

Justification

Despite recommendations in the general population, in reproductive-aged women generally, including those with PCOS, the role of anti-obesity pharmacological agents remains unclear. Given the absence of useful evidence in PCOS and in reproductive aged women generally, the GDG were unable to make any evidence-based recommendations in women with PCOS. However, informed by evidence and guidelines on the use of anti-obesity pharmacological agents in the management of obesity in non-PCOS adults, a consensus recommendation has been made. There are known contraindications and side effects of these medications that need to be considered and monitored. Concerns about cost effectiveness was also considered by the group, based on evidence in the general population.

4.6 Anti-androgen pharmacological agents

Are anti-androgen pharmacological agents alone or in combination, effective for management of hormonal and clinical PCOS features and weight in adolescents and adults with PCOS?

Clinical need for the question

The most common androgen-related features of PCOS are hirsutism, acne and androgen-related alopecia (see [Chapter 1: Screening, diagnostic assessment, risk assessment and life-stage](#)). Given the adverse impact of clinical hyperandrogenism on emotional wellbeing and QoL (see [Chapter 2: Prevalence, screening, diagnostic assessment and treatment of emotional wellbeing](#)), and the high priority given to clinical hyperandrogenism outcomes during guideline development, this clinical question was prioritised. Cosmetic and COCP therapy are first line treatments for hirsutism in women, including in PCOS. There are few studies of anti-androgen pharmacological agents in the treatment of PCOS and there are limited relevant studies on the use of anti-androgens in other populations that can guide practice in PCOS, with the majority of studies involving anti-androgen pharmacological agents combined with COCPs (see [Section 4.3 COCP in combination with other agents](#)). Overall, the role of anti-androgens remains controversial and this question was prioritised. Pure anti-androgens were prioritised and reviewed here across flutamide, finasteride and spironolactone. Other agents such as synthetic progestin with anti-androgenic properties were not prioritised for review in this guideline.

Summary of systematic review evidence

Anti-androgen versus placebo

One study of adolescents was identified to address this comparison [455]. Due to the lack of direct comparisons between groups (no p values reported for between groups for end of treatment data), it is uncertain whether there were any differences in this very low quality study with very low certainty for outcomes: BMI (kg/m^2); Modified Ferriman-Gallwey score (mFG); SHBG ($\mu\text{g}/\text{ml}$); Testosterone (ng/dL); DHEAS ($\mu\text{mol}/\text{L}$); Androstenedione (ng/ml); GI related adverse effects. Side effects were not reported.

Anti-androgen + lifestyle versus placebo + lifestyle

One study was identified to address this comparison in adults [442]. Due to the lack of direct comparisons between groups (no p values reported for between groups for end of treatment data), it is uncertain whether there were any differences in this moderate quality study with moderate certainty for outcomes: Weight (kg); BMI (kg/m^2); Number of cycles in previous 6 months; Hirsutism (FG score); SHBG (nmol/L); FAI (pg/ml); Testosterone (ng/ml); DHEAS ($\mu\text{g}/\text{ml}$); Androstenedione (ng/dl); Fasting insulin ($\mu\text{U}/\text{ml}$); Fasting glucose (mg/ml); Response of glucose to OGTT- glucose AUC ($\text{mg}/\text{ml}\cdot\text{min}$); Response of insulin to OGTT- insulin AUC ($\mu\text{U}/\text{ml}\cdot\text{min}$); QUICKI; ISI; HDL (mg/dL); LDL (mg/dl); Triglycerides (mg/dl).

The only side effect reported in the anti-androgen group was a mild increment in transaminase levels.

Anti-androgen (daily) versus anti-androgen (every 3 days)

Two RCTs that address this comparison in adults were identified [456, 457]. While a statistically significant improvement was found in hirsutism FG score with use of the frequency of every 3 days over daily anti-androgens, we remain cautious due to very low certainty in effect estimates and the quality of evidence. No statistically significant differences were found for: BMI, testosterone, SHBG and fasting insulin.

GI related side effects were found in the group taking anti-androgen every 3 days (compared to those on daily treatment).

Anti-androgen + diet versus metformin + anti-androgen + diet

Three RCTs that address this comparison in adults were identified [441, 442, 444]. While a statistically significant improvement was found in fasting glucose and HOMA-IR with the addition of metformin to anti-androgen and lifestyle; and in triglycerides with anti-androgens and lifestyle (without metformin); we remain cautious due to low to very low certainty in effect estimates and the quality of evidence. No statistically significant differences were found for: Weight, WHR, BMI [kg/m²], Number of cycles/year, Number of cycles in previous 6 months, FAI (pg/ml), Hirsutism [FG score], SHBG [nmol/l], Testosterone [nmol/l], Fasting insulin [?IU/mL], QUICKI, OGTT [mg/dl], Total cholesterol (mM/l), HDL (mmol/l), LDL (mmol/l).

As noted above, it is difficult to offer definitive evaluation of the use of anti-androgens because of the poor quality of evidence and lack of valid randomised controlled studies.

As the undesirable effect of antiandrogens is mostly related to mild hepatotoxicity, lifestyle does not seem to alleviate such a risk. Conversely, it seems that the addition of metformin does not increase either the risk of elevated liver indices or general side effects (same of, even increased, compliance with treatment in one study). The potential for teratogenicity for anti-androgens especially when used as a single agent in women at risk for conception limits the use of these medications. There is no evident dose-response relationship.

Summary of narrative review evidence

Other relevant evidence and guidelines not specific to the PCOS population, were considered to inform these recommendations, include those around side effects of anti-androgens. The GDG considered it is mandatory to use concomitant contraception with anti-androgens in order to avoid foetal male under virilisation in the event of unplanned pregnancy [458]. Consistent with the Endocrine Society guidelines we recommend against antiandrogen monotherapy unless adequate contraception is used and note that cosmetic and COCP therapy are first line treatments for hirsutism in women including in PCOS [459]. Due to the growth cycle of hair, at least a 6 – 12 months course treatment is optimal to evaluate the effectiveness of the antiandrogen treatment in improving hirsutism and/or acne [458].

Recommendations

-
- | | | |
|-----------|--|--|
| 4.6.1 EBR | Where COCPs are contraindicated or poorly tolerated, in the presence of other effective forms of contraception, anti-androgens could be considered to treat hirsutism and androgen-related alopecia. | 
 |
| 4.6.2 CPP | Specific types or doses of antiandrogens cannot currently be recommended with inadequate evidence in PCOS. | |
-

Justification

There was insufficient evidence to make an evidence-based recommendation. The group recognised plausible reasons for anticipating differences in the relative effectiveness of anti-androgens for different PCOS phenotypes, ages and anthropometric characteristics. It was also acknowledged that the various anti androgens have different efficacy and side effects. However, evidence to inform use of these agents alone was poor for all identified agents. There is no evidence on the direct and indirect costs of using anti-androgens, however the cost of available treatment is relatively high. Approval status and cost of these agents also varies across countries, with challenges in access and availability and contraception is considered mandatory in reproductive age women. For these reasons, most anti-androgen use in PCOS is in combination with COCPs (see [Section 4.3](#)), however use could be considered with other forms of contraception.

4.7 Inositol

Is inositol alone or in combination with other therapies, effective for management of hormonal and clinical PCOS features and weight in adolescents and adults with PCOS?

Clinical need for the question

Women with PCOS are commonly treated with insulin sensitising agents due to insulin resistance and hyperinsulinemia, common features of the syndrome both in obese and non-obese women. Mild gastrointestinal side effects related to metformin, and more serious adverse effects related to glitazones, other medical options are needed in treating insulin resistance in women with PCOS. Inositol (myo-inositol and di-chiro inositol) is a nutritional supplement that acts as a second messenger and has been shown to play a role in insulin signaling transduction [460]. Previous studies have focused on insulin resistance and hormonal profiles and gestational diabetes in women with PCOS.

Summary of systematic review evidence

A Cochrane systematic review [461] was identified to address this question and compared inositol with placebo. No further, more current evidence was identified. Findings from meta-analysis demonstrated that whilst serum SHBG (nmol/L) favoured inositol, there were no statistically significant differences between inositol and placebo for BMI, waist-hip ratio, ovulation (no. that ovulated), serum testosterone (nmol/L), triglyceride (mmol/L), cholesterol (mmol/L), fasting glucose (mmol/L) or fasting insulin (uIU/L).

Summary of narrative review evidence

In a more recent systematic review published after the evidence synthesis for this guideline, yet completed before the GDG meeting, ovulation rate and menstrual cycles appear to improve with inositol in women with PCOS [460, 462]. Furthermore, some data also suggests inositol may be effective in decreasing risk for GDM [463]. The literature however is limited, many key questions remain [460] and research is prioritised. Many of the included studies focused on combinations of therapy such as inositol and folate and adequate studies of inositol alone were not available.

Recommendations

-
- 4.7.1 EBR Inositol (in any form) should currently be considered an experimental therapy in PCOS, with emerging evidence on efficacy highlighting the need for further research.    
-
- 4.7.2 CPP Women taking inositol and other complementary therapies are encouraged to advise their health professional.
-

Justification

Whilst the evidence at this time on the benefit of inositol (in all forms) was inadequate to make an evidence-based recommendation, there is some emerging data suggesting metabolic, hormonal and ovulatory benefits. As this agent is freely available as a nutritional supplement, at low to moderate cost and appears to have a limited side effect profile, it may warrant consideration for use despite limited and low quality evidence. As with other supplements or complementary therapies, women taking this agent are encouraged to advise their health care team.

Chapter Five

Assessment and treatment of infertility

The evidence synthesis team, guideline lead and guideline development group (GDG) members were involved in the original Australian evidenced-based guideline in PCOS, and in 2014 the World Health Organisation (WHO) commissioned evidence synthesis update and development of guidelines for the management of anovulatory infertility in women with PCOS [464].

Here we expand the prioritised questions aligned with international consultation, extend the GDG, update and expand evidence synthesis, and complete a full Grading of Recommendations, Assessment, Development, and Evaluation (GRADE) framework evaluation. The WHO guidance document is referenced below where relevant, and a summary of subsequent and expanded evidence is provided.

5.1a Assessment of factors that may affect fertility, treatment response or pregnancy outcomes

Should women with PCOS undergo pre-conception (pre-pregnancy) evaluation (assessment) for (and where possible correction of) risk factors that may adversely affect fertility and response to infertility therapy?

Should women with PCOS, and with or without infertility, undergo pre-conception (pre-pregnancy) evaluation (assessment) for (and where possible correction of) risk factors that may lead to adverse (early or late) pregnancy outcomes?

Should women with PCOS undergo close (early or late) pregnancy monitoring for adverse pregnancy outcomes?

Clinical need for the questions

Ovulatory disturbance is a key diagnostic feature of PCOS, leading to infertility, and women with PCOS also have adverse pregnancy outcomes. Modifiable lifestyle factors, especially excess weight, exacerbate infertility, response to infertility treatment and pregnancy health and prevention of weight gain and where needed lifestyle intervention for weight loss is recommended ([Chapter 3](#)). The prevalence of miscarriage appears increased in PCOS with more research needed. Whilst there is clear recognition of the need to optimise preconception and pregnancy health in the general population, there is currently no evidence-based guideline in these areas in high-risk women with PCOS.

Summary of narrative evidence

A systematic review was not conducted to answer this question, which was reviewed narratively based on clinical expertise.

Modifiable risk factors known to impact fertility and response to Assisted Reproductive Technology (ART): BMI < 18 or > 25kg/m², waist to hip ratio (WHR – central adiposity), smoking status, alcohol consumption, prescribed and recreational drug use, untreated sexually transmitted infections, nutritional status, supplementation with folate, vitamin D and dental health have been identified as modifiable risk factors preconception (2, 3, 5, 13, 26). Anxiety, depression and psychological symptoms can impact relationship health, sexual intimacy and ART treatment adherence (19), whilst mental health care supports treatment adherence, relationship health and quality of life (QoL). These factors should be optimised, aligned with WHO guidance, and priority areas and recommendations for the general population [465].

Pregnancy and fertility complications: Women with PCOS are at an increased risk of gestational diabetes (GDM), preterm birth, pre-eclampsia, miscarriage, still birth, longer time to conception and poor embryo development, reduced embryo implantation rates, ovarian hyper stimulation syndrome (OHSS) (1) and ectopic pregnancy (18), which are also exacerbated by obesity.

Weight loss: Lifestyle management is recommended for weight loss when the BMI is $>25\text{kg}/\text{m}^2$ (see Chapter 3). A 2014 systematic review on weight loss prior to ART, noted improved natural conception, number of embryos for transfer, ART pregnancies, live birth rate, cancelled cycles, miscarriage rates and number of ART cycles required to achieve a pregnancy (20). A 2017 systematic review and meta-analysis, (14) found that lifestyle interventions benefited weight loss and natural pregnancy rate, with limited evidence for live birth rate or birth weight, yet natural birth rate did increase (16, 27). Lifestyle intervention also results in significant broader health benefits in pregnancy and beyond. Intensive weight loss is usually avoided just prior to conception with associated adverse outcomes including cycle cancellation and decrease in fertilisation, implantation, ongoing pregnancy and live birth (17). Bariatric surgery is generally considered second-line to improve fertility outcomes in PCOS with anovulation and significant obesity ($\text{BMI} \geq 35\text{kg}/\text{m}^2$) resistant to intensive lifestyle modification and/or pharmacotherapy (17).

Prospective randomised studies of preconception interventions that evaluate broad screening and lifestyle intervention are lacking in the general population and in PCOS [466], especially when considering pregnancy outcomes. However, aligned with lifestyle recommendations in PCOS outlined in Chapter 3, healthy lifestyle and lifestyle intervention should be considered in all women with PCOS, especially preconception and those with infertility based on risk, potential benefit and unlikely risk of adverse effects, whilst highlighting the critical need for more research.

Antenatal care: Close monitoring of weight and screening for hyperglycaemia early in pregnancy are recommended, especially in high-risk populations given the associated morbidity in pregnancy [467, 468]. In antenatal care, there was no evidence to guide screening for GDM or hypertension specifically in women with PCOS, although evidence shows an increased risk in PCOS and screening approaches in the general population involve identification of women at high risk.

Recommendations

- 5.1.1 CPP Factors such as blood glucose, weight, blood pressure, smoking, alcohol, diet, exercise, sleep and mental, emotional and sexual health need to be optimised in women with PCOS, to improve reproductive and obstetric outcomes, aligned with recommendations in the general population.
Refer to [Lifestyle](#), [Emotional Wellbeing](#) and [Diabetes](#) risk sections
- 5.1.2 CPP Monitoring during pregnancy is important in women with PCOS, given increased risk of adverse maternal and offspring outcomes.

Justification

General population recommendations highlight the vital role of healthy lifestyle, weight loss where women are overweight, smoking cessation, omitting alcohol, exercise and management of mental health issues to optimise reproductive outcomes, especially in high-risk groups, which includes in PCOS. Recommendations here are expected to improve efficacy and potentially reduce ART costs. Women with infertility and their health professionals are attuned to the need for healthy lifestyle and prevention strategies and are likely to accept these recommendations and consider them feasible. In antenatal care, recommendations for screening and monitoring in PCOS can only be informed by increased risks in pregnancy in PCOS with a lack of PCOS specific intervention studies. Additional resources may be required in implementation.

5.1b Tubal patency testing

Should women with PCOS and infertility due to anovulation alone with normal semen analysis, have tubal patency testing prior to starting ovulation induction with timed intercourse or IUI treatment or delayed tubal patency testing?

Clinical need for the question

One of the leading causes of female infertility is tubal pathology, potentially affecting around 30% of infertile women [469]. The diagnostic assessment of infertility often includes tubal testing by hysterosalpingography or laparoscopy as outlined in the WHO evidence report on infertility management in PCOS. PCOS is the most frequent cause of anovulation in infertile women and ovulation induction is the most common treatment, however there is little information about the prevalence of tubal pathology or the need for intrauterine insemination with normal semen analysis in infertile women with PCOS.

Summary of narrative evidence

A systematic review was not conducted to answer this question and this was reviewed narratively based on clinical expertise. There is no evidence to support that hydrosalpinges or other fallopian tube disorders are more frequent in PCOS women [470]. Yet the assessment of tubal patency is considered in infertility workup, as outlined in the WHO evidence report on infertility treatment in PCOS. Whilst adverse effects from this intervention are not common, false positives have been described and tubal patency testing may be more appropriate when targeted to those at increased risk of tubal infertility [471]. In this context, consideration of risks for tubal pathology are clinically appropriate, including:

- a. Previous abdominal or pelvic sepsis,
- b. Previous pelvic and/or abdominal surgery
- c. Cases of recurrent acute pelvic pain [472],
- d. History of sexual transmitted diseases or pelvic inflammatory disease or
- e. Endometriosis

Recommendations

5.1.3 CCR In women with PCOS and infertility due to anovulation alone with normal semen analysis, the risks, benefits, costs and timing of tubal patency testing should be discussed on an individual basis.

5.1.4 CCR Tubal patency testing should be considered prior to ovulation induction in women with PCOS where there is suspected tubal infertility.

Justification

If the patient has a clinical history of factors associated with tubal infertility it was deemed that hysterosalpingography could be considered, consistent with routine assessment of infertility. Hysterosalpingography requires dilation of the cervix that generally produces some discomfort, false positives are described and other related complications are uncommon. A lack of evidence to guide practice was noted in PCOS when considering these recommendations, however general population approaches were judged as applicable in this population, where other risk factors are present.

5.2 Ovulation induction principles

In reviewing the literature on pharmacological treatment for ovulation induction, general principles emerged that apply across all recommendations. These have been extracted into a set of clinical practice points to inform women and guide health professionals when considering or recommending pharmacological therapy for ovulation induction in PCOS. These practice points apply to all pharmacological treatments prioritised and addressed in the guidelines. In addition, duration of ovulation induction was considered under general principles.

5.2.1 CPP The use of ovulation induction agents, including letrozole, metformin and clomiphene citrate is off label in many countries. Where off label use of ovulation induction agents is allowed, health professionals need to inform women and discuss the evidence, possible concerns and side effects.

5.2.2 CPP Pregnancy needs to be excluded prior to ovulation induction.

5.2.3 CPP Unsuccessful, prolonged use of ovulation induction agents needs to be avoided, due to poor success rates.

5.3 Letrozole

In women with PCOS, are aromatase inhibitors effective for improving fertility outcomes?

Clinical need for the question

Aromatase inhibitors (AI) are effective as ovulation-inducing agents, including letrozole and anastrozole, with letrozole being the most widely used [473, 474]. These agents prevent the aromatase-induced conversion of androgens to oestrogens, including in the ovary. Yet their mechanisms of ovulation induction are unknown, however they increase secretion of follicle-stimulating hormone (FSH) stimulating ovarian follicle development and maturation [475]. The efficacy, adverse effects and overall role of letrozole in oral ovulation induction have remained controversial.

Summary of systematic review evidence

*Al*s versus placebo

One small RCT [476] with a low risk of bias compared letrozole to placebo in women with clomiphene citrate (CC) resistant PCOS and found that letrozole was better than placebo for ovulation rate per patient (Letrozole: 6 patients/18 patients (33.33%), Placebo: 0 patients/18 patients (0%), $p=0.006$) but there was no difference between letrozole and placebo for pregnancy rate per patient or live birth rate per patient. It is important to note that the findings from this study are of low certainty due to serious risk of imprecision. This study was included in a meta-analysis by Franik 2014 [477] and Misso 2012 [478], however since there is only one study, the meta-analyses do not provide additional evidence.

*Al*s versus CC

Thirteen RCTs compared letrozole with CC. Seven of these RCTs had a high risk of bias [479-485], two had a moderate risk of bias [486, 487] and four had a low risk of bias [488-491]. Upon meta-analysis, we found that letrozole was better than CC for ovulation rate per patient; pregnancy rate per patient; and live birth rate per patient. There was no difference between letrozole and CC for multiple pregnancy rate per patient; and miscarriage rate per patient. When subgroup analysis was conducted for studies that included women with PCOS who were therapy naïve, there was no difference between the two interventions for any outcome though we note that for pregnancy rate per patient the OR 1.68 [95% CI 0.96, 2.94] had an I^2 of 0% and a p value of 0.07.

Al versus CC + metformin

One RCT with moderate risk of bias found that there is no statistical difference between letrozole and CC plus metformin for ovulation rate per cycle, pregnancy rate per cycle, miscarriage rate per pregnancy and multiple pregnancy rate per pregnancy in CC-resistant women with PCOS [492]. This study was included in a meta-analysis by Franik 2014 [477] and Misso 2012 [478], however since there is only one study, the meta-analysis does not provide additional evidence.

Al versus laparoscopic ovarian surgery

Three RCTs with low risk of bias [493-495] compared letrozole to laparoscopic ovarian surgery (LOS) and found that there was insufficient evidence of a difference between letrozole and LOS. One of the RCTs in 147 women with CC resistance found that letrozole was better than LOS for ovulation rate per cycle [493], however the evidence is of low certainty. The systematic review by Farquhar 2012 [496] combined these studies in meta-analysis for pregnancy rate per patient, multiple pregnancy rate per pregnancy and miscarriage rate per pregnancy and there was no statistical difference between the two interventions.

Summary of narrative review evidence

Aromatase catalyses the conversion of androgens to oestrogens, including in the ovary and increase FSH secretion [475], stimulating ovarian follicle development and maturation. AIs prevent this conversion. These agents were originally used to improve pregnancy rates and limit adverse effects [497, 498], especially with clomiphene resistance and failure [498-501]. Letrozole has side effects include gastrointestinal disturbances, hot flushes, headache and back pain [502, 503] and concerns have been raised on potential teratogenic effects [504] in an abstract, as yet unconfirmed in peer-reviewed publications, yet this has sparked a series of warnings to avoid use of AI in infertility. Multiple subsequent case series [486, 505-508], multi-centre RCTs [503, 509] and a recent systematic review and meta-analysis [510], all failed to note an increased congenital anomaly rate with prevalence of anomalies with letrozole or clomiphene under 5% (the expected anomaly rate in this population is 5-8% [511]).

Recommendations

-
- 5.3.1 EBR Letrozole should be considered first line pharmacological treatment for ovulation induction in women with PCOS with anovulatory infertility and no other infertility factors to improve ovulation, pregnancy and live birth rates. 
- 5.3.2 CPP Where letrozole is not available or use is not permitted or cost is prohibitive, health professionals can use other ovulation induction agents. 
- 5.3.3 CPP Health professionals and women need to be aware that the risk of multiple pregnancy appears to be less with letrozole, compared to clomiphene citrate.
-

Justification

Women with PCOS are significantly more likely both to ovulate and to have a live birth after use of letrozole compared to clomiphene, the previous first line agent. The likelihood of live birth is increased 40-60% with letrozole compared to clomiphene. Similarly, failure to ovulate (letrozole resistance) is lower with letrozole versus clomiphene. Multiple pregnancy rates appear lower than clomiphene. Hot flushes, generally the least desired side effect of any anti-oestrogen, is less common with letrozole than clomiphene, but still present. Fatigue and dizziness are more common. The balance of benefits in terms of improved live births with letrozole and less hot flushes was considered to currently outweigh the adverse effects of relatively increased fatigue and dizziness, multiple pregnancy, and unconfirmed concerns about higher congenital anomalies.

5.4 Clomiphene citrate and/or metformin

In women with PCOS, is clomiphene citrate effective for improving fertility outcomes?

In women with PCOS, is metformin effective for improving fertility outcomes?

In women with PCOS and a BMI > 30-32, what is the effectiveness of metformin compared to clomiphene citrate for improving fertility outcomes?

Clinical need for the questions

Clomiphene citrate (CC) is a selective oestrogen receptor modulator with both oestrogenic and anti-oestrogenic properties [512]. It was first approved for use in women with anovulation in 1967 [513] and acts as an anti-oestrogen [475]. CC resistance and failure is well documented [514] and a discrepancy is noted between good ovulation rates and lower pregnancy rates, due to the anti-oestrogenic effects of CC on the endometrium and cervical mucus. Twin pregnancy and triplets with CC are 5–7% and 0.3%, respectively and OHSS is less than 1% [515]. The potential for borderline increased risk of ovarian tumours with 12 cycles or more has been noted [516].

Insulin resistance is common in PCOS [517, 518], driving ovarian androgen biosynthesis and increased bioavailability of free androgens. Excess local ovarian androgen production augmented by hyperinsulinaemia causes premature follicular atresia and anovulation [519]. This has led to insulin-sensitising drugs use in ovulation induction. Metformin has been most widely studied in PCOS and has the most reassuring safety profile [520]. Efficacy has been controversial and therapeutic regimens are not well standardised in clinical practice, with variable doses in use [319].

Summary of systematic review evidence

Metformin versus placebo

One systematic review [521] with up to fourteen studies; and one RCT [522] were identified to address this comparison. Metformin was better than placebo for live birth rate per participant, pregnancy rate per participant and ovulation rate per participant. Pregnancy rate and ovulation rate remained statistically significantly better than placebo when subgrouped by BMI ($BMI < 30\text{kg}/\text{m}^2$ and $BMI > 30$ or $32\text{kg}/\text{m}^2$ subgroups); however live birth rate lost statistical significance when subgrouped by BMI. There was no statistically significant difference between metformin and placebo for miscarriage rate per pregnancy (including when subgrouped). Gastrointestinal upsets were statistically significantly lower with placebo than metformin (including when subgrouped). Multiple pregnancy and OHSS were not reported in the systematic review. It is important to note that the findings for live birth rate and miscarriage rate are of low certainty due to serious risk of bias and serious risk of imprecision in the body of evidence; and findings for pregnancy rate, ovulation rate and adverse events are of moderate certainty due to serious risk of bias. Risk of bias appraisals and GRADE assessments have been adopted from previous versions of this guideline [464].

In an RCT of 149 participants, with moderate certainty, there were no statistically significant differences between metformin and placebo for pregnancy rate per participant, multiple pregnancy rate per pregnancy or miscarriage rate per pregnancy. The majority of the trials stopped metformin at diagnosis of pregnancy or at week 12. Note: insufficient evidence of a differential effect of metformin on BMI.

Clomiphene citrate v placebo

One high quality systematic review with low risk of bias found that CC was better than placebo for pregnancy rate per participant and ovulation rate per participant, however the evidence was of very low certainty due to very serious risk of bias and imprecision.

Metformin versus clomiphene citrate

One systematic review [521] with up to seven studies was identified to address this comparison. There were no statistically significant differences between metformin and clomiphene for live birth rate per pregnancy, multiple pregnancy per pregnancy, miscarriage rate per pregnancy, pregnancy rate or ovulation rate. When subgrouped by BMI, CC was better than metformin for live birth rate, pregnancy rate and ovulation rate in $BMI > 30\text{kg}/\text{m}^2$; and metformin was better than CC for pregnancy rate in $BMI < 30\text{kg}/\text{m}^2$. Adverse events and OHSS were not reported in the systematic review. It is important to note that the findings for live birth rate, multiple pregnancy rate and pregnancy rate are of very low certainty due to very serious risk of bias, serious risk of imprecision and for live birth rate, also serious risk of inconsistency; findings for miscarriage rate and ovulation rate are of low certainty due to serious risk of bias and serious risk of imprecision in the body of evidence.

Metformin versus metformin + clomiphene citrate

One high quality systematic review with low risk of bias evaluating two RCTs with a mean $BMI \geq 30\text{ kg}/\text{m}^2$ [523] and two RCTs (one medium quality RCT with moderate risk of bias [524] and one low quality RCT with high risk of bias [525] were identified by the search. Metformin plus CC was better than metformin alone for ovulation rate, pregnancy rate and live birth rate. There was no statistically significant difference between metformin plus CC and metformin alone for miscarriage rate or adverse events.

Clomiphene citrate versus metformin + clomiphene citrate

One systematic review [521] with up to twenty-one studies; and one RCT [526] were identified to address this comparison. Metformin plus CC was statistically significantly better than CC alone for pregnancy rate per participant and ovulation rate per participant, including when subgrouped by BMI ($BMI < 30\text{kg}/\text{m}^2$ and $BMI > 30$ subgroups). Adverse events were statistically significantly better with CC alone than with metformin plus CC. There was no statistically significant difference between metformin plus CC and CC alone for live birth rate per pregnancy, multiple pregnancy rate per pregnancy or miscarriage rate per pregnancy. OHSS was not reported in the systematic review. It is important to note that the findings for live birth rate, multiple pregnancy and miscarriage rate are of low certainty due to serious risk of bias and serious risk of imprecision in the body of evidence; and findings for pregnancy rate, ovulation rate and adverse events are of moderate certainty due to serious risk of bias. The additional RCT Maged 2015 [526] was insufficient evidence to supplement the findings of Morley 2017 [521].

Clomiphene citrate versus aromatase inhibitors (letrozole)

Thirteen RCTs (level II) compared letrozole with CC. Seven of these RCTs had a high risk of bias [479-485], two had a moderate risk of bias [486, 487] and four had a low risk of bias [488-491]. Upon meta-analysis, we found that letrozole was better than CC for ovulation rate per patient [479, 480, 482, 484, 486, 487, 490, 491]; pregnancy rate per patient [479-491]; and per cycle [482, 483, 491]; and live birth rate per patient [480, 486, 488, 490, 491]. There was no difference between letrozole and CC for ovulation rate per cycle [482, 483, 488, 489, 491]; multiple pregnancy rate per patient [479, 481, 482, 485, 486, 489-491]; and miscarriage rate per patient [480-482, 486-491]. When subgroup analysis was conducted for studies that included women with PCOS who were therapy naïve, there was no difference between the two interventions for any outcome though we note that for pregnancy rate per patient the OR 1.68 [95% CI 0.96, 2.94] had an I² of 0% and a p value of 0.07.

Clomiphene citrate versus gonadotrophin

Two RCTs were identified by the search to address this comparison. One RCT was low quality with high risk of bias [527] compared recombinant FSH with CC in women with PCOS who were therapy naïve and found that there was no difference between the two interventions for all fertility outcomes. The second was a multi-centre RCT with moderate risk of bias [528] comparing CC with low dose gonadotrophins, as the first line therapy for ovulation induction in anovulatory women with PCOS who were therapy naïve. They reported with per protocol analysis that the clinical pregnancy rate was significantly higher in the gonadotrophin treated group. Furthermore, the chance of pregnancy

was almost double in the first treatment cycle when compared to CC. Brown 2016 [529] meta-analysed these same two RCTs combining data for live birth rate and ongoing pregnancy rate and found that gonadotrophins were better than CC (OR 0.64 [0.41, 0.98] p=0.041, I²=0%). Meta-analysis of the two studies for clinical pregnancy rate found that CC was better than gonadotrophins (OR 0.61 [0.40, 0.93] p=0.021, I²=0%). It is important to be cautious of these results (using per protocol event rates), as the number of participants randomised has been used as the denominator when the denominator should have been the number of participants per protocol.

Clomiphene citrate versus clomiphene citrate + gonadotrophin)

Two RCTs were identified to address this comparison, however there was insufficient evidence to determine whether one intervention was better than the other [530, 531].

Recommendations

5.4.1	EBR	Clomiphene citrate could be used alone in women with PCOS with anovulatory infertility and no other infertility factors to improve ovulation and pregnancy rates.	❖❖❖ ⊕○○○
5.4.2	EBR	Metformin could be used alone in women with PCOS, with anovulatory infertility and no other infertility factors, to improve ovulation, pregnancy and live birth rates, although women should be informed that there are more effective ovulation induction agents.	❖❖❖ ⊕⊕⊕○
5.4.3	EBR	Clomiphene citrate could be used in preference, when considering clomiphene citrate or metformin for ovulation induction in women with PCOS who are obese (BMI is $\geq 30 \text{ kg/m}^2$) with anovulatory infertility and no other infertility factors.	❖❖❖ ⊕⊕○○
5.4.4	EBR	If metformin is being used for ovulation induction in women with PCOS who are obese ($\text{BMI} \geq 30\text{kg/m}^2$) with anovulatory infertility and no other infertility factors, clomiphene citrate could be added to improve ovulation, pregnancy and live birth rates.	❖❖❖ ⊕⊕○○
5.4.5	EBR	Clomiphene citrate could be combined with metformin, rather than persisting with clomiphene citrate alone, in women with PCOS who are clomiphene citrate-resistant, with anovulatory infertility and no other infertility factors, to improve ovulation and pregnancy rates.	❖❖❖ ⊕⊕○○
5.4.6	CPP	The risk of multiple pregnancy is increased with clomiphene citrate use and therefore monitoring needs to be considered.	

Justification

CC therapy requires specialist care. Costs to the patient of monitoring (tests and specialist visits) and accessibility to specialist care may present barriers, however increased costs will be offset by reduced multiple pregnancies. Metformin is low cost, accessible and can be used alone and/or in combination with CC, given efficacy on systematic review. Usual doses of metformin range from 1500mg (most commonly) to 1700mg per day for non-fertility studies. A change in usual care may result as clinicians may now be more likely to prescribe metformin. Metformin may be associated with mild gastrointestinal related adverse events (see [Chapter 4](#)). Whilst use is evidence-based, patient explanation and consent is appropriate as metformin therapy for infertility is off label.

5.5 Gonadotrophins

In women with PCOS, are gonadotrophins effective for improving fertility outcomes?

Clinical need for the question

Gonadotropin therapy is used clinically in anovulatory PCOS who have been treated with other first line ovulation induction agents if they have failed to ovulate or if responses reduce chances of conception (e.g., persistent hypersecretion of luteinizing hormone (LH), or an anti-estrogenic endometrial effects). To prevent overstimulation and multiple pregnancy, the traditional standard step-up regimens [532] were replaced by either low-dose step-up regimens [533, 534] or step-down regimens [535] with gonadotropins used alone and different gonadotropin preparations appearing to work equally well [536]. It can be difficult to predict stimulation responses in PCOS and to achieve a single dominant follicle to reduce multiple pregnancy and OHSS and careful monitoring of follicular development by ultrasound is required with triggers only used with two or less follicles over 14mm. The efficacy, safety and role of gonadotrophins compared to other alternatives including single or combined oral ovulation induction agents or laparoscopic surgery remains unclear.

Summary of systematic review evidence

Gonadotrophin versus clomiphene citrate

Two RCTs were identified by the search to address this comparison. One RCT was low quality with high risk of bias [527] compared recombinant FSH with CC in women with PCOS who were therapy naïve and found that there was no difference between the two interventions for all fertility outcomes. The second was a multi-centre RCT with moderate risk of bias [528] comparing CC with low dose gonadotrophins, as the first line therapy for ovulation induction in anovulatory women with PCOS who were therapy naïve. They reported with per protocol analysis that the clinical pregnancy rate was significantly higher in the gonadotrophin treated group. Furthermore the chance of pregnancy was almost double in the first treatment cycle when compared to CC. Brown [529] meta-analysed these same two RCTs combining data for live birth rate and ongoing pregnancy rate and found that gonadotrophins were better than CC (OR 0.64 [0.41, 0.98] p=0.041, I²=0%). Meta-analysis of the two studies for clinical pregnancy rate found that CC was better than gonadotrophins (OR 0.61 [0.40, 0.93] p=0.021, I²=0%). It is important to be cautious of these results (using per protocol event rates), as the number of participants randomised has been used as the denominator when the denominator should have been the number of participants per protocol.

Gonadotrophins versus clomiphene citrate + metformin

Two RCTs compared FSH with CC plus metformin [537, 538]. The RCTs found that FSH was better than CC plus metformin for ovulation rate per participant and pregnancy rate per participant. There was no statistical difference between the two interventions for live birth rate per participant, multiple pregnancy rate per pregnancy, OHSS, miscarriage rate per pregnancy or gastrointestinal (GI) side effects or adverse events. A systematic review by Abu Hashim [539] conducted meta-analysis including studies that do not meet our PICO (patient, intervention, comparison, outcome), however some sensitivity analysis was conducted with the two RCTs listed below. A sensitivity analysis for ovulation rate in 263 patients demonstrated that gonadotrophins are better for ovulation rate (OR 0.13; 95% CI 0.07–0.25; p < 0.00001, I² = 7%); but there was no statistically significant difference between the two interventions for multiple pregnancy rate (n = 263, OR 0.33; 95% CI 0.06–1.68; p = 0.18, heterogeneity not reported).

Gonadotrophins versus gonadotrophins + metformin

One RCT with moderate risk of bias found that FSH plus metformin was better than FSH alone for live birth rate per participant, ovulation rate per participant and pregnancy rate per participant [538]. There was no statistical difference between the two interventions for multiple pregnancy rate per pregnancy, miscarriage rate per pregnancy or adverse events.

Gonadotrophins versus laparoscopic ovarian surgery

One high quality systematic review of RCTs (level I) with low risk of bias compared LOS to gonadotrophins and found that there was no difference between the interventions for live birth rate per patient and pregnancy rate per patient, ovulation rate per patient and miscarriage rate per pregnancy, but LOS was better than gonadotrophins for multiple pregnancy rate (OR 0.13 [0.03 to 0.59] I² = 0%, 4 studies, 303 participants) [496].

Gonadotrophins versus gonadotrophins + clomiphene citrate

One RCT [540] with moderate risk of bias found that FSH plus CC was better than FSH alone for ovulation rate per woman randomised and per protocol, total FSH dose used per woman randomised and per protocol, and duration of stimulation per woman randomised and per protocol. There was no statistical difference between the two interventions for pregnancy rate and live birth rate per woman randomised and per protocol.

Recommendations

5.5.1	EBR	Gonadotrophins could be used as second line pharmacological agents in women with PCOS who have failed first line oral ovulation induction therapy and are anovulatory and infertile, with no other infertility factors.	❖❖❖ ⊕⊕○○
5.5.2	EBR	Gonadotrophins could be considered as first line treatment, in the presence of ultrasound monitoring, following counselling on cost and potential risk of multiple pregnancy, in women with PCOS with anovulatory infertility and no other infertility factors.	❖❖❖ ⊕⊕○○
5.5.3	EBR	Gonadotrophins, where available and affordable, should be used in preference to clomiphene citrate combined with metformin therapy for ovulation induction, in women with PCOS with anovulatory infertility, clomiphene citrate-resistance and no other infertility factors, to improve ovulation, pregnancy and live birth rates.	❖❖❖❖ ⊕⊕⊕○
5.5.4	EBR	Gonadotrophins with the addition of metformin, could be used rather than gonadotrophin alone, in women with PCOS with anovulatory infertility, clomiphene citrate-resistance and no other infertility factors, to improve ovulation, pregnancy and live birth rates.	❖❖❖ ⊕⊕⊕○
5.5.5	EBR	Either gonadotrophins or laparoscopic ovarian surgery could be used in women with PCOS with anovulatory infertility, clomiphene citrate-resistance and no other infertility factors, following counselling on benefits and risks of each therapy.	❖❖❖❖ ⊕⊕⊕○
5.5.6	CPP	Where gonadotrophins are prescribed, considerations include:	
		<ul style="list-style-type: none">● cost and availability● expertise required for use in ovulation induction● degree of intensive ultrasound monitoring required● lack of difference in clinical efficacy of available gonadotrophin preparations● low dose gonadotrophin protocols optimise monofollicular development● risk and implications of potential multiple pregnancy	
5.5.7	CPP	Gonadotrophin induced ovulation is only triggered when there are fewer than three mature follicles and needs to be cancelled if there are more than two mature follicles with the patient advised to avoid unprotected intercourse.	

Justification

Gonadotrophin therapy is suitable for improving infertility in women with PCOS in specialist care, with close monitoring. Gonadotrophin therapy provides better per cycle and cumulative pregnancy and live birth rates compared with the use of oral anti-oestrogens and/or no therapy in anovulatory women with PCOS; and there is no evidence of teratogenicity. It is important to note that gonadotrophin therapy requires daily injections and the need for intensive monitoring with ultrasound; with a risk of multiple pregnancy and increased cost of medication compared with oral agents.

5.6 Anti-obesity agents

In women with PCOS, are anti-obesity pharmacological agents effective for improving fertility outcomes?

Clinical need for the question

A 2017 systematic review and meta-analysis [541], found that lifestyle interventions benefited weight loss and natural pregnancy rate, with limited evidence for live birth rate or birth weight, yet natural birth rate did increase [294, 301]. Hence, the impact of non-pharmacological lifestyle interventions on live birth rates remains controversial. Engagement and adherence in lifestyle interventions are challenging. There is a need to assess other weight loss methods, such as pharmacological agents commenced in the preconception period, with some evidence they can induce weight loss and improve fertility outcomes in PCOS.

Summary of systematic review evidence

We did not identify any evidence in women with PCOS to answer the question and therefore the literature has been reviewed narratively.

Summary of narrative evidence

A randomised trial (that did not meet the inclusion criteria for this systematic review due to a change in interventions and combination of treatments) evaluated pre-conception treatment in women with PCOS with a) lifestyle weight loss intervention incorporating caloric restriction, increased physical activity and pharmacological agent (initially sibutramine, and then orlistat), b) oral contraceptive pill c) combined lifestyle and contraceptive pill on fertility outcomes [542]. The trial randomised 149 women and was prematurely stopped due to supposed futility with a low likelihood of showing a clinically meaningful difference. Given the small sample size in a three-arm trial, with no control group, no meaningful conclusions can be inferred. Within the lifestyle arm, including anti-obesity agents, there was a significant reduction in weight from baseline (-6.2Kg, 95% CI -07.1 to -5.3), and compared to the women on COCP pre-conception, those on lifestyle with anti-obesity agents showed no differences in pregnancy outcomes. Evidence for these agents in other relevant population groups is lacking.

Recommendations

-
- 5.6.1 CCR Pharmacological anti-obesity agents should be considered an experimental therapy in women with PCOS for the purpose of improving fertility, with risk to benefit ratios currently too uncertain to advocate this as fertility therapy.
-

Justification

With inadequate evidence in both PCOS and infertility generally, the risk/benefit ratio is currently too uncertain to advocate this as a fertility treatment and it was deemed that it should remain an experimental treatment for this indication.

5.7 Laparoscopic ovarian surgery

In women with PCOS, is ovarian surgery effective for improving fertility outcomes?

Clinical need for the question

Observations that women with PCOS resumed regular ovulation following ovarian biopsies, led to development of surgical wedge resection via laparotomy [543]. Observational data looked promising, but surgery was surpassed by ovulation induction agents, until less invasive laparoscopic surgery [544], with potential for less adhesions and lower cost. Minor methodological variations are reported (electrocautery, laser vaporization, multiple ovarian biopsies and others), all seemingly with effects on the endocrine profile. OHSS and multiple pregnancy risks are lower than with other options, but other risks potentially are higher, and clarification of the role of LOS, particularly in comparison to other treatments, is needed in infertile women with PCOS.

Summary of systematic review evidence

Laparoscopic ovarian surgery versus metformin

Two medium quality RCTs (level II) (published across three papers) with a moderate risk of bias compared LOS to metformin and found that there was insufficient evidence to make a recommendation about LOS compared to metformin for live birth rate per patient, ovulation rate per cycle, pregnancy rate per cycle, pregnancy rate per patient, multiple pregnancies, miscarriage rate per pregnancy, adverse effects and QoL [545-547] largely because the evidence was conflicting. One RCT reported that LOS was better than metformin for ovulation (OR 2.05; [1.4–2.9] p=0.001) and pregnancy rate (per cycle: OR 2.19 [1.03–4.63] p=0.03; per patient: OR 2.47 [1.05–5.81] p=0.03) [545] and the other study reported that metformin was better than LOS for live birth rate (metformin: 82.1%, LOS: 64.5%, p<0.05), pregnancy rate per cycle (metformin: 18.6%, LOS: 13.4%, p<0.05), and miscarriage rate (metformin: 15.4%, LOS: 29.0%, p<0.05) [546, 547]. Both medium quality single centre studies had a small sample size and moderate risk of bias and therefore need to be interpreted with caution.

Laparoscopic ovarian surgery versus clomiphene citrate

Two high quality RCTs (level II) with a low risk of bias compared LOS to CC [548, 549] and found that there was no difference between LOS and CC for live birth rate per patient and pregnancy rate per patient, ovulation rate per patient and miscarriage rate per pregnancy [548, 549]. There was insufficient evidence to support or refute the use of LOS over CC for multiple pregnancies [548, 549].

Laparoscopic ovarian surgery versus clomiphene citrate + metformin

Three low to moderate quality RCTs with low to moderate risk of bias compared LOS to CC plus metformin (all three studies reported in Farquhar 2012 systematic review [496]). Meta-analyses found that CC plus metformin (CC+M) was better than LOS for live birth rate, but there was no difference for pregnancy rate per patient, multiple pregnancy rate, or miscarriage rate per pregnancy [496]. There was insufficient evidence to support or refute the use of LOS over CC plus metformin for ovulation rate per patient, and OHSS [496].

Laparoscopic ovarian surgery versus aromatase inhibitors

Three RCTs with low risk of bias [493-495] compared letrozole to LOS and found that there was insufficient evidence of a difference between letrozole and LOS. One of the RCTs in 147 women with CC resistance found that letrozole was better than LOS for ovulation rate per cycle [493], however the evidence is of low certainty. The systematic review by Farquhar 2012 [496] combined these studies in meta-analysis for pregnancy rate per patient, multiple pregnancy rate per pregnancy and miscarriage rate per pregnancy and there was no statistical difference between the two interventions.

Laparoscopic ovarian surgery versus aromatase inhibitors + metformin

One low quality RCT with moderate risk of bias compared LOS with letrozole plus metformin and found that there was insufficient evidence of a difference between the two interventions for ovulation, pregnancy and miscarriage rate per pregnancy [550].

Laparoscopic ovarian surgery versus gonadotrophins

One high quality systematic review of RCTs (level I) with low risk of bias compared LOS to FSHs and found that there was no difference between the interventions for live birth rate per patient and pregnancy rate per patient, ovulation rate per patient and miscarriage rate per pregnancy, but LOS was better than FSH for multiple pregnancy rate (OR 0.13 [0.03 to 0.59] $I^2 = 0\%$, 4 studies, 303 participants) [496].

Summary of narrative review evidence

Observational data was sourced to evaluate long-term impacts. A 15-25 year follow-up of nearly 150 women after ovarian wedge resection shows that regular menstrual patterns lasting up to 25 years after surgery were restored in 88% of patients with a cumulative pregnancy/live birth rate of 78% [551]. This was considered along with the RCT data.

Recommendations

5.7.1	EBR	Laparoscopic ovarian surgery could be second line therapy for women with PCOS, who are clomiphene citrate resistant, with anovulatory infertility and no other infertility factors.	❖❖❖ ⊕⊕○○
5.7.2	CCR	Laparoscopic ovarian surgery could potentially be offered as first line treatment if laparoscopy is indicated for another reason in women with PCOS with anovulatory infertility and no other infertility factors.	❖❖❖
5.7.3	CPP	Risks need to be explained to all women with PCOS considering laparoscopic ovarian surgery.	
5.7.4	CPP	Where laparoscopic ovarian surgery is to be recommended, the following need to be considered:	
		<ul style="list-style-type: none">● comparative cost● expertise required for use in ovulation induction● intra-operative and post-operative risks are higher in women who are overweight and obese● there may be a small associated risk of lower ovarian reserve or loss of ovarian function● periadnexal adhesion formation may be an associated risk.	

Justification

LOS is an intervention that can lead to a singleton birth in women with PCOS. There is no convincing evidence of inferiority over other common ovulation induction agents, there is no need for monitoring (because of mono-ovulation) and only a background risk of multiple pregnancy. However, it is important to note that LOS is an invasive surgical intervention; there is a small risk of reduced ovarian reserve or loss of ovarian function; and adhesion formation should be considered. Issues covered in the clinical practice points should be carefully considered.

5.8 Bariatric surgery

In women with PCOS, what is the effectiveness of lifestyle interventions compared to bariatric surgery for improving fertility and adverse outcomes?

Clinical need for the question

Obesity is increasing in prevalence throughout the world, as is morbid obesity ($\text{BMI} \geq 40 \text{ kg/m}^2$) [552]. Women with PCOS have higher rates of weight gain and of obesity, adversely affecting fertility. Weight loss improves outcomes as previously outlined. In severe obesity, lifestyle interventions have limited efficacy. Substantial efficacy of bariatric surgery on weight loss has been demonstrated in severely obese women. Potential benefits need to be balanced with the delay in infertility treatment and pregnancy for surgery and stabilisation of weight, the risks of bariatric surgery and the potential risks of pregnancy after bariatric surgery. Controversy persists around efficacy for fertility and pregnancy outcomes, optimal timing, adverse effects and comparative efficacy with other treatments, as well as on adverse effects on subsequent pregnancies.

Summary of systematic review evidence

We did not identify any evidence in women with PCOS to answer the question and therefore the literature has been reviewed narratively.

Summary of narrative review evidence

UK clinical guidelines for obesity management in the general population [553] recommend considering bariatric surgery with a $\text{BMI} \geq 35 \text{ kg/m}^2$ with one or more severe complications, expected to improve with weight loss and failure of structured lifestyle intervention [553]. Obesity surgery can be considered after non-surgical treatment has failed with a $\text{BMI} \geq 40 \text{ kg/m}^2$ and obesity surgery can be first line treatment with a $\text{BMI} \geq 50 \text{ kg/m}^2$ [554]. Other guidelines recommend lower barriers to surgery [555]. For type of surgery, Vertical Sleeve Gastrectomy (VSG) has overtaken the Roux-en-Y Gastric Bypass (RYGB) and gastric band surgery as the most commonly performed bariatric surgery with lower operative morbidity [556]. Adjustable gastric banding, once the choice for women planning pregnancy is now less common given complications and overall lower long-term weight loss [556].

High quality RCTs of bariatric surgery versus medical management in DM2 show persistent benefits and superiority of weight loss and bariatric surgery in curing or ameliorating diabetes [557, 558]. Yet these studies are absent in PCOS for fertility and pregnancy outcomes, with current PCOS studies poorly designed [559], and with failure to report key perinatal outcomes to inform risk to benefit ratio. In PCOS, the balance between delaying infertility treatment and pregnancy whilst undertaking bariatric surgery and attaining stable post-operative weight, is also unclear [560], as is the optimal type of bariatric surgery.

Bariatric surgery can cause malabsorption and psychological issues including disordered eating [254] and may adversely affect maternal and neonatal health. Adequate intake and absorption of iron, folate, iodine and other nutrients are of concern. While supplement use is widely recommended following bariatric surgery especially for pregnant women, there are reports of poor compliance [561] and challenges tolerating fortified foods such as bread. National registries (surgery, pregnancy, infants) show that obese women who undergo bariatric surgery and conceive compared to similarly obese controls, had more small for gestational age babies, shorter gestations, and a trend towards increased neonatal mortality [562], with similar findings in retrospective studies [563]. Benefits have included less GDM and large for gestational age babies.

Recommendations

5.8.1 CCR Bariatric surgery should be considered an experimental therapy in women with PCOS, for the purpose of having a healthy baby, with risk to benefit ratios currently too uncertain to advocate this as fertility therapy.

5.8.2 CPP If bariatric surgery is to be prescribed, the following needs to be considered:

- comparative cost
- the need for a structured weight management program involving diet, physical activity and interventions to improve psychological, musculoskeletal and cardiovascular health to continue post-operatively
- perinatal risks such as small for gestational age, premature delivery, possibly increased infant mortality
- potential benefits such as reduced incidence of large for gestational age fetus and gestational diabetes
- recommendations for pregnancy avoidance during periods of rapid weight loss and for at least 12 months after bariatric surgery with appropriate contraception.

If pregnancy occurs, the following need to be considered:

- awareness and preventative management of pre-and post-operative nutritional deficiencies is important, ideally in a specialist interdisciplinary care setting
- monitoring of fetal growth during pregnancy.

Justification

Bariatric surgery improves weight loss and can improve comorbidities associated with PCOS. However, evidence in relation to fertility and pregnancy outcomes is limited, with some concerns about potential perinatal adverse effects of bariatric surgery. Overall, the indications, role and comparative effectiveness with other fertility therapies, ideal timing, optimal type of surgery, adverse effects and risk to benefit ratio in PCOS are still to be resolved. Given the concerns about the potential perinatal adverse effects of bariatric surgery and the remaining controversies, no recommendation can be made at this time about the use of bariatric surgery to improve fertility and pregnancy outcomes in women with PCOS.

5.9a In-vitro fertilisation

In women with PCOS, is stimulated In-vitro fertilisation/Intracytoplasmic Sperm Injection effective for improving fertility outcomes?

Clinical need for the question

Ovulation induction therapies are first and second line in infertility management in women with PCOS, anovulation and no other fertility factors. Yet resistance to and failure of ovulation induction therapies and inability to overcome other concomitant causes of infertility means that Assisted Reproductive Technology (ART) therapies including In-vitro fertilisation (IVF) and intracytoplasmic sperm injection (ICSI) used in male factor infertility, have a role in PCOS. IVF has risks and limitations, yet also offers the opportunity for pregnancy and live birth. Challenges exist across the diversity of protocols available for IVF and concerns in PCOS including OHSS, high oestradiol levels, accelerated endometrial maturation and optimally the use of “freeze all” interventions. The clinical practice questions here include indications, timing and comparative efficacy with other treatments, yet RCTs in this area are very limited in women with anovulatory PCOS.

Summary of systematic review evidence

We did not identify any evidence in women with PCOS to answer the question and therefore the literature has been reviewed narratively.

Summary of narrative review evidence

There are no RCTs identified by the guideline development team, comparing stimulated IVF ± ICSI therapy with ovulation induction in women diagnosed with PCOS. The role of IVF in PCOS was explored by the WHO guidance group, and the review and recommendations were considered here by the GDG in making their recommendations [464]. Factors that influenced considerations here include access, cost and risks. The patient and societal benefits of ovulation induction compared with IVF treatments in anovulatory PCOS women require RCTs and systematic analysis. Outcomes as time to conception, cost of therapy, QoL, OHSS risk, multiple pregnancy, miscarriage and livebirth rates should be investigated.

Recommendations

-
- 5.9.1 CCR In the absence of an absolute indication for IVF ± ICSI, women with PCOS and anovulatory infertility could be offered IVF as third line therapy where first or second line ovulation induction therapies have failed. ❖❖❖
-
- 5.9.2 CPP In women with anovulatory PCOS, the use of IVF is effective and when elective single embryo transfer is used, multiple pregnancies can be minimised.
-
- 5.9.3 CPP Women with PCOS undergoing IVF ± ICSI therapy need to be counselled prior to starting treatment including on:
- availability, cost and convenience
 - increased risk of ovarian hyperstimulation syndrome
 - options to reduce the risk of ovarian hyperstimulation.
-

Justification

The GDG deemed IVF should be considered after failed ovulation induction treatment with high pregnancy rates per cycle, especially in younger women. Given the risks and the high costs that can be prohibitive for many patients, IVF should be considered third line medical therapy. It was noted that conception and delivery are highly valued by health professionals and women with PCOS and even when cost and risks are increased, many may elect to undertake IVF. Health Professionals must weigh benefits and risk when advising PCOS patients to enable an informed decision.

5.9b Gonadotropin releasing hormone protocol

In women with PCOS undergoing IVF/ICSI treatment, is the gonadotropin releasing hormone antagonist protocol or gonadotropin releasing hormone agonist long protocol the most effective for improving fertility outcomes?

Clinical need for the question

Women with PCOS are particularly vulnerable to OHSS with IVF ± ICSI treatment, prompting caution and leading to exploration of different protocols including with gonadotropin releasing hormone (GnRH) and other options including in-vitro maturation (see below) [564]. One of the proposed methods to reduce the risk of OHSS is to use a GnRH antagonist (as opposed to an agonist) [565-568]. There is acknowledged complexity in interpreting outcomes from IVF treatments in PCOS, with variable protocols and endpoint reporting, requiring close evaluation of the literature. One of the proposed methods to reduce the risk of OHSS is to use a GnRH antagonist (as opposed to an agonist) to suppress pituitary luteinising hormone (LH) secretion.

Summary of systematic review evidence

In the eight included studies of low [569-571], moderate [572-575], and high risk of bias [576] comparing an antagonist protocol with a long agonist protocol, there were statistically significant differences in the amount of gonadotropin required (5 studies in favour of the antagonist protocol) [569-571, 574, 576], in the duration of gonadotropin use (6 studies in favour of the antagonist protocol) [570-574, 576], in OHSS rates (2 studies in favour of the antagonist protocol) [571, 573]. No statistically significant differences were found between groups for clinical pregnancy rates, miscarriage rates, number of oocytes collected, cancellation rates, and multiple pregnancy rates.

Recommendations

-
- 5.9.6 EBR A gonadotrophin releasing hormone antagonist protocol is preferred in women with PCOS undergoing an IVF ± ICSI cycle, over a gonadotrophin releasing hormone agonist long protocol, to reduce the duration of stimulation, total gonadotrophin dose and incidence of ovarian hyperstimulation syndrome (OHSS). 

-
- 5.9.7 CPP Human chorionic gonadotrophins is best used at the lowest doses to trigger final oocyte maturation in women with PCOS undergoing an IVF ± ICSI cycle to reduce the incidence of OHSS.
-
- 5.9.8 CPP Triggering final oocyte maturation with a gonadotropin-releasing hormone (GnRH) agonist and freezing all suitable embryos could be considered in women with PCOS having an IVF/ICSI cycle with a GnRH antagonist protocol and at an increased risk of developing OHSS or where fresh embryo transfer is not planned.
-
- 5.9.9 CPP In IVF ± ICSI cycles in women with PCOS, consideration needs to be given to an elective freeze of all embryos.
-

Justification

The duration of stimulation with a GnRH antagonist approach is around a day shorter than the standard 'long-down regulation' approach with a GnRH agonist. The rate of OHSS appears less with a GnRH antagonist approach in comparison to the standard 'long-down regulation' approach with a GnRH agonist. The effect size is difficult to quantify, as all most of these studies used a high dose human chorionic gonadotrophin (hCG) trigger in both arms, whereas this may not reflect clinical practice. There does not appear to be an increase in undesirable side effects with an antagonist down-regulation approach. The choice to trigger final oocyte maturation with GnRH agonist instead of hCG is important to prevent OHSS.

5.9c Trigger type

In women with PCOS undergoing GnRH antagonist IVF/ICSI treatment, is the use of hCG trigger or GnRH agonist trigger the most effective for improving fertility outcomes?

Clinical need for the question

One of the prominent causes of OHSS is the occurrence in women with PCOS undergoing ovarian hyperstimulation for IVF, particularly where hCG is used to trigger ovulation. Early in 1990 an alternative to exogenous hCG triggering emerged with GnRH-agonist use, providing an additional ovulatory option for IVF. A single bolus of GnRH-agonist administration during late follicular development in women with PCOS treated with gonadotropins, results in a surge of endogenous FSH and LH for final oocyte maturation and fertilisation. OHSS appears reduced yet lower pregnancy rates with GnRH-agonist triggers are observed and may vary when transferring fresh versus frozen thawed embryos in cycles from the same cohort, suggesting that the pregnancy rate is dependent of endometrial quality. An alternative option therefore in women with PCOS at high risk of OHSS, is to freeze oocytes or embryos after GnRH agonist triggering and transfer the embryos in subsequent cycles. The choice to trigger final oocyte maturation with GnRH-agonist, instead of hCG, and to transfer frozen embryos requires clarification.

Summary of systematic review evidence

We did not identify any evidence in women with PCOS to answer the question and therefore the literature has been reviewed narratively.

Summary of narrative review evidence

This question was addressed in a Cochrane review in 2014 [577]. In 17 RCTs ($n = 1847$), in fresh autologous cycles, GnRH-agonists were associated with a lower live birth rate than HCG (OR 0.47, 95% CI 0.31 to 0.70; five RCTs, 532 women, $I^2 = 56\%$, moderate-quality evidence), yet there was also a lower incidence of mild, moderate or severe OHSS than with HCG (OR 0.15, 95% CI 0.05 to 0.47; eight RCTs, 989 women, $I^2 = 42\%$, moderate-quality evidence). In fresh autologous cycles, GnRH-agonists were associated with a lower ongoing pregnancy rate than HCG (OR 0.70, 95% CI 0.54 to 0.91; 11 studies, 1198 women, $I^2 = 59\%$, low-quality evidence) and a higher early miscarriage rate (OR 1.74, 95% CI 1.10 to 2.75; 11 RCTs, 1198 women, $I^2 = 1\%$, moderate-quality evidence). However, the effect was dependent on the type of luteal phase support provided. Multiple pregnancy rates were similar. The authors concluded that final oocyte maturation triggering with GnRH-agonist instead of hCG in fresh autologous GnRH-antagonist IVF \pm ICSI cycles prevents OHSS to the detriment of the live birth rate. In donor-recipient cycles, use of GnRH agonists instead of hCG resulted in a lower incidence of OHSS, with no evidence of a difference in live birth rate. GnRH agonist as an oocyte maturation trigger could be useful for women who choose to avoid fresh transfers, where donate oocytes are used or in women who wish to freeze their eggs for later use.

Recommendations

See recommendations in [5.9b GnRH protocol](#).

Justification

The choice to trigger final oocyte maturation with GnRH-agonist instead of hCG is important in prevention of OHSS as hCG alone induces oocyte maturation but is associated with OHSS. GnRH-agonist triggers are associated with lower pregnancy rates, primarily in fresh embryo transfers, which can be overcome in frozen cycles.

5.9d Choice of FSH

In women with PCOS undergoing (controlled) ovarian (hyper) stimulation for IVF/ICSI, does the choice of FSH effect fertility outcomes?

Clinical need for the question

FSH can be purified from human urine (uFSH) or synthesised from recombinant DNA techniques (rFSH). Urinary preparations have impurities with LH activity known to stimulate androgen production in theca cells and completing maturation of follicles. However, it is known that less than 1% of follicular LH receptors needs to be occupied in order to elicit maximal steroidogenesis and it is therefore possible that enough endogenous LH is present during controlled ovarian stimulation to promote androgen synthesis and oocyte maturation without the need for extra LH activity in FSH preparations. The perceived clinical benefits of rFSH versus uFSH are the subject of ongoing debate and both types of preparations remain commonly used.

Summary of systematic review evidence

One small study (80 participants) of moderate risk of bias compared rFSH with human menopausal gonadotropin (hMG) and found that rFSH was better for the duration of ovarian stimulation required and the number of oocytes retrieved; whereas hMG was better for the maximum serum estradiol level [578]. No statistically significant differences were found between groups for the total dose of gonadotropin used, OHSS rate, clinical pregnancy rate per cycle and take home baby rate per cycle.

Summary of narrative review evidence

Given the limited evidence in PCOS, additional information was sought from rFSH and uFSH use in the general population. In a Cochrane systematic review and meta-analysis, 42 trials with a total of 9606 couples compared rFSH against three different uFSH preparations [579]. rFSH irrespective of the down-regulation protocol, did not result in a statistically significant different live birth rate or OHSS rate, concluding that clinical choice of gonadotrophin should depend on availability, convenience and costs and that further research on these comparisons is unlikely to identify substantive differences in effectiveness or safety.

Recommendation

5.9.4 CCR Urinary or recombinant follicle stimulation hormone can be used in women with PCOS undergoing controlled ovarian hyperstimulation for IVF ± ICSI, with insufficient evidence to recommend specific follicle stimulating hormone (FSH) preparations.

Justification

Only one small study in PCOS has been identified investigating uFSH versus rFSH in PCOS during ovarian stimulation for IVF/ICSI [578]. This study shows similar results to a systematic review and meta-analysis in the general IVF population, where extensive research has concluded no significant difference in birth rate or OHSS was detected and no further research in the general population was recommended. Hence clinical choice of gonadotrophin should depend on availability, convenience and costs.

5.9e Exogenous luteinizing hormone (LH)

In women with PCOS undergoing (controlled) ovarian (hyper) stimulation for IVF/ICSI, is exogenous LH treatment during IVF ± ICSI effective for improving fertility outcome?

Clinical need for the question

Options have been explored to reduce OHSS risk in IVF/ICSI in PCOS. The chronic low dose step-up protocol with exogenous FSH in securing single (fewer) dominant follicle selection is an alternative method to avoid multi-follicular development. During late follicular development, LH is essential to achieve adequate ovarian steroidogenesis and develop the subsequent capacity of the follicle to ovulate and luteinize. Increased LH secretion or elevated LH/FSH ratio in PCOS may influence fertility, with inhibition of oocyte maturation, deleterious effects on granulosa cell steroidogenesis and endometrial receptivity and with potential increased early pregnancy loss [580-582]. The lack of clarity around the role of exogenous LH in the setting of IVF/ICSI prompted this clinical question.

Summary of systematic review evidence

We did not identify any evidence in women with PCOS to answer the question and therefore the literature has been reviewed narratively.

Summary of narrative review evidence

Obesity adversely impacts on ovulation and on responses to ovulation induction in PCOS [282]. In PCOS, granulosa cells respond to LH at a relatively earlier follicular stage and are significantly more responsive than for ovulatory women with PCOS or women without PCOS [581]. Granulosa cell differentiation may be prematurely advanced. Controlled ovarian stimulation for multiple follicular development in ART can be performed in a variety of ways to increase efficacy and reduce risks. Systematic reviews and meta-analysis have demonstrated that there is no significant difference between different ovarian stimulation protocols (hMG, purified FSH, recombinant FSH) regarding the fertility outcomes. Therefore, clinical gonadotropin choice depends on availability, convenience, and cost. In standard IVF/ICSI protocols, the types of controlled ovarian stimulation (FSH alone or addition of LH as a supplement) have little impact on the fertility outcomes [579, 583]. Endogenous LH levels may fall too low in older women (>35) during ovarian stimulation, especially with GnRH-antagonist use and LH supplementation has been proposed. However, a multicentre RCT of exogenous LH during the follicular phase showed no fertility benefits outcomes in women over 35 [584]. No current study investigates efficacy of exogenous LH supplement for fertility outcomes in PCOS during IVF/ICSI. Careful monitoring of follicular development during ovarian stimulation is critical.

Recommendation

5.9.5 CCR Exogenous recombinant luteinising hormone treatment should not be routinely used in combination with follicle stimulating hormone therapy in women with PCOS undergoing controlled ovarian hyperstimulation for IVF ± ICSI.

Justification

There is no anticipated effect or benefit to add exogenous LH supplement in women with PCOS undergoing ovarian stimulation for IVF ± ICSI. There is insufficient evidence to determine the benefits of using or not using exogenous LH.

5.9f Adjunct metformin

In women with PCOS undergoing (controlled) ovarian (hyper) stimulation for IVF ± ICSI, is adjunct metformin effective for improving fertility outcomes?

Clinical need for the question

IVF ± ICSI treatment in women with PCOS is usually recommended either third-line (after failed ovulation induction) or in those with other infertility factors such as tubal damage, severe endometriosis or male factors [585]. IVF ± ICSI treatment in PCOS poses challenges, including OHSS [586]. Metformin has been studied to restore ovulation and enhance pregnancy rates in PCOS [587], through a range of mechanisms [522, 588, 589]. These mechanisms provide a physiological rationale for management of insulin resistance in IVF in PCOS. It has also been suggested that metformin may reduce serum estradiol levels during ovarian stimulation and it has also been hypothesised that metformin may reduce the production of vascular endothelial growth factor, both of which are important factors involved in the pathophysiology of OHSS [590]. Therefore, it was deemed important to explore the effectiveness and safety of metformin as a co-treatment in achieving pregnancy or live birth and reducing OHSS in IVF in PCOS.

Summary of systematic review evidence

Six RCTs of low [588, 591, 592], moderate [522], and high risk of bias [593, 594] found that IVF with adjuvant metformin was better for OHSS, clinical pregnancy rate, cancellation rate and live birth rate. No statistically significant differences were found between groups for the amount of gonadotropins used, the duration of ovarian stimulation, miscarriage rates, number of oocytes collected, and multiple pregnancy rates.

Summary of narrative review evidence

A Cochrane review [595] was identified by the search, however it included studies that did not meet the selection criteria for this question. The guideline development group (GDG) considered the meta-analyses in the Cochrane review as clinically relevant and noted that there was no evidence of a difference with adjunct metformin for live birth rate, miscarriage rate, number of oocytes collected, days of ovarian stimulation or cycle cancellation rate; and clinical pregnancy rate was increased with adjuvant metformin whilst OHSS reduced. Mild generally self-limiting side-effects were noted with adjunct metformin, as outlined in [Chapter 4](#).

Recommendations

5.9.10 EBR	Adjunct metformin therapy could be used before and/or during follicle stimulating hormone ovarian stimulation in women with PCOS undergoing a IVF ± ICSI therapy with a GnRH agonist protocol, to improve the clinical pregnancy rate and reduce the risk of OHSS.	❖❖❖ ⊕⊕○○
5.9.11 CCR	In a GnRH agonist protocol with adjunct metformin therapy, in women with PCOS undergoing IVF ± ICSI treatment, the following could be considered: <ul style="list-style-type: none">• metformin commencement at the start of GnRH agonist treatment• metformin use at a dose of between 1000mg to 2550mg daily• metformin cessation at the time of the pregnancy test or menses (unless the metformin therapy is otherwise indicated)• metformin side-effects (see above metformin section)	❖❖❖
5.9.12 CPP	In IVF ± ICSI cycles, women with PCOS could be counselled on potential benefits of adjunct metformin in a GnRH antagonist protocol to reduce risk of ovarian hyperstimulation syndrome (see above for metformin therapy considerations).	

Justification

Women and health professionals would generally value an increased clinical pregnancy rate (with no evidence of a difference in miscarriage rate) and reduced OHSS (with its associated morbidity and rarely mortality). Gastrointestinal side effects were recognised, but noted as mild and self-limiting and may be minimised with lower metformin starting dose and extended release preparations. Metformin was noted to be low cost and readily available, and while off label use was generally allowed, explanation is required for use.

5.9g In-vitro maturation

In women with PCOS, is in-vitro maturation (IVM) effective for improving fertility outcomes?

Clinical need for the question

Where IVF is indicated in PCOS, OHSS risks are increased with gonadotrophin stimulation. IVM of oocytes limits or omits ovarian stimulation prior to oocyte retrieval, with maturation of oocytes post retrieval, avoiding OHSS risk [564]. The definition of an IVM cycle requires clarification [596], as cycles employing an hCG trigger injection are generally associated with asynchronous oocyte maturation rates, poor embryo implantation rates and lower pregnancy rates [597, 598]. There are no RCTs of IVM versus ICSI or ovulation induction in PCOS, however observational studies suggest that offspring from IVM are not adversely affected [599]. Given that IVM is used in practice and has theoretical benefits, this question was prioritised.

Summary of systematic review evidence

We did not identify any evidence in women with PCOS to answer the question and therefore the literature has been reviewed narratively.

Summary of narrative review evidence

With an absence of relevant RCTs [600], retrospective studies suggest IVM is similarly successful for live birth with frozen embryos generated with IVM as embryo transfers generated by standard IVF treatment [564]. However, pregnancy rates are reduced and miscarriage rates are higher if a fresh embryo transfer is performed with IVM [564]. Embryo development appears slower with a greater degree of embryo arrest in IVM [601, 602].

Recommendations

5.9.13 CPP The term in vitro maturation (IVM) treatment cycle is applied to “the maturation in vitro of immature cumulus oocyte complexes collected from antral follicles” (encompassing both stimulated and unstimulated cycles, but without the use of a human gonadotrophin trigger).

5.9.14 CCR In units with sufficient expertise, IVM could be offered to achieve pregnancy and livebirth rates approaching those of standard IVF ± ICSI treatment without the risk of OHSS for women with PCOS, where an embryo is generated, then vitrified and thawed and transferred in a subsequent cycle. 

Justification

The GDG deemed that key elements to consider with IVM included; a clear definition of the term IVM, use in clinical units with sufficient expertise and advantages of reduced risk of OHSS. The group considered the lack of evidence as important. It was considered that IVM could be offered to achieve pregnancy and live birth rates that may approach those of standard IVF ± ICSI treatment, where frozen embryos are used. Given the lack of evidence the group voted for a conditional consensus recommendation that neither favoured this option or other options (IVF), with strong research recommendations.

Chapter Six

Guideline development methods

This guideline was developed as outlined in National Health and Medical Research Council (NHMRC) standards and procedures for rigorously developed external guidelines [603] and according to the GRADE (Grading of Recommendations, Assessment, Development and Evaluation) approach [15]. These methods were aligned with European Society of Human Reproduction and Embryology (ESHRE) approaches to guideline development [605].

The work builds on the original Australian guideline in PCOS [148], the update in 2014 as well as the World Health Organisation (WHO) guideline in infertility management [464] and Androgen Excess and PCOS Society (AEPCOS) Statement on improving emotional wellbeing in PCOS [109].

The International evidence-based guideline for the assessment and management of PCOS underpins an international initiative to engage women affected by PCOS and their health professionals to improve health outcomes. Extensive international health professional and consumer engagement informed the gaps, needs, priorities and core clinical outcomes for the guideline. Thirty-seven organisations were engaged with formal partnership with ESHRE and American Society for Reproductive Medicine (ASRM). Guideline development groups (GDGs) included members nominated by the engaged international societies. Society-nominated panel members included women with PCOS, paediatricians, endocrinologists, gynaecologists, primary care physicians, reproductive endocrinologists, psychiatrists, psychologists, dietitians, exercise physiologist, public health experts, researchers and other co-opted experts as required. They were supported by an experienced project management, evidence synthesis and translation team to develop the guideline. Here we provide a comprehensive review of the evidence and formulate recommendations using the GRADE Framework.

Governance and process

Governance included an international advisory board from six continents, a project board, five GDGs, a paediatric advisory panel, advisors and a translation committee (See [Figure 1](#)). The Australian Centre for Research Excellence in PCOS (CREPCOS) and the NHMRC partnered with the ESHRE and ASRM to deliver the guideline. The majority of the funding was provided by the Australian government, with contributions from ESHRE and ASRM. Four advisory, five project board and fifteen GDG face to face meetings occurred across Europe, USA and Australia over 15 months, and enabled guideline training, development and informed translation. Sixty prioritised clinical questions were addressed with evidence synthesis involving 40 systematic and 20 narrative reviews, generating 170 recommendations and practice points. Feedback from the thirty-seven engaged societies and their convened special interest groups of experts and consumers as well as public consultation have informed the final guideline.

Multidisciplinary international guideline development groups

GDGs were convened to address each of the five key clinical areas. Expertise was sought through PCOS networks to ensure multidisciplinary participation within each GDG. Each GDG comprised a chair, professional group members with specific expertise in PCOS and the clinical area of interest (i.e. psychologists/psychiatrist in the emotional wellbeing GDG), a consumer representative, evidence officers and representative to consider cultural aspects.

[See Appendix III](#). Co-opted experts were also included as needed.

Consumer participation

In the development of this guideline, we have sought not only to inform or consult with women affected by PCOS, but to partner with and empower women with PCOS, who are the ultimate beneficiaries of this work. We have engaged with international consumer bodies in PCOS and infertility to this end. This included Polycystic Ovary Syndrome Association Australia (POSAA) (Australia), Verity (United Kingdom), PCOS Challenge (United States), RESOLVE: The National Fertility Association (United States), and Victorian Assisted Reproductive Treatment Authority (VARTA) (Australia), who were actively engaged throughout the guideline process.

An international survey was completed by 1800 women and focus groups were held with women with PCOS to inform gaps in care, guideline priority questions, prioritised outcomes for each intervention and to inform guideline translation, education and support needs and preferred methods of delivery.

Consumer representatives participated in the development of the Centre for Research Excellence funding submission, in the guideline Project Board, International consumer advisory group and in the GDGs. Consumers have been involved in every stage, including development of the guideline scope, public consultation on the scope and developing and refining the clinical questions and recommendations as part of the GDGs. Consumer representatives are also extensively engaged and are partnering in the guideline translation activities.

Indigenous representation and CALD (culturally and linguistically diverse)

Ethnicity and culture was considered when making all recommendations. Indigenous representation was present on the PCOS Australian Alliance Strategic Advisory Group (a member of the Australian Indigenous Doctors Association) and the GDGs comprised clinicians with experience working with CALD and Indigenous communities. The translation of the guideline allows for adaptions on cultural and ethnicity grounds.

Conflict of interest and confidentiality

Conflict of interest has been proactively managed throughout the guideline development process as outlined in NHMRC Procedures and requirements for meeting the 2011 NHMRC standard for clinical practice guidelines [603]. All members of the GDGs have provided signed declarations of interest and a confidentiality agreement. Additionally, declarations of interest were a standing agenda item at each monthly meeting and GDG members were requested to detail areas for potential conflict.

The process for managing conflict of interest and confidentiality and recorded declarations can be provided on request (MCHRI-PCOS-Guideline-Group-l@monash.edu).

Training of GDGs in evidence review and guideline development methods

All GDG members attended a workshop, where the methods of reviewing evidence and guideline development were described in detail. The purpose of this workshop was to familiarise the chairs and GDG members with:

- the process of guideline development overall
- the process of identifying, appraising and synthesising evidence in a format to facilitate the formulation of evidence-based recommendations
- grading the strength of evidence and its suitability to support evidence-based recommendations
- when to facilitate discussion and clinical judgement to formulate clinical consensus recommendations in the absence of evidence.

Clinical question development and prioritisation

An International survey and Delphi exercise was conducted to develop and prioritise clinical questions to be addressed. A further prioritisation exercise was conducted within the topic specific GDGs and consumer advisory groups to rank the importance of clinical questions to guide the evidence team and to reach consensus on which clinical questions were to be addressed by a systematic review or by narrative review.

Systematic reviews were performed for highly prioritised questions and for those areas of greatest controversy. Narrative evidence reviews were completed a) where recent or concurrent systematic reviews were being completed by GDG members that could be captured on narrative review; b) where questions were less well suited to a PICO systematic review format; c) for lower prioritised questions or d) where there was insufficient evidence identified for a question where a systematic review was conducted.

Forty questions were addressed by guideline systematic reviews, many others by systematic reviews captured in the narrative reviews and some by narrative reviews of isolated PCOS studies supported by systematic reviews/guidelines in the general population.

The clinical questions addressed by each GDG are as follows:

GDG 1 – Screening, diagnostic assessment, risk assessment and life-stage

- At what time point after onset of menarche do irregular cycles indicate ongoing menstrual dysfunction related to PCOS?
- In women with suspected PCOS, what is the most effective measure to diagnose PCOS related hyperandrogenism (biochemical)?
- In women with suspected PCOS, what is the most effective measure to diagnose PCOS related hyperandrogenism (clinical)?
- What is the most effective ultrasound criteria to diagnose PCOS?
- Is anti-mullerian hormone (AMH) effective for diagnosis of PCOS?
- Is AMH effective to diagnosis of PCOM?
- What is the post-menopausal phenotype of PCOS?
- Are women with PCOS at increased risk for cardiovascular disease (CVD)?
- In women with PCOS, what is the most effective tool/method to assess risk of CVD?
- Are women with PCOS at increased risk for impaired glucose tolerance (IGT), gestational diabetes (GDM) and type 2 diabetes mellitus (T2DM)?
- In women with PCOS, what is the most effective tool/method to assess risk of T2DM?
- Are women with PCOS at increased risk for sleep apnoea?
- What is the method/tool most effective to screen for sleep apnoea in PCOS?
- What is the risk of PCOS in relatives of women with PCOS and should they be screened?
- What is the disease risk in relatives of PCOS (CVD, T2DM)?

GDG 2 - Prevalence, screening, diagnostic assessment and management of emotional wellbeing

- In women with PCOS: 1) What is the prevalence and severity of reduced quality of life (QoL)? And 2) Should QoL be assessed as part of standard care?
- In women with PCOS, what is the most effective tool/method to screen for symptoms of depression and anxiety?
- In women with PCOS, what is the most effective tool/method to assess quality of life?
- Is psychological therapy effective for management and support of depression and/or anxiety, disordered eating, body image distress, self-esteem, feminine identity or psychosexual dysfunction in women with PCOS?
- Is acupuncture effective for management and support of depression and/or anxiety, disordered eating, body image distress, self-esteem, feminine identity or psychosexual dysfunction in women with PCOS?
- Are anti-depressants and anxiolytics effective for management and support of depression and/or anxiety or disordered eating in women with PCOS?
- What is the effectiveness of different models of care compared to usual care?
- In women with PCOS, what is the most effective tool/method to screen body image distress?
- In women with PCOS, what is the most effective tool/method to screen disordered eating?
- In women with PCOS, what is the most effective tool/method to screen psychosexual dysfunction?

GDG 3 – Lifestyle management and models of care

- In women with PCOS, are lifestyle interventions (compared to minimal or nothing) effective for anthropometric, metabolic, reproductive, fertility, QoL and emotional wellbeing outcomes?
- In women with PCOS, are diet interventions (compared to different diets) effective for improving anthropometric, metabolic, fertility, and emotional wellbeing outcomes?
- In women with PCOS, are exercise interventions (compared to different exercises) effective for improving anthropometric, metabolic, reproductive, fertility, QoL and emotional wellbeing outcomes?
- In women with PCOS, are behavioural interventions (compared to different types of behavioural interventions) effective for improving anthropometric, metabolic, reproductive, fertility, QoL and emotional wellbeing outcomes?
- Are women with PCOS at increased risk of obesity?
- In women with PCOS, does obesity impact on prevalence and severity of hormonal and clinical features?

GDG 4 – Medical treatment

- Is the oral contraceptive pill alone or in combination, effective for management of hormonal and clinical PCOS features in adolescents and adults with PCOS?
- Is metformin alone or in combination, effective for management of hormonal and clinical PCOS features and weight in adolescents and adults with PCOS?
- Are anti-obesity pharmacological agents alone or in combination, effective for management of hormonal and clinical PCOS features and weight in adolescents and adults with PCOS?
- Are anti-androgen pharmacological agents alone or in combination, effective for management of hormonal and clinical PCOS features and weight in adolescents and adults with PCOS?
- Is inositol alone or in combination with other therapies, effective for management of hormonal and clinical PCOS features and weight in adolescents and adults with PCOS?

GDG 5 – Screening, diagnostic assessment and management of infertility

- Should women with PCOS and infertility undergo pre-conception (pre-pregnancy) evaluation (assessment) for (and where possible correction of) risk factors that may adversely affect fertility and response to infertility therapy?
 - Should women with PCOS undergo pre-conception (pre-pregnancy) evaluation (assessment) for (and where possible correction of) risk factors that may lead to adverse (early or late) pregnancy outcomes?
 - Should women with PCOS undergo close (early or late) pregnancy monitoring for adverse pregnancy outcomes?
 - Should women with PCOS and infertility due to anovulation alone with normal semen analysis have tubal patency testing prior to starting ovulation induction with timed intercourse or intrauterine insemination (IUI) treatment or delayed tubal patency testing?
 - In women with PCOS, is clomiphene citrate (CC) effective for improving fertility outcomes?
 - In women with PCOS, is metformin effective for improving fertility outcomes?
 - In women with PCOS and a BMI <30-32, what is the effectiveness of metformin compared to CC for improving fertility outcomes?
 - In women with PCOS, are aromatase inhibitors (AIs) effective for improving fertility outcomes?
 - In women with PCOS, are gonadotrophins effective for improving fertility outcomes?
 - In women with PCOS undergoing (controlled) ovarian (hyper) stimulation for IVF/ICSI (In-vitro fertilisation/Intra-cytoplasmic sperm injection), does the choice of follicle-stimulating hormone (FSH) effect fertility outcomes?
 - In women with PCOS undergoing (controlled) ovarian (hyper) stimulation for IVF/ICSI, is exogenous luteinizing hormone (LH) treatment during IVF/ICSI effective for improving fertility outcomes?
 - In women with PCOS, is stimulated IVF/ICSI effective for improving fertility outcomes?
 - In women with PCOS undergoing IVF/ICSI treatment, is the gonadotropin-releasing hormone (GnRH) antagonist protocol or GnRH agonist long protocol the most effective for improving fertility outcomes?
 - In women with PCOS undergoing (controlled) ovarian (hyper) stimulation for IVF/ICSI, is adjuvant metformin effective for improving fertility outcomes?
 - In women with PCOS undergoing GnRH antagonist IVF/ICSI treatment, is the use of human chorionic gonadotropin (hCG) trigger or GnRH agonist trigger the most effective for improving fertility outcomes?
 - In women with PCOS, is In Vitro Maturation (IVM) effective for improving fertility outcomes?
 - In women with PCOS, are anti-obesity pharmacological agents effective for improving fertility outcomes?
 - In women with PCOS, is ovarian surgery effective for improving fertility outcomes?
 - In women with PCOS, what is the effectiveness of lifestyle interventions compared to bariatric surgery for improving fertility and adverse outcomes?
- * Not all questions resulted in a recommendation. Where evidence was inadequate only research recommendations were made and are captured in a separate document.

Outcome prioritisation using the GRADE method

The most relevant outcomes were prioritised by ranking their importance by health professionals and consumers to help resolve or clarify disagreements and assist with grading the evidence. The importance of outcomes may vary across cultures and from different perspectives e.g. patients, public, health professionals or policy-makers. Table 6 outlines the considerations when deciding importance of outcomes [15]. GDG members, including consumers also participated in this exercise.

Table 6: Steps for considering the relative importance of outcomes

What	Assessment and prioritisation of outcomes as critical, important but not critical, or low importance. Requires judgement of the balance between the desirable and undesirable health outcomes of an intervention.
Why	To focus attention on those outcomes that are considered most important when conducting evidence review and to resolve or clarify disagreements. To support making a recommendation and to determine the strength of the recommendation.
How	Scoping the relevant literature. By asking GDG members, including consumers to prioritise outcomes in light of the considerations for 'what' and 'why'.
Evidence	These judgments are ideally informed by a systematic review of the literature focusing on what the target population considers as critical or important outcomes for decision-making. Prior knowledge of the research evidence through systematic reviews; and information about values, preferences or utilities has been explored in the original guideline, that was systematic in nature, will inform this process. Additionally, the collective experience of the GDG members, including consumers, will be used using transparent methods for documenting and considering them, such as a Delphi process.

To facilitate ranking of outcomes according to their importance the following scale was be used [15].

RATING SCALE:

1	2	3	4	5	6	7	8	9
of least importance							of most importance	
Of limited importance for making a decision (not included in evidence profile)		Important, but not critical for making a decision (included in evidence profile)				Critical for making a decision (included in evidence profile)		

Outcomes considered critical (rated 7-9) most greatly influenced a recommendation and the overall quality of evidence supporting the recommendation and the strength of the recommendation.

Adaptation of existing evidence-based guidelines

Given the time and resource-intensive nature of guideline development, existing high quality evidence-based guidelines that address the clinical questions and PICO (Population, Intervention, Comparison, Outcome) of interest should be sought for adaptation before starting a new one. Apart from the original Australian guideline, to date no international PCOS guideline covering all health aspects related to the syndrome is available. The evidence-based sections of the WHO guideline, supported by this evidence synthesis team is aligned with the scope here, yet is now out of date. The NICE guideline is limited in scope and is not available electronically outside the UK. It too is adapted from the 2011 Australian guideline. Professional society positions statements or clinical practice guidelines are more limited in scope, do not follow AGREE II (Appraisal of Guidelines for Research and Evaluation) process, involve more limited expertise and geographical representation and are often conflicting in recommendations. Here we have updated and expanded the scope and evidence contained in the 2011 Australian guideline and, where appropriate methods have been applied, integrated the WHO guideline.

Evidence reviews to answer the clinical questions

Evidence reviews were conducted for each clinical question and from the evidence reviews, the GDGs were able to develop guideline recommendations. The evidence reviews for each question can be found in the supplementary Technical report. The links between the body of evidence, the clinical need for the question and the clinical impact of the resulting recommendation(s), including potential changes in usual care and the way care is organised, acceptability, feasibility and resource implications are clearly explained in the accompanying GRADE evidence to decision framework supporting the recommendation.

Selection criteria

The PICO framework was used by the GDGs to explore the components of each clinical question and finalise the selection criteria for each question. These components were used to include and exclude studies in the evidence review. Details of the selection criteria for each question can be found in the supplementary Technical report.

The highest form of evidence, the most current (within 5 years), comprehensive (with the most outcomes relevant to PICO) and high quality systematic review that meets our benchmark criteria (see table 7) and meets the selection criteria, was used to inform a recommendation. Additional systematic reviews that met benchmark and selection criteria were used if it reported additional outcomes relevant to the PICO, that were not addressed in the first, most comprehensive systematic review. Additional randomised controlled trials (RCT(s)) that met the selection criteria and were not included in the systematic reviews were also used. Where a systematic review met the benchmark criteria but did not meet the selection criteria, or synthesised studies that did not meet out selection criteria, the risk of bias appraisals from that systematic review were adopted.

Table 7. Benchmark criteria for a systematic review to be included:

-
- 1** Must have completed a search in at least Medline and another relevant database;
 - 2** Must have listed key search terms;
 - 3** Must have listed selection criteria;
 - 4** Must have used an appropriate framework to assess risk of bias/quality appraisal; and
 - 5** Where the evidence is sought for an intervention question and a systematic review has included non-RCTs, the analysis must be subgrouped by RCTs to be eligible for inclusion.
-

Systematic search for evidence

A broad-ranging systematic search for terms related to PCOS was developed by the evidence team. This PCOS search string was then combined with specific searches tailored for each clinical question according to the PICO developed by the GDG. The search terms used to identify studies addressing the population of interest (i.e. women with PCOS) were only limited to PCOS terms. Therefore, studies addressing women with PCOS in all cultural, geographical and socioeconomic backgrounds and settings would be identified by the search. Furthermore, while a formal analysis of cost effectiveness was not performed in this guideline, any study addressing a clinical question (PICO) that also reported cost effectiveness would be captured and addressed in the GRADE process. The search strategy was limited to English language articles and limits on year of publication are specified in the PICO for each clinical question according to whether an update search was conducted or in cases where interventions were only available from a particular point in time.

The following electronic databases were employed to identify relevant literature:

- CINAHL (Cumulative Index to Nursing and Allied Health Literature)
- The Cochrane Library
- Cochrane Database of Systematic Reviews (Cochrane Reviews)
- Database of Abstracts of Reviews of Effects (Other Reviews)
- Cochrane Central Register of Controlled Trials (Clinical Trials)
- Cochrane Database of Methodology Reviews (Methods Reviews)
- The Cochrane Methodology Register (Methods Studies)
- Health Technology Assessment Database (Technology Assessments)
- NHS Economic Evaluation Database (Economic Evaluations)
- EMBASE
- EBM Reviews (OVID)
- Medline (OVID)
- Medline in-process and other non-indexed citations (OVID)
- PsycINFO (OVID)

The bibliographies of relevant studies identified by the search strategy and relevant reviews/meta-analysis were also searched for identification of additional studies. Details of the search strategies and search results for each evidence review can be found in the supplementary Technical report.

Inclusion of studies

To determine the literature to be assessed further, a reviewer scanned the titles, abstracts and keywords of every record retrieved by the search strategy. Full articles were retrieved for further assessment if the information given suggested that the study met the selection criteria. Studies were selected by one reviewer in consultation with colleagues, using the PICO selection criteria established a priori. Where there was any doubt regarding these criteria from the information given in the title and abstract, the full article was retrieved for clarification.

Appraisal of the methodological quality/risk of bias of the evidence

Methodological quality of the included studies was assessed using criteria developed a priori according to study design (i.e. quality appraisal criteria used for an RCT is different to that used for a cohort study) [604]. Individual quality items were investigated using a descriptive component approach. Any disagreement or uncertainty was resolved by discussion among the GDG to reach a consensus. Using this approach, each study was allocated a risk of bias rating (see Table 8). Quality appraisal tables for each evidence review can be found in the supporting document titled Technical report.

Table 8. Risk of bias ratings [604]

RATING	DESCRIPTION
Low	All of the criteria have been fulfilled or where criteria have not been fulfilled it is very unlikely the conclusions of the study would be affected.
Moderate	Some of the criteria have been fulfilled and those criteria that have not been fulfilled may affect the conclusions of the study.
High	Few or no criteria fulfilled or the conclusions of the study are likely or very likely to be affected.
Insufficient information	Not enough information provided on methodological quality to be able to determine risk of bias.

Data extraction

Data, according to the selection criteria, were extracted from included studies using a specially developed data extraction form [604]. Information was collected on general details (title, authors, reference/source, country, year of publication, setting), participants (age, sex, inclusion/exclusion criteria, withdrawals/losses to follow-up, subgroups), results (point estimates and measures of variability, frequency counts for dichotomous variables, number of participants, intention-to-treat analysis) and validity results. Data extraction tables for each evidence review can be found in the supporting Technical report.

Data synthesis

In order to make a summary statement about the effect of the intervention and thus inform evidence-based recommendations, data were presented qualitatively by presenting the findings narratively in tables or discussion text; or quantitatively, using statistical methods such as meta-analyses. A meta-analysis is a statistical technique for combining (pooling) the results of a number of studies, that report data for the same outcome for the same intervention, to produce a summary statistic to represent the effect of one intervention compared to another. When high-quality trials are used, a meta-analysis summary statistic can be more powerful than an individual study to confirm or refute effectiveness of an intervention and thus to inform an evidence-based recommendation. Data were summarised statistically using meta-analyses if data were available, sufficiently homogenous, and of sufficient quality. Clinical homogeneity was satisfied when participants, interventions, outcome measures and timing of outcome measurement were considered to be similar. The Review Manager 5.3 software was used for meta-analyses. Where appropriate, subgroup analysis was conducted according to factors that may cause variations in outcomes, are likely to be a confounder, or may change the way the treatment works e.g. age, subtype or duration of treatment. These can be found in the supporting Technical report.

Quality (certainty) of the body of evidence using GRADE evidence profiles

A GRADE evidence profile was prepared for each comparison within each clinical question addressed by a systematic review. For each prioritised outcome, a certainty rating was documented with consideration of the following:

- information about the number and design of studies addressing the outcome; and
- judgments about the quality of the studies and/or synthesised evidence, such as risk of bias, inconsistency, indirectness, imprecision and any other considerations that may influence the quality of the evidence.

The definitions of these factors are described below:

- overall quality of evidence rating using the judgments made above (see ratings in table 9);
- key statistical data; and
- classification of the importance of the outcome.

The certainty of evidence reflects the extent to which our confidence in an estimate of the effect is adequate to support a particular recommendation [15].

Although the quality of evidence represents a continuum, the GRADE approach results in an assessment of the quality of a body of evidence in one of four grades (adapted from GRADE [15]).

Table 9. Quality of evidence

High	⊕⊕⊕⊕	We are very confident that the true effect lies close to that of the estimate of the effect.
Moderate	⊕⊕⊕○	We are moderately confident in the effect estimate: The true effect is likely to be close to the estimate of the effect, but there is a possibility that it is substantially different.
Low	⊕⊕○○	Our confidence in the effect estimate is limited: The true effect may be substantially different from the estimate of the effect.
Very Low	⊕○○○	We have very little confidence in the effect estimate: The true effect is likely to be substantially different from the estimate of effect.

GRADE note that the quality of evidence is a continuum; any discrete categorisation involves some degree of arbitrariness. Nevertheless, advantages of simplicity, transparency, and vividness outweigh these limitations [15]. Evidence profiles can be found in the Technical report.

Formulation of recommendations using the GRADE evidence to decision framework

The Evidence to Decision (EtD) framework was used to document the judgments and decisions using the GRADE method for development of evidence-based recommendations. The framework prompts transparent documentation and discussion of decisions through assessment of the evidence, clinical expertise and patient preference for factors including:

- desirable and undesirable effects of the intervention;
- certainty of the evidence;
- values associated with the recommended intervention;
- balance of effects;
- resource requirements;
- cost-effectiveness;
- equity; acceptability;
- feasibility;
- subgroup considerations;
- implementation considerations;
- monitoring and evaluation; and
- research priorities.

Using the framework, each of the evidence-based and consensus recommendations are given an overall grading of conditional or strong [15]. Clinical practice points have also been included, where important issues (such as safety, side effects or risks) arose from discussion of evidence-based or clinical consensus recommendations.

Table 10. Recommendation types

EBR	Evidence sufficient to inform an evidence-based recommendation (EBR)
CCR	In the absence of adequate evidence in PCOS, a clinical consensus recommendation (CCR) was made
CPP	Evidence not sought. A clinical practice point (CPP) was made where important issues arose from discussion of evidence-based or clinical consensus recommendations

The strength of the recommendations can be identified throughout the guideline by the following (adapted from ESHRE manual for guideline development [605] and the GRADE approach [15]):

Table 11: Strength of recommendations (adapted from GRADE [15] and ESHRE Manual [605])

TARGET GROUP	STRONG RECOMMENDATIONS*	CONDITIONAL (WEAK) RECOMMENDATIONS FOR THE OPTION (TEST OR TREATMENT)	CONDITIONAL (WEAK) RECOMMENDATION FOR EITHER THE OPTION OR THE COMPARISON	RESEARCH ONLY RECOMMENDATIONS	CLINICAL PRACTICE POINTS (CPP)**
CONSUMERS	Most people in your situation would want the recommended course of action and only a small proportion would not.	The majority of people in your situation would want the recommended course of action, but some would not.	There is considerable lack of clarity over whether the majority of people in your situation would want the recommended course of action or not.	The test or intervention should only be considered by patients and clinicians within the setting of a research trial for which appropriate approvals and safety precautions have been established.	Clinicians, patients and policy makers are informed on the clinical implications relevant to implementation of recommendations.
HEALTH PROFESSIONALS	Most patients should receive the recommended course of action.	Recognise that different choices will be appropriate for different patients and that greater effort is needed with individuals to arrive at management decisions consistent with values and preferences. Decision aids and shared decision making are important here.		The test or intervention should only be considered by patients and clinicians within the setting of a research trial for which appropriate approvals and safety precautions have been established.	
POLICY MAKERS	The recommendation can be adopted as policy in most situations.	Policy making needs to consider perspectives and involvement of diverse stakeholders.	Policy decisions remain unclear.	Policy makers need to be aware of the need for evidence gaps and health professional and consumer prioritised research gaps.	

* Strong recommendations based on high quality evidence will apply to most patients for whom these recommendations are made, but they may not apply to all patients in all conditions; no recommendation can take into account all of the often-compelling unique features of individual patients and clinical circumstances.

** A clinical practice point (CPP) is developed by the GDG to support recommendations. Advice can be provided to enhance shared decision making, and on factors to be considered in implementing a specific test or intervention

The words “should”, “could” and “should not” do not directly reflect the strength (strong or conditional) allocated to a recommendation and are independent descriptors intended to reflect the judgment of the multidisciplinary GDG on the practical application of the recommendation, balancing benefits and harms. Where the word “should” is used in the recommendations, the GDG judged that the benefits of the recommendation (whether evidence-based or clinical consensus) clearly exceed the harms, and that the recommendation can be trusted to guide practice. Where the word “could” is used, either the quality of evidence was underpowered, or the available studies demonstrated little clear advantage of one approach over another, or the balance of benefits to harm was unclear. Where the words “should not” are used, there is either a lack of appropriate evidence, or the harms outweigh the benefits.

Evidence to decision frameworks can be found in the supplementary document titled Technical report. Each recommendation is supported by a discussion (in the chapters of this document) about the clinical need for the question, the body of evidence identified to answer the question and a clinical justification for the recommendation(s).

The GDGs acknowledge that lack of evidence is not evidence of lack of effect and have attempted to reflect this in the strength of the grading given to recommendations on interventions that are not supported by evidence. In addition, some interventions were not supported by evidence in the recommendations due to lack of evidence of effect. The GDGs acknowledge that this refers to lack of evidence of effect over placebo; that is, patients may receive some beneficial outcomes from the intervention but these do not exceed the beneficial effects that can be expected from a placebo therapy [606].

Public consultation

Public and targeted consultation will be conducted for a period of thirty days commencing 10th February to 12th March 2018 in accordance with the legislative requirements set out in section 14A of the National Health and Medical Research Council Act 1992 as outlined in the NHMRC Procedures and requirements for meeting the 2011 NHMRC standard for clinical practice guidelines [603]. The public consultation strategy is available upon request, email MCHRI-PCOS-Guideline-Group-l@monash.edu.

External review

This guideline was reviewed by the International Advisory Group, independently by relevant professional colleges and societies and through public consultation.

Scheduled review and update of the guideline

The GDGs will be re-convened to review relevant sections of this guideline if any of the following occur within five years:

- a change in the indications registered by regulatory bodies for any drug included in this guideline; or
- publication of any new major randomised controlled trials or systematic reviews that potentially have a bearing on the safety of the recommendations in this guideline

After five years the societies and organisations will be reengaged, the guideline panels revised and reconvened and the guideline updated as per NHMRC processes.

Dissemination and implementation

A comprehensive, international dissemination and implementation program is underway to amplify the impact of the international guideline for the assessment and treatment of PCOS. The three guiding principles underpinning the translation and dissemination program are:

- 1 all components of the translation program are informed by the needs and preferences of PCOS consumers;
- 2 all translation materials are co-created with, and attuned to, the needs of end-users; and
- 3 dissemination strategies are multi-faceted, multi-modal and refined to the communications channels of end-users.

The aims of the 18 month, international translation program are to:

- build the capability of health professionals to deliver high-quality, evidence-based assessment and management of PCOS;
- augment the health literacy of PCOS health consumers, leading to improved health outcomes;
- promote a best-practice PCOS model of care; and
- orientate international health policy towards an evidence-based, best practice approach.

Significant outcomes of the plan include a consistent and improved standard of care and greater consumer empowerment by enhancing both consumer engagement and the capacity of health professionals to deliver high quality, evidence-based care.

Central to the success of the program is the active engagement of thirty-seven international collaborators and partners who represent the leading, invested health organisations such as European Society of Human Reproduction and Embryology (ESHRE) and the American Society for Reproductive Medicine (ASRM). Health experts from these organisations have leveraged their extensive influence within the health sector to promote the uptake of PCOS guideline recommendations. In addition, a further essential component is the engagement of leading consumer groups such as the Polycystic Ovary Syndrome Association of Australia (POSAA), Verity in the United Kingdom, PCOS Challenge: The National Polycystic Ovary Syndrome Association in the United States and organisations with strong links to health consumers such as Jean Hailes for Women's Health and the Victorian Assisted Reproductive Treatment Authority (VARTA) in Australia. Guideline leads are involved in the establishment of a core outcome set in PCOS, to be implemented into clinical data sets to evaluate alignment with evidence-based care. Finally, the translation and dissemination plan is supported by a comprehensive evaluation framework, measuring international impacts and outcomes.

Project board

ROLE	NAME	DISCIPLINE	ORGANISATIONAL AFFILIATION / REGION
Chair Senior Supplier Endocrinology Representative	Professor Helena Teede	Endocrinologist	Centre for Research Excellence in Polycystic Ovary Syndrome, Australia
Senior user	Mrs Veryan McAllister	Consumer lead	Polycystic Ovary Syndrome Association of Australia
Senior user Senior Supplier Allied Health Representative	Associate Professor Lisa Moran	Dietitian	Centre for Research Excellence in Polycystic Ovary Syndrome, Australia
Senior user General Practitioner Representative	Doctor Mala Thondan	General Practitioner	Harp Family Medical Centre, Australia
Senior user Senior supplier Gynaecology Representative European Society of Human Reproduction and Embryology Representative	Professor Joop Laven	Obstetrician-Gynaecologist; Reproductive Endocrinologist	Erasmus MC Rotterdam, Netherlands
Senior supplier Gynaecology Representative	Doctor Michael Costello	Obstetrician-Gynaecologist;	University of NSW, Australia
Senior supplier American Society for Reproductive Medicine Representative	Professor Anuja Dokras	Reproductive Endocrinologist	University of Pennsylvania, USA
Senior supplier European Society of Human Reproduction and Embryology Representative	Associate Professor Terhi Piltonen	Obstetrician-Gynaecologist; Reproductive Endocrinologist	Oulu University Hospital, University of Oulu, Finland
Senior supplier Evidence Synthesis Lead and Guidelines Advisor	Doctor Marie Misso	Evidence synthesis and guidelines advisor	Centre for Research Excellence in Polycystic Ovary Syndrome, Australia

Appendix II:

International Advisory Panel

ROLE	TITLE	NAME	DISCIPLINE	ORGANISATION	COUNTRY
Chair	Professor	Bart Fauser	Obstetrician-Gynaecologist	University Medical Center Utrecht	Netherlands
Deputy Chair	Professor	Robert Norman	Obstetrician-Gynaecologist; Reproductive Endocrinologist; Chemical pathologist	The University of Adelaide	Australia
Member	Professor	Juha Tapanainen	Obstetrician-Gynaecologist	University of Helsinki	Finland
Member	Professor	Zephne van der Spuy	Obstetrician-Gynaecologist Specialist Reproductive Medicine	University of Cape Town	South Africa
Member	Professor	Duru Shah	Obstetrician-Gynaecologist	Gynaecworld	India
Member	Professor	Richard Legro	Obstetrician-Gynaecologist; Reproductive Endocrinologist	Penn State Clinical and Translational Institute	USA
Member	Professor	Frank Broekmans	Gynaecologist Specialist Reproductive Medicine	University Medical Centre Utrecht	Netherlands
Member	Doctor	Anuja Dokras	Reproductive Endocrinologist and infertility	University of Pennsylvania	USA
Member	Doctor	Marie Misso	Evidence Synthesis and Guidelines Advisor	Monash Centre for Health Research and Implementation	Australia
Member	Professor	Chii-Ruey Tzeng	Obstetrician-Gynaecologist	Taipei Medical University Hospital	Taiwan
Member	Professor	Jie Qiao	Obstetrician-Gynaecologist	Peking University Third Hospital	China
Member	Professor	Poli Mara Spritzer	Reproductive Endocrinologist	Federal University of Rio Grande Do Sul	Brazil

Appendix III:

Guideline development groups

Terms of reference for each committee can be provided upon request (MCHRI-PCOS-Guideline-Group-I@monash.edu).

GDG1: Topic area – Screening, diagnostic assessment, risk assessment and life-stage

GDG ROLE	TITLE	NAME	DISCIPLINE	ORGANISATION	COUNTRY
Chair	Professor	Joop Laven	Obstetrician-Gynaecologist; Reproductive Endocrinologist	Erasmus MC Rotterdam	Netherlands
Deputy Chair	Professor	Robert Norman	Obstetrician-Gynaecologist; Reproductive Endocrinologist; Chemical pathologist	The University of Adelaide	Australia
Member	Professor	Marianne Andersen	Endocrinologist	Odense University Hospital	Denmark
Member	Professor	Ricardo Azziz	Reproductive Endocrinologist	State University of New York System Administration	USA
Member	Professor	Preeti Dabadghao	Endocrinologist	Sanjay Gandhi Postgraduate Institute of Medical Sciences	India
Member	Professor	Didier Dewailly	Endocrinologist	University of Lille	France
Member	Professor	Stephen Franks	Endocrinologist	Imperial College London	United Kingdom
Member	Professor	Kathleen Hoeger	Reproductive Endocrinologist	University of Rochester	USA
Member	Doctor	Samantha Hutchison	Endocrinologist	Monash Health	Australia
Member	Professor	Ernest Ng	Obstetrician-Gynaecologist	Department of Obstetrics & Gynaecology, The University of Hong Kong	China
Member	Professor	Sharon Oberfield	Paediatric endocrinologist	Columbia University Medical Center	USA

GDG ROLE	TITLE	NAME	DISCIPLINE	ORGANISATION	COUNTRY
Member	Professor	Duru Shah	Obstetrician-Gynaecologist	Gynaecworld	India
Co-opted	Doctor	Jane Woolcock	Obstetrician-Gynaecologist	Women's and Children's Hospital Adelaide	Australia
Co-opted	Assistant Professor	Marla Lujan	Nutritional Science	Cornell University	USA
Co-opted	Associate Professor	Darren Mansfield	Respiratory Physician	Monash Health	Australia
Member	Doctor	Femke Hohmann	General Practitioner	Huisartsenpraktijk Hohmann & De Vet, Rotterdam	Netherlands
Member	Ms	Sasha Ottey	Non-profit Executive Director; Consumer	PCOS Challenge: The National Polycystic Ovary Syndrome Association	USA

GDG2: Topic area – Prevalence, screening, diagnostic assessment and management of emotional wellbeing

GDG ROLE	TITLE	NAME	DISCIPLINE	ORGANISATION	COUNTRY
Chair	Professor	Anuja Dokras	Reproductive Endocrinologist and infertility	University of Pennsylvania	USA
Deputy Chair	Professor	Elisabet Stener-Victorin	Researcher in Reproductive Endocrinology and Metabolism	Karolinska Institutet	Sweden
Member	Associate Professor	Leah Brennan	Psychologist	Australian Catholic University	Australia
Member	Doctor	Rhonda Garad	Registered Nurse	Monash Centre for Health Research and Implementation	Australia
Member	Doctor	Melanie Gibson-Helm	Women's Public Health Researcher	Monash University	Australia
Co-opted	Professor	Jayashri Kulkarni	Psychiatrist	Monash Alfred Psychiatry Research Centre	Australia
Member	Professor	Rong Li	Obstetrician-gynaecologist	Reproductive Medical Center, Peking University Third Hospital	China
Member	Professor	Jane Speight	Health Psychologist	Deakin University	Australia
Member	Associate Professor	Maria Vogiatzi	Pediatric Endocrinologist	Children's Hospital of Philadelphia, University of Pennsylvania	USA
Member	Professor	Bulent Yildiz	Endocrinologist	Hacettepe University	Turkey
Member		Veryan McAllister	Consumer	Polycystic Ovary Syndrome Association Australia	Australia
Member	Doctor	Mala Thondan	General practitioner	Harp Family Medical Centre	Australia

GDG3: Topic area – Lifestyle management and models of care

GDG ROLE	TITLE	NAME	DISCIPLINE	ORGANISATION	COUNTRY
Chair	Associate Professor	Lisa Moran	Dietitian; Research Fellow	Monash Centre for Health Research and Implementation	Australia
Deputy Chair	Associate Professor	Nigel Stepto	Accredited Exercise Physiologist	Victoria University	Australia
Member	Associate Professor	Jacqueline Boyle	Obstetrician-Gynaecologist	Monash Centre for Health Research and Implementation	Australia
Member	Doctor	Cheryce Harrison	Research Fellow	Monash Centre for Health Research and Implementation	Australia
Member	Professor	Angelica Hirschberg	Obstetrician-Gynaecologist	Karolinska Institutet	Sweden
Member	Doctor	Kate Marsh	Dietitian	Northside Nutrition & Dietetics	Australia
Member	Associate Professor	Leanne Redman	Obesity; Lifestyle Interventions	Pennington Biomedical Research Center	USA
Member	Professor	Chandrika Wijeyaratne	Endocrinology and Reproductive Medicine	Department of Obstetrics and Gynaecology, Faculty of Medicine, University of Colombo	Sri Lanka
Co-opted	Associate Professor	Leah Brennan	Psychologist	Australian Catholic University	Australia
Co-opted	Miss	Eliza Tassone	Consumer	Monash University	Australia
Co-opted	Doctor	Mala Thondan	General practitioner	Harp Family Medical Centre	Australia

GDG4: Topic area - Medical treatment

GDG ROLE	TITLE	NAME	DISCIPLINE	ORGANISATION	COUNTRY
Chair	Professor	Helena Teede	Endocrinologist	Monash Centre for Health Research and Implementation	Australia
Deputy Chair	Associate Professor	Terhi Piltonen	Obstetrician-Gynaecologist; Reproductive Endocrinologist	Oulu University Hospital, University of Oulu	Finland
Member	Doctor	Anju Joham	Endocrinologist	Monash Health	Australia
Member	Professor	Jaideep Malhotra	Obstetrician-Gynaecologist	Rainbow Hospital	India
Member	Professor	Ben Mol	Obstetrician-Gynaecologist	Monash University	Australia
Member	Doctor	Alexia Peña	Paediatric Endocrinologist	The Robinson Research Institute at the University of Adelaide	Australia
Member	Doctor	Daniela Romualdi	Obstetrician-Gynaecologist	Fondazione Policlinico Universitario Agostino Gemelli, Rome	Italy
Member	Professor	Selma Witchel	Paediatric Endocrinologist	Children's Hospital of Pittsburgh of UPMC, University of Pittsburgh	USA
Member	Ms	Veryan McAllister	Consumer	Polycystic Ovary Syndrome Association Australia	Australia
Member	Doctor	Mala Thondan	General practitioner	Harp Family Medical Centre	Australia

GDG5: Topic area – Screening, diagnostic assessment and management of infertility

GDG ROLE	TITLE	NAME	DISCIPLINE	ORGANISATION	COUNTRY
Chair	Doctor	Michael Costello	Obstetrician-Gynaecologist	University of NSW	Australia
Deputy Chair	Professor	Robert Norman	Obstetrician-Gynaecologist; Reproductive Endocrinologist; Chemical pathologist	The University of Adelaide	Australia
Member	Professor	Adam Balen	Reproductive Medicine	Leeds Teaching Hospitals	United Kingdom
Member	Professor	Luigi Devoto	Reproductive Endocrinologist	University of Chile. Faculty of Medicine	Chile
Member	Professor	Roger Hart	Obstetrician-Gynaecologist; Reproductive Endocrinologist	The University of Western Australia	Australia
Member		Cailin Jordan	Psychologist	Genea Hollywood Fertility	Australia
Member	Professor	Richard Legro	Obstetrician-Gynaecologist; Reproductive Endocrinologist	Penn State Clinical and Translational Institute	USA
Member	Doctor	Edgar Mocanu	Obstetrician-Gynaecologist	Rotunda Hospital	Ireland
Member	Professor	Jie Qiao	Obstetrician-Gynaecologist	Peking University Third Hospital	China
Member	Professor	Raymond Rodgers	Reproductive Endocrinologist	The Robinson Research Institute at the University of Adelaide	Australia
Member	Professor	Luk Rombauts	Obstetrician-Gynaecologist; Infertility Specialist	Monash Health	Australia
Member	Professor	Shakila Thangaratinam	Obstetrician-Gynaecologist; Clinical Academic	Queen Mary University of London	United Kingdom
Member	Professor	Eszter Vanky	Obstetrician-Gynaecologist	Department of Clinical and Molecular Medicine, Norwegian University of Science and Technology	Norway
Member		Louise Johnson	Consumer focused organisation representative	Victorian Assisted reproductive Treatment Authority	Australia

Guideline development technical team members

- Professor Helena Teede, Project Director, Monash Centre for Health Research and Implementation, Monash Public Health, Monash University
- Doctor Marie Misso, Evidence Synthesis Lead and Guidelines Advisor, Monash Centre for Health Research and Implementation, Monash Public Health, Monash University
- Ms Linda Downes, Project Manager – Monash Centre for Health Research and Implementation
- Doctor Rhonda Garad, Senior Project Officer, Knowledge Translation in Polycystic Ovary Syndrome, Monash Centre for Health Research and Implementation, Monash Public Health, Monash University
- Miss Eliza Tassone, Evidence Synthesis Officer, Monash Centre for Health Research and Implementation
- Mr Estifanos Baye, Evidence Synthesis Officer, Monash Centre for Health Research and Implementation
- Ms Ching Shan Wan, Evidence Synthesis Officer, Monash Centre for Health Research and Implementation

Paediatric GDG panel membership

ROLE	TITLE	NAME	DISCIPLINE	ORGANISATION	COUNTRY
Chair	Professor	Helena Teede	Endocrinologist	Monash Centre for Health Research and Implementation	Australia
Member	Professor	Kathleen Hoeger	Reproductive Endocrinologist	University of Rochester	USA
Member	Professor	Sharon Oberfield	Paediatric endocrinologist	Columbia University Medical Center	USA
Member	Professor	Selma Witchel	Paediatric Endocrinologist	Children's Hospital of Pittsburgh of UPMC, University of Pittsburgh	USA
Member	Doctor	Alexia Peña	Paediatric Endocrinologist	The Robinson Research Institute at the University of Adelaide	Australia

Appendix IV:

Berlin Questionnaire

©1997 IONSLEEP

Sleep Evaluation in Primary Care

1 Complete the following:

Height

Weight

Age

Male / Female

Category 1

2 Do you snore?

- Yes No
 Don't know

If you snore:

3 Your snoring is?

- Slightly louder than breathing
 As loud as talking
 Louder than talking
 Very loud. Can be heard in adjacent rooms.

4 How often do you snore

- Nearly every day 3-4 times a week
 1-2 times a week 1-2 times a month
 Never or nearly never

5 Has your snoring ever bothered other people?

- Yes No

6 Has anyone noticed that you quit breathing during your sleep?

- Nearly every day 3-4 times a week
 1-2 times a week 1-2 times a month
 Never or nearly never

Category 2

7 How often do you feel tired or fatigued after your sleep?

- Nearly every day 3-4 times a week
 1-2 times a week 1-2 times a month
 Never or nearly never

8 During your waketime, do you feel tired, fatigued or not up to par?

- Nearly every day 3-4 times a week
 1-2 times a week 1-2 times a month
 Never or nearly never

9 Have you ever nodded off or fallen asleep while driving a vehicle?

- Yes No

If yes: how often does it occur?

- Nearly every day 3-4 times a week
 1-2 times a week 1-2 times a month
 Never or nearly never

Category 3

10 Do you have high blood pressure?

- Yes No
 Don't know

BMI =

Scoring questions: Any answer within box outline is a positive response.

Scoring categories:

Category 1 is positive with 2 or more positive responses to questions 2-6

Category 2 is positive with 2 or more positive responses to questions 7-9

Category 3 is positive with 1 positive response and / or a BMI >30

Final result: 2 or more positive categories indicates a high likelihood of sleep disordered breathing.

Appendix V:

Abbreviations and acronyms

AUC	Area under the receiver operating characteristic curve (analysis)	NICE	National Institute for Health and Clinical Excellence
BMI	Body mass index	NIH	National Institutes of Health
CI	95% confidence interval	Non-CCR	Non-clomiphene citrate resistant
CVD	Cardiovascular disease	COCP	Combined oral contraceptive pill
CCR	Clomiphene citrate resistant	OGTT	Oral glucose tolerance test
Dietitian	Accredited Practising Dietitian	OHSS	Ovarian hyperstimulation syndrome
DM2	Type 2 diabetes mellitus	OR	Odds ratio
FBG	Fasting blood glucose	OSA	Obstructive sleep apnea
FSH	Follicle stimulating hormone	PCOM	Polycystic ovary morphology
GAD	Generalised Anxiety disorder scale	PCOS	Polycystic ovary syndrome
GDM	Gestational Diabetes	PCOSQ	PCOS quality of life questionnaire
GnRH	Gonadotrophin releasing hormone	PHQ	Patient Health questionnaire
hCG	Human Chorionic Gonadotrophin	OR	Odds ratio
ICSI	Intracytoplasmic sperm injection	PCO	Polycystic ovary
IGT	Impaired glucose tolerance	PCOS	Polycystic ovary syndrome
HbA1c	Glycated haemoglobin	PICO	Participants / Population, Intervention / Exposure, Comparison/Control, Outcome
HDL-C	High density lipoprotein cholesterol	POSAA	Polycystic Ovary Syndrome Association Australia
HOMA-IR	Homeostasis model of assessment-insulin resistance	QoL	Quality of life
IR	Insulin resistance	RCT	Randomised controlled trial
IVM	In vitro maturation	RR	Relative risk
IVF	In vitro fertilisation	SHBG	Sex hormone-binding globulin
LDL-C	Low density lipoprotein cholesterol	TGA	Therapeutic Goods Administration (Australian Government)
LH	Luteinising hormone	P-value	Measure of statistical precision
MPCOSQ	Modified PCOS quality of life questionnaire		

Appendix VI:

Glossary

Sources for this glossary include: The Cochrane Resources Glossary (<http://www.cochrane.org/glossary/5>), Jean Hailes for Women's Health (<http://www.jeanhailes.org.au>), Diabetes Australia (<http://www.diabetesaustralia.com.au>), Better Health Channel (<http://www.betterhealth.vic.gov.au>), the 2009 NHMRC Clinical practice guideline for the prevention of venous thromboembolism (deep vein thrombosis and pulmonary embolism) in patients admitted to Australian hospitals [607] and the 2009 NHMRC levels of evidence and grades for recommendations for developers of guidelines [608].

Adverse effect	An adverse event for which the causal relation between the drug/intervention and the event is at least a reasonable possibility.
Aerobic exercise/activity	Any physical activity that produces energy by combining oxygen with blood glucose or body fat.
AGREE II	An international collaboration of researchers and policy makers whose aim is to improve the quality and effectiveness of clinical practice guidelines (http://www.agreertrust.org). The AGREE II instrument developed by the collaboration is designed to assess the quality of clinical guidelines.
Algorithm	A flow chart of the clinical decision pathway described in the guideline, where recommendations are presented in boxes, linked with arrows.
Anovulation	A condition in which the ovary does not produce and release an egg each menstrual cycle.
Anxiety	When fears or thoughts that are chronic (constant) and distressing interfere with daily living.
Area under the receiver operating characteristic curve (AUC)	In this guideline, it is used as a method of analysis that measures the ability and reliability of a risk assessment method or diagnostic test to correctly identify the optimal balance between false-positive and false-negative tests.
Assess	In this guideline, assess refers to the process of identifying the severity of the condition
Blood pressure	Blood pressure is the pressure of the blood in the arteries as it is pumped around the body by the heart.
Body image	The way a person may feel, think and view their body including their appearance.
Body mass index (BMI)	A calculated number used to discriminate between lean, overweight, obesity and morbid obesity, calculated from an individual's height (kg) and weight (m). $\text{BMI} = (\text{weight}/\text{height})^2$
Cardiometabolic	Metabolic factors that increase the risk of cardiovascular disease.
Cardiovascular disease (CVD)	A condition that affects either the heart or major blood vessels (arteries) supplying the heart, brain and other parts of the body.
Clinical impact	The potential benefit from application of the recommendations in the guideline on the treatment or treatment outcomes of the target population.
Clinical question (guideline development)	One of a set of questions about an intervention or process that define the content of the evidence reviews and subsequent recommendations in the guideline.

Clomiphene citrate resistant (CCR)	When the patient is unable to ovulate with clomiphene citrate treatment.
Clomiphene citrate failure	When the patient is able to ovulate with clomiphene citrate treatment but does not conceive.
Clomiphene citrate sensitive	When the patient is able to ovulate and conceive with clomiphene citrate treatment.
Cochrane review	Cochrane Reviews are systematic summaries of evidence of the effects of healthcare interventions. The specific methods used in a Review are described in the text of the review. Cochrane Reviews are prepared using Review Manager (RevMan) software provided by the Collaboration, and adhere to a structured format that is described in the Cochrane Handbook for Systematic Reviews of Interventions.
Co-morbidity	The presence of one or more diseases or conditions other than those of primary interest. In a study looking at treatment for one disease or condition, some of the individuals may have other diseases or conditions that could affect their outcomes. (A co-morbidity may be a confounder.)
Compliance	The extent to which a person adheres to the health advice agreed with healthcare professionals. May also be referred to as 'adherence' or 'concordance'.
Confidence interval	A range of values for an unknown population parameter with a stated 'confidence' (conventionally 95%) that it contains the true value. The interval is calculated from sample data, and generally straddles the sample estimate. The 'confidence' value means that if the method used to calculate the interval is repeated many times, then that proportion of intervals will actually contain the true value.
Congenital adrenal hyperplasia	Congenital adrenal hyperplasia is a condition where the enzyme needed by the adrenal gland to make the hormones cortisol and aldosterone is lacking and thus the body produces more androgen and causes male characteristics to appear early or inappropriately.
Consensus methods	Techniques that aim to reach an agreement on a particular issue. Formal consensus methods include Delphi and nominal group techniques, and consensus development conferences. In the development of clinical guidelines, consensus methods may be used where there is a lack of strong research evidence on a particular topic. Expert consensus methods will aim to reach agreement between experts in a particular field.
Contraindication	A condition or factor that serves as a reason to withhold a certain medical treatment.
Depression	Depression is more than low mood and sadness at a loss and is a serious medical illness. It is the result of chemical imbalances in the brain. The sufferer feels extremely sad, dejected and unmotivated.
Diagnostic accuracy	The accuracy of a test to diagnose a condition which can be expressed through sensitivity and specificity, positive and negative predictive values, or positive and negative diagnostic likelihood ratios.
Disordered eating	Eating and weight related symptoms commonly associated with an eating disorder including behavioural (e.g. bingeing, restriction), cognitive (e.g. dietary restraint, negative body image) and emotional (e.g. Emotional eating) factors.
Dosage	The prescribed amount of a drug to be taken, including the size and timing of the doses.
Eating disorder	Eating disorders include anorexia, bulimia nervosa and other binge eating disorders.
Effect (as in effect measure, treatment effect, estimate of effect, effect size)	The observed association between interventions and outcomes or a statistic to summarise the strength of the observed association.

Evidence statement table	A table summarising the results of a collection of studies which, taken together, represent the evidence supporting a particular recommendation or series of recommendations in a guideline.
Exclusion criteria (for a systematic evidence review)	Explicit criteria used to decide which studies should be excluded from consideration as potential sources of evidence.
Heterogeneity	<p>Describes the variation in, or diversity of, participants, interventions, and measurement of outcomes across a set of studies, or the variation in internal validity of those studies. It can be used specifically, as statistical heterogeneity, to describe the degree of variation in the effect estimates from a set of studies. Also used to indicate the presence of variability among studies beyond the amount expected due solely to the play of chance.</p> <p>The term is used in meta-analyses and systematic reviews when the results or estimates of effects of treatment from separate studies seem to be very different – in terms of the size of treatment effects or even to the extent that some indicate beneficial and others suggest adverse treatment effects. Such results may occur as a result of differences between studies in terms of the patient populations, outcome measures, definition of variables or duration of follow-up.</p>
Hormonal profile	Cyclical levels of hormones.
Hyperandrogenism	<p>Clinical hyperandrogenism is characterised by hirsutism, acne and male pattern alopecia.</p> <p>Biochemical hyperandrogenism is characterised by excessive production and/or secretion of androgens.</p>
Impaired fasting glucose	When fasting morning blood glucose levels are higher than normal but not high enough to diagnose diabetes.
Impaired glucose tolerance	When glucose levels are above normal during or after an oral glucose tolerance test but are not high enough to diagnose diabetes.
Incidence	The number of new occurrences of something in a population over a particular period of time, e.g. the number of cases of a disease in a country over one year.
Inclusion criteria (for a systematic evidence review)	Explicit criteria used to decide which studies should be considered as potential sources of evidence.
Infertility (women)	Infertility problems in women include failure to ovulate, blockages in the fallopian tubes, and disorders of the uterus, such as fibroids or endometriosis.
Interdisciplinary care	An interdisciplinary care model is the collaboration between a woman with PCOS and a care team who have shared goals for her total wellbeing.
Intervention	Any action intended to benefit the patient, for example, drug treatment, surgical procedure, psychological therapy.
Insulin resistance (IR)	A rise in glucose occurs because the body can't make enough insulin or the insulin produced is not working properly.
Irregular cycles / oligomenorrhea	When the duration of menstrual cycles is > 35 or < 21 days.
Laparoscopy	A medical procedure used to examine the interior of the abdominal or pelvic cavities to diagnose or treat (or both) a number of different diseases and conditions, including female infertility.
Lean	BMI ≤ 25kg/m ²

Lipid profile	A group of blood tests that are often ordered together to determine risk of cardiovascular disease, including total cholesterol, HDL-C, LDL-C and triglycerides.
Menarche	The onset of the first period of the menstrual cycle, which occurs on average between the ages of 11 and 14 years.
Meta-analysis	A statistical technique for combining (pooling) the results of a number of studies that address the same question and report on the same outcomes to produce a summary result. The aim is to derive more precise and clear information from a large data pool. It is generally more reliably likely to confirm or refute a hypothesis than the individual trials.
Morbidly obese	BMI $\geq 35\text{kg/m}^2$
Non-clomiphene citrate resistant (Non-CCR)	Those who are either clomiphene citrate sensitive or who have unknown clomiphene citrate sensitivity.
Obese	BMI $\geq 30\text{-}35\text{kg/m}^2$
Odds ratio (OR)	The ratio of the odds of an event in one group to the odds of an event in another group. In studies of treatment effect, the odds in the treatment group are usually divided by the odds in the control group. An odds ratio of one indicates no difference between comparison groups. For undesirable outcomes an OR that is less than one indicates that the intervention was effective in reducing the risk of that outcome.
Oligo-anovulation	Clinically, irregular cycles lasting <21 or more than 35 days or less than 8 periods per year. Metabolically, hormonally and reproductively, the absence of raised serum progesterone greater than 20nmol/l 7 days prior to a period.
Oligomenorrhea / irregular cycles	When the duration of menstrual cycles is >35 or <21 days.
Oral glucose tolerance test (OGTT)	A test to diagnose diabetes where a high-glucose drink is given and blood samples are checked at regular intervals for two hours.
Ovarian hyperstimulation syndrome (OHSS)	A condition where too many follicles develop (following ovulation induction) which can result in marked abdominal swelling, nausea, vomiting and diarrhoea, lower abdominal pain and shortness of breath.
Overweight	BMI $\geq 25.1\text{-}30\text{kg/m}^2$
Ovulation	Ovulation is the release of an egg from one of the ovaries.
Ovulation induction	Ovulation induction is the use of medication to stimulate the ovary to increase egg production.
Polycystic ovaries	Characterised by clusters of blister-like cysts on the ovary.
Polycystic ovary syndrome (PCOS)	PCOS is a chronic metabolic and hormonal condition, which can impact on physical health and emotional wellbeing.
Placebo	An inactive substance or preparation used as a control in an experiment or test to determine the effectiveness of a medicinal drug. Placebos are used in clinical trials to blind people to their treatment allocation. Placebos should be indistinguishable from the active intervention to ensure adequate blinding.
Post-operative	The period after a patient leaves the operating theatre, following surgery.
Prediabetes	Where blood glucose levels are higher than normal, but not high enough to be classified as diabetes. Pre-diabetes includes impaired fasting glucose and impaired glucose tolerance.
Pre-operative	The period before surgery commences.
Psychosexual dysfunction	Sexual problems or difficulties that have a psychological origin based in cognitions and/or emotions such as depression, low self-esteem and negative body image.

P value	Measure of statistical precision. The probability that an observed difference could have occurred by chance, assuming that there is in fact no underlying difference between the means of the observations. If the probability is less than 1 in 20, the P value is less than 0.05; a result with a P value of less than 0.05 is conventionally considered to be 'statistically significant'.
Randomisation	Allocation of participants in a research study to two or more alternative groups using a chance procedure, such as computer-generated random numbers. This approach is used in an attempt to ensure there is an even distribution of participants with different characteristics between groups and thus reduce sources of bias.
Randomised controlled trial (RCT)	A comparative study in which participants are randomly allocated to two or more alternative groups and followed up to examine differences in outcomes between the groups.
Resource implication	The likely impact of the recommendation in terms of cost, workforce or other health system resources.
Risk of bias	Also called methodological quality, it is the degree to which the results of a study are likely to approximate the 'truth' for the participants recruited in a study (that is, are the results free of bias?). It refers to the integrity of the design and specifically the extent to which the design and conduct of a study are likely to have prevented bias. More rigorously designed (better quality, low risk of bias) trials are more likely to yield results that are closer to the truth.
Relative risk (RR)	The ratio of risks in two groups. In intervention studies, it is the ratio of the risk in the intervention group to the risk in the control group. A relative risk (also called risk ratio) of one indicates no difference between comparison groups. For undesirable outcomes, a relative risk that is less than one indicates that the intervention was effective in reducing the risk of that outcome.
Screen	In this guideline, screen refers to the process of identifying whether the condition exists and is the first step in offering appropriate management
Selection criteria	Explicit standards used by guideline development groups to decide which studies should be included and excluded from consideration as potential sources of evidence.
Stakeholder	Those with an interest in the topic. Stakeholders include healthcare professionals, patient/consumer and carer groups, manufacturers and sponsors.
Statistical power	The ability to demonstrate an association when one exists. Power is related to sample size; the larger the sample size, the greater the power and the lower the risk that a possible association could be missed.
Systematic review	A review of a clearly formulated question that uses systematic and explicit methods to identify, select, and critically appraise relevant research, and to collect and analyse data from the studies that are included in the review. Statistical methods (meta-analysis) may or may not be used to analyse and summarise the results of the included studies.
Therapy naive	A patient who has not been administered prior treatment for the condition.
Type 2 diabetes mellitus (DM2)	When the pancreas makes some insulin but it is not produced in the amount your body needs and it does not work effectively. Type 2 diabetes results from a combination of genetic and environmental factors and risk is greatly increased when associated with lifestyle factors such as high blood pressure, overweight or obesity, insufficient physical activity, poor diet and the classic 'apple shape' body where extra weight is carried around the waist.

Appendix VII:

Evidence-based guideline development pathway

Diagram 1: Key steps in seeking NHMRC approval of externally developed guidelines

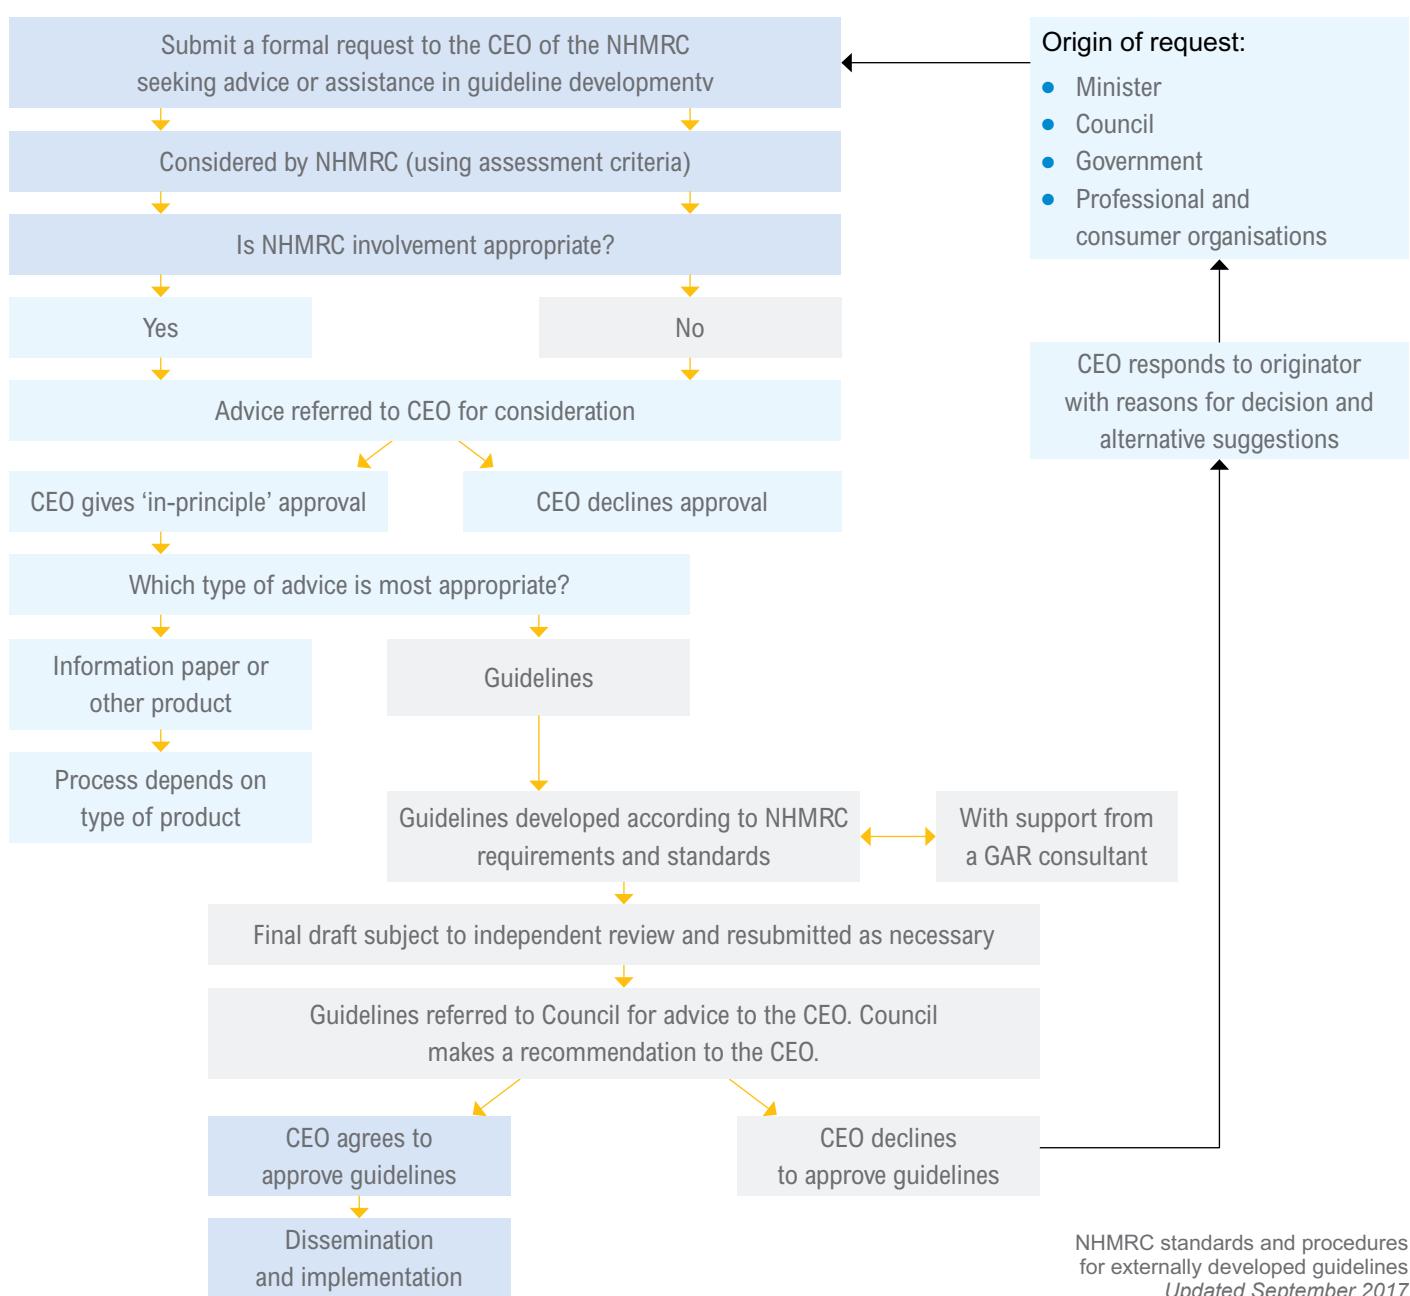

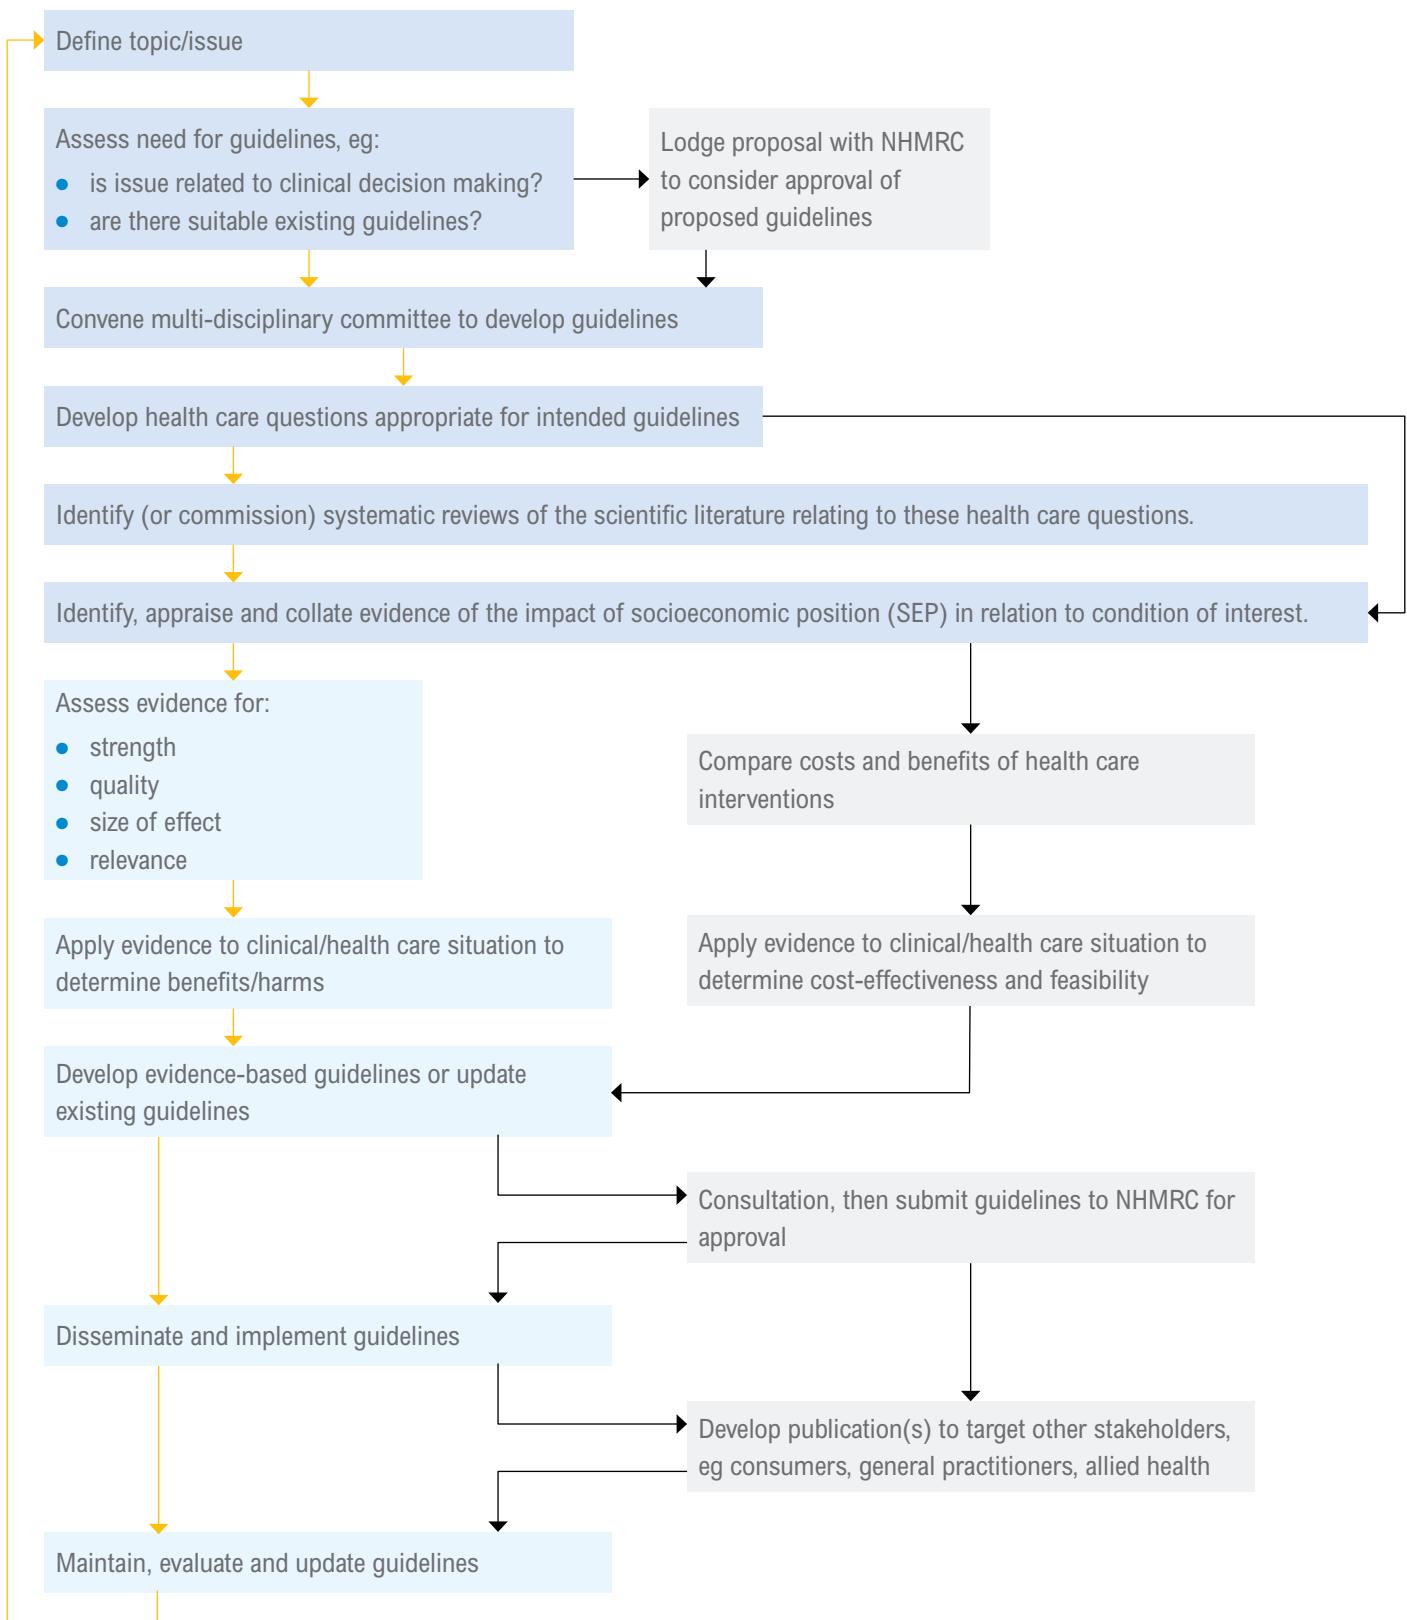

Diagram 2:

Flow chart of the NHMRC's development process for evidence-based guidelines

NHMRC standards and procedures for externally developed guidelines
Updated September 2007

Appendix VIII:

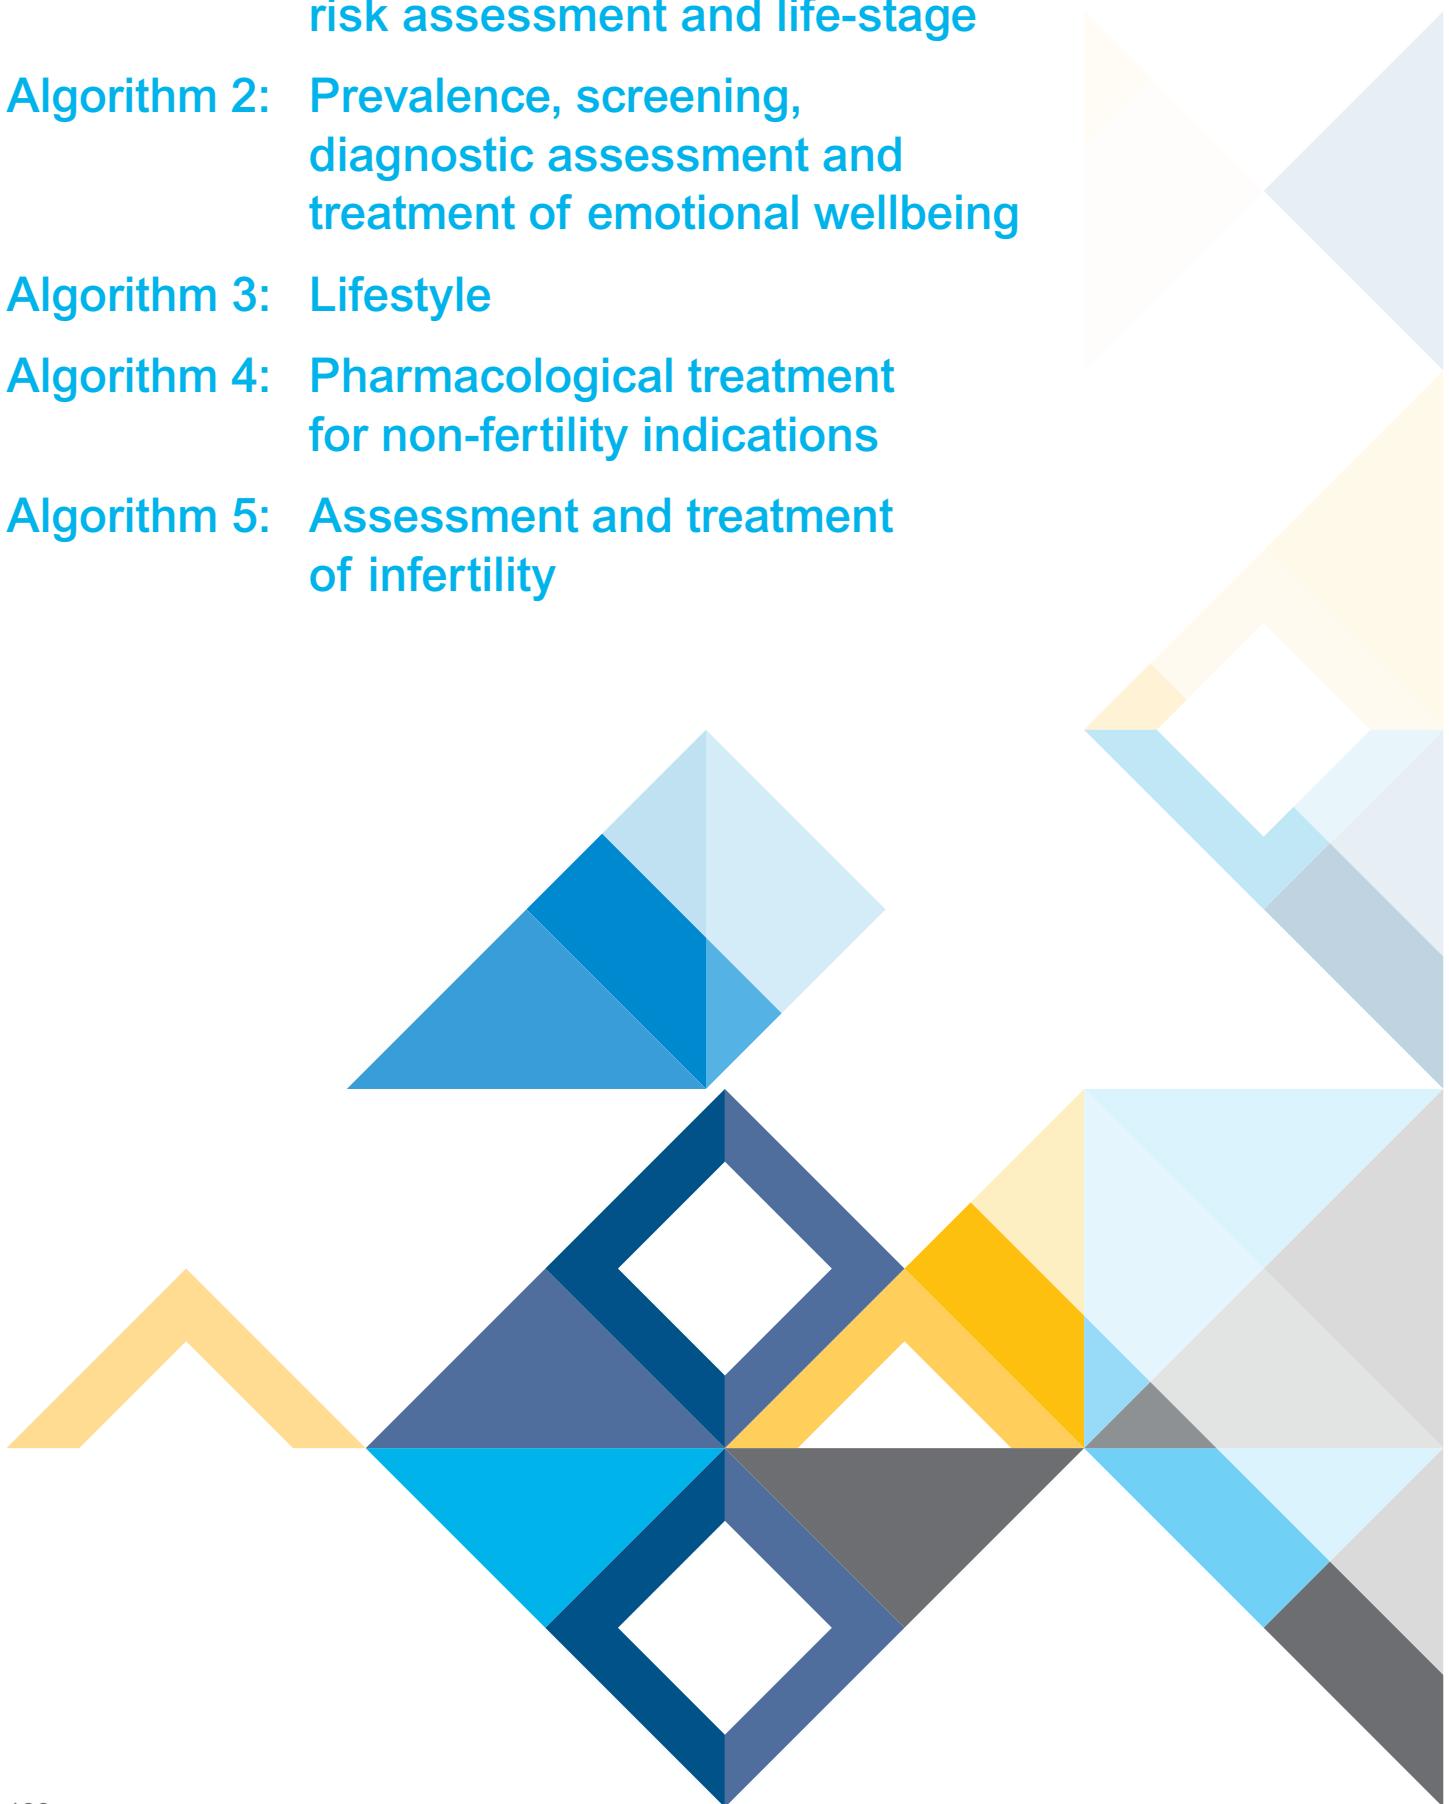

Algorithm 1: Screening, diagnostic assessment, risk assessment and life-stage

Algorithm 2: Prevalence, screening, diagnostic assessment and treatment of emotional wellbeing

Algorithm 3: Lifestyle

Algorithm 4: Pharmacological treatment for non-fertility indications

Algorithm 5: Assessment and treatment of infertility

Algorithm 1: Screening, diagnostic assessment, risk assessment and life-stage

Step 1: Irregular cycles + clinical hyperandrogenism

(exclude other causes)* = diagnosis

Step 2: If no clinical hyperandrogenism

Test for biochemical hyperandrogenism (exclude other causes)* = diagnosis

Step 3: If ONLY irregular cycles OR hyperandrogenism

Adolescents ultrasound is not indicated = consider at risk of PCOS and reassess later

Adults - request ultrasound for PCOM, if positive (exclude other causes)* = diagnosis

* Exclusion of other causes requires TSH, Prolactin levels, FSH and if clinical status indicates other causes need to be excluded
(e.g. CAH, Cushings, adrenal tumours etc)

Hypogonadotropic hypogonadism, generally due to low body fat or intensive exercise, should also be excluded clinically and with LH and FSH levels.

Diagnostic Criteria

Irregular menstrual cycles

- normal in the first year post menarche = pubertal transition.
- > 1 to < 3 years post menarche: < 21 or > 45 days.
- > 3 years post menarche to perimenopause: < 21 or > 35 days or < 8 cycles per year.
- > 1 year post menarche > 90 days for any one cycle.
- Primary amenorrhea by age 15 or > 3 years post thelarche (breast development).

With irregular cycles, PCOS should be considered and assessed according to the guidelines.

Ovulatory dysfunction can still occur with regular cycles. If anovulation suspected test progesterone levels.

Clinical hyperandrogenism

Comprehensive history and physical examination for clinical hyperandrogenism. Adults: acne, alopecia and hirsutism and in adolescents severe acne and hirsutism.

Be aware of potential negative psychosocial impact of clinical hyperandrogenism. Perception of unwanted face and body hair and/or alopecia are important, regardless of apparent clinical severity.

Standardised visual scales are preferred when assessing hirsutism such as the modified Ferriman Gallway score (mFG). A cut-off score of ≥ 4 -6 indicates hirsutism, depending on ethnicity. It is acknowledged that self-treatment is common and can limit clinical assessment.

The Ludwig visual score is preferred for assessing the degree and distribution of alopecia.

Hirsutism prevalence is same across ethnicities. mFG cut-offs for hirsutism and severity, vary by ethnicity.

Only terminal hairs relevant in pathological hirsutism (untreated > 5 mm long, variable shape and pigmented).

Biochemical hyperandrogenism

Use calculated free testosterone, free androgen index or calculated bioavailable testosterone in diagnosis.

Androstenedione and dehydroepiandrosterone sulfate (DHEAS) have limited role in PCOS diagnosis.

High quality assays needed for most accurate assessment. Direct free testosterone assays not preferred. Interpretation of androgen levels should be guided by the reference ranges of the laboratory used.

Reliable assessment of biochemical hyperandrogenism not possible on hormonal contraception. Consider withdrawal for ≥ 3 months before testing, advising non-hormonal contraception during this time.

In diagnosis, biochemical hyperandrogenism most useful when clinical hyperandrogenism is unclear.

Where levels are well above laboratory reference ranges, other causes should be considered. History of symptom onset and progression is critical in assessing for neoplasia, however, some androgen-secreting neoplasms may only induce mild to moderate increases in biochemical hyperandrogenism.

Ultrasound and polycystic ovarian morphology (PCOM)

Ultrasound should not be used for the diagnosis of PCOS in those with a gynaecological age of < 8 years (< 8 years after menarche), due to the high incidence of multi-follicular ovaries in this life stage.

The transvaginal ultrasound approach is preferred in the diagnosis of PCOS, if sexually active and if acceptable to the individual being assessed.

Using endovaginal ultrasound transducers with a frequency bandwidth that includes 8MHz, the threshold for PCOM should be a follicle number per ovary of ≥ 20 and/or an ovarian volume $\geq 10\text{ml}$ on either ovary, ensuring no corpora lutea, cysts or dominant follicles are present.

If using older technology, the threshold for PCOM could be an ovarian volume $\geq 10\text{ml}$ on either ovary.

In patients with irregular menstrual cycles and hyperandrogenism, an ovarian ultrasound is not necessary for PCOS diagnosis; however ultrasound will identify the complete PCOS phenotype.

Transabdominal ultrasound should primarily report ovarian volume with a threshold of $\geq 10\text{ml}$, given the difficulty of reliably assessing follicle number with this approach.

Ethnic variation

Consider ethnic variation in PCOS including:

- relatively mild phenotypes in Caucasians.
- higher BMI in Caucasians, especially North America and Australia.
- more severe hirsutism in Middle Eastern, Hispanic and Mediterranean women.
- increased central adiposity, insulin resistance, diabetes, metabolic risks and acanthosis nigricans in South East Asians and Indigenous Australians.
- lower BMI and milder hirsutism in East Asians.
- higher BMI and metabolic features in Africans.

Anti-müllerian hormone (AMH)

Serum AMH levels should not yet be used as an alternative for the detection of PCOM or to diagnose PCOS.

Cardiovascular disease risk and weight management

All with PCOS should be offered regular monitoring for weight change and excess weight, in consultation with and where acceptable to the individual. Monitoring could be at each visit or at a minimum 6-12 monthly, with frequency planned and agreed between the health professional and the individual.

Weight, height and ideally waist circumference should be measured and BMI calculated.

- BMI categories and waist circumference should follow World Health Organisation guidelines also noting ethnic and adolescent ranges.
- Consideration for Asian and high risk ethnic groups including monitoring waist circumference.

All with PCOS should be assessed for individual cardiovascular risk factors and global CVD risk.

If screening reveals CVD risk factors including obesity, cigarette smoking, dyslipidemia, hypertension, impaired glucose tolerance and lack of physical activity, women with PCOS should be considered at increased risk of CVD.

Overweight and obese women with PCOS, regardless of age, should have a fasting lipid profile (total cholesterol, low density lipoprotein cholesterol, high density lipoprotein cholesterol and triglyceride level at diagnosis). Thereafter, measurement should be guided by the results and the global CVD risk.

All women with PCOS should have blood pressure measured annually.

CVD risk in women with PCOS remains unclear pending high quality studies, however prevalence of CVD risk factors is increased, warranting awareness and consideration of screening.

Gestational diabetes, impaired glucose tolerance and type 2 diabetes

Regardless of age, gestational diabetes, impaired glucose tolerance and type 2 diabetes (5 fold in Asia, 4 fold in the Americas and 3 fold in Europe) are increased in PCOS, with risk independent of, yet exacerbated by obesity.

Glycaemic status should be assessed at baseline in all with PCOS and thereafter, every one to three years, based on presence of other diabetes risk factors.

In high risk women with PCOS (including a BMI > 25kg/m² or in Asians > 23kg/m², history of abnormal glucose tolerance or family history of diabetes, hypertension or high risk ethnicity) an oral glucose tolerance test (OGTT) is recommended. Otherwise a fasting glucose or HbA1c should be performed.

An OGTT should be offered in all with PCOS when planning pregnancy or seeking fertility treatment, given increased hyperglycaemia and comorbidities in pregnancy.

If not performed preconception, an OGTT should be offered at < 20 weeks gestation, and all women with PCOS should be offered the test at 24-28 weeks gestation

Obstructive sleep apnea (OSA)

Screening should only be considered for OSA in PCOS to identify and alleviate related symptoms, such as snoring, waking unrefreshed from sleep, daytime sleepiness, and the potential for fatigue to contribute to mood disorders. Screening should not be considered with the intention of improving cardiometabolic risk, with inadequate evidence for metabolic benefits of OSA treatment in PCOS and in general populations.

A simple screening questionnaire, preferably the Berlin tool, could be applied and if positive, referral.

A positive screen raises the likelihood of OSA, however it does not quantify symptom burden and alone does not justify treatment. If women with PCOS have OSA symptoms and a positive screen, they should ideally be referred to a specialist centre for further evaluation.

Endometrial cancer

Health professionals and women with PCOS should be aware of a two to six fold increased risk of endometrial cancer, which often presents before menopause; however absolute risk remains relatively low.

Health professionals should have a low threshold for investigation of endometrial cancer in PCOS, with transvaginal ultrasound and/or endometrial biopsy recommended with persistent thickened endometrium and/or risk factors including prolonged amenorrhea, abnormal vaginal bleeding or excess weight. Routine ultrasound screening of endometrial thickness in PCOS is not recommended.

Optimal prevention for endometrial hyperplasia and endometrial cancer is not known. A pragmatic approach could include COCP or progestin therapy in those with cycles longer than 90 days.

Algorithm 2: Prevalence, screening, diagnostic assessment and treatment of emotional wellbeing

Psychological domains	Screening protocol / tools	Intervention
Quality of life (QoL)	Lower QoL scores in general and PCOS specific tools such as the modified PCOSQ tool.	Capture and consider women's perceptions of their symptoms, impact on their QoL and priorities. Target treatment to areas of greatest concern to those with PCOS.
Anxiety and depressive symptoms	<p>High prevalence of moderate to severe anxiety and depressive symptoms in adults; and a likely increased prevalence in adolescents.</p> <p>Routine screening for all at diagnosis and subsequently based on clinical judgement, considering risk factors, comorbidities and life events.</p> <p>Suggested screening based on regional guidelines OR initial questions could include:</p> <p>Over the last 2 weeks, how often have you been bothered by the following problems:</p> <ul style="list-style-type: none"> • Feeling down, depressed or hopeless? • Little interest or pleasure in doing things? • Feeling nervous, anxious or on edge? • Not being able to stop or control worrying? <p>* Factors including obesity, infertility, hirsutism need consideration along with use of hormonal medications in PCOS, which may independently exacerbate depressive and anxiety symptoms and other aspects of emotional wellbeing.</p>	<p>If responses to initial screening questions positive:</p> <p>Assess risk factors and symptoms using age, culturally and regionally appropriate tools, such as the Patient Health Questionnaire (PHQ) or the Generalised Anxiety Disorder Scale (GAD7) and/or refer to an appropriate professional for further assessment.</p> <ul style="list-style-type: none"> • If treatment is warranted, psychological therapy and/or pharmacological treatment should be offered to women with PCOS, informed by regional clinical practice guidelines. <p>Pharmacological treatment:</p> <p>Avoid inappropriate treatment with antidepressants or anxiolytics and consider impact on weight. Where mental health disorders are clearly documented and persistent, or if suicidal symptoms are present, treatment of depression or anxiety should be informed by clinical regional practice guidelines.</p>
Psychosexual dysfunction	<p>Decreased scores on sexual function screen.</p> <p>If concerns identified, screen adult women with PCOS.</p> <p>Note: Obesity and infertility are common in PCOS and also impact sexual function.</p>	If psychosexual dysfunction is suspected, further assessment, referral or treatment should follow as appropriate.
Body Image	<p>Negative body image has been described in PCOS and can be screened based on regional guidelines or by a stepped approach.</p> <p>Initial questions could include:</p> <ul style="list-style-type: none"> • Do you worry a lot about the way you look and wish you could think about it less? • On a typical day, do you spend more than 1 hour per day worrying about your appearance? • What specific concerns do you have about your appearance? • What effect does it have on your life? • Does it make it hard to do your work or be with your friends and family? 	Consider the impact of PCOS features such as hirsutism, acne, and weight gain in assessing and addressing body image in PCOS.
Eating disorders and disordered eating	<p>High prevalence of eating disorders and disordered eating has been described and can be screened based on regional guidelines or by using the following stepped approach.</p> <p>Initial screening questions can include:</p> <ul style="list-style-type: none"> • Does your weight affect the way you feel about yourself? • Are you satisfied with your eating patterns? <p>Or the SCOFF tool can be used.</p>	<p>If concerns are identified, further screening should involve:</p> <ul style="list-style-type: none"> • Assessment of risk factors and symptoms using age, culturally and regionally appropriate tools. • Referral to an appropriate health professional for further mental health assessment and diagnostic interview. If this is not the patient's usual healthcare provider, inform.

Algorithm 3: Lifestyle

Lifestyle

Effectiveness of lifestyle interventions

Healthy lifestyle behaviours (healthy eating and regular physical activity) should be recommended in all women with PCOS including those with excess weight, to achieve and/or maintain healthy weight and to optimise health, and quality of life across the life course. Ethnic groups at high cardiometabolic risk require more consideration.

Achievable goals such as 5% to 10% weight loss in those with excess weight yields significant clinical improvements and is considered successful weight reduction within six months. Ongoing monitoring is important in weight loss and maintenance. Consider referral to a professional to assist with healthy lifestyle.

SMART (Specific, Measurable, Achievable, Realistic and Timely) goal setting and self-monitoring can enable achievement of realistic lifestyle goals.

Psychological factors such as anxiety and depressive symptoms, body image concerns and disordered eating need consideration to optimise healthy lifestyle engagement.

All patient interactions should be patient-centred and value women's individualised healthy lifestyle preferences and cultural, socioeconomic and ethnic differences.

Adolescent and ethnic-specific body mass index and waist circumference categories should be considered when optimising lifestyle and weight.

Behavioural strategies

Lifestyle interventions (may also include cognitive behavioural interventions) could include goal-setting, self-monitoring, stimulus control, problem solving, assertiveness training, slower eating, reinforcing changes and relapse prevention, to optimise weight management, healthy lifestyle and emotional wellbeing in women with PCOS.

Dietary intervention

General healthy eating principles should be followed for all women with PCOS across the life course, with no one dietary type recommended in PCOS.

To achieve weight loss in those with excess weight, an energy deficit of 30% or 500 - 750 kcal/day (1,200 - 1,500 kcal/day) could be prescribed for women, also considering individual energy requirements, body weight, food preferences and physical activity levels and an individualised approach.

Exercise intervention

Health professionals should encourage and advise the following for prevention of weight gain and maintenance of health:

- in adults from 18-64 years, a minimum of 150 min/week of moderate intensity physical activity or 75 min/week of vigorous intensities or an equivalent combination of both including muscle strengthening activities on 2 non-consecutive days/week.
- in adolescents, at least 60 minutes of moderate to vigorous intensity physical activity/day including those that strengthen muscle and bone at least 3 times weekly.
- activity be performed in at least 10 minute bouts or around 1000 steps, aiming to achieve at least 30 minutes daily on most days.

Health professionals should encourage and advise the following for modest weight-loss, prevention of weight-regain and greater health benefits including:

- a minimum of 250 min/week of moderate intensity activities or 150 min/week of vigorous intensity or an equivalent combination of both, and
- muscle strengthening activities involving major muscle groups on 2 non-consecutive days/week and minimised sedentary, screen or sitting time.

Physical activity can be incidental or structured. Self-monitoring, including with fitness tracking devices and technologies, could support and promote active lifestyles.

Obesity and weight assessment

Women with PCOS have higher weight gain and obesity which can impact health and emotional wellbeing. In addressing this, consider related stigma, negative body image and/or low self-esteem by use of a respectful and considerate approach, considering personal sensitivities, marginalisation and potential weight-related stigma.

Prevention of weight gain, monitoring of weight and encouraging evidence-based and socio-culturally appropriate healthy lifestyle is important in PCOS from adolescence.

Algorithm 4: Pharmacological treatment for non-fertility indications

Off label prescribing: COCPs, metformin and other pharmacological treatments are generally off label in PCOS, as pharmaceutical companies have not applied for approval in PCOS. However, off label use is predominantly evidence-based and is allowed in many countries. Where it is allowed, health professionals should inform women and discuss the evidence, possible concerns and side effects of treatment.

In those with a clear PCOS diagnosis or in adolescents at risk of PCOS (with symptoms)

Education + lifestyle + first line pharmacological therapy for hyperandrogenism and irregular cycles

COCP First line

Use lowest effective oestrogen dose (20-30 micrograms ethinyl oestradiol or equivalent)

Consider natural oestrogen preparations balancing efficacy, metabolic risk profile, side effects, cost and availability

Follow WHO COCP general population guidelines for relative and absolute contraindications and risks

35 micrograms ethynodiol diacetate plus cyproterone acetate not first line in PCOS due to increased adverse effects

Hirsutism requires COCP and additional cosmetic therapy for at least 6 months

Consider additional PCOS related risk factors such as high BMI, hyperlipidemia and hypertension

Note:

Other contraceptives don't increase hepatic SHBG production with limited efficacy for hyperandrogenism

Second line pharmacological therapies

COCP + lifestyle + metformin

No COCP preparation is superior in PCOS.

Should be considered in women with PCOS for management of metabolic features, where COCP + lifestyle does not achieve goals.

Could be considered in adolescents with PCOS and $BMI \geq 25\text{kg}/\text{m}^2$ where COCP and lifestyle changes do not achieve desired goals.

Most beneficial in high metabolic risk groups including those with diabetes risk factors, impaired glucose tolerance or high-risk ethnic groups.

COCP + anti-androgens

Evidence in PCOS relatively limited.

Anti-androgens must be used with contraception to prevent male fetal virilisation.

Can be considered after 6/12 cosmetic treatment + COCP if they fail to reach hirsutism goals.

Can be considered with androgenic alopecia.

Metformin + lifestyle

With lifestyle, in adults should be considered for weight, hormonal and metabolic outcomes and could be considered in adolescents.

Most useful with $BMI \geq 25\text{kg}/\text{m}^2$ and in high risk ethnic groups.

Side-effects, including GI effects, are dose related and self-limiting.

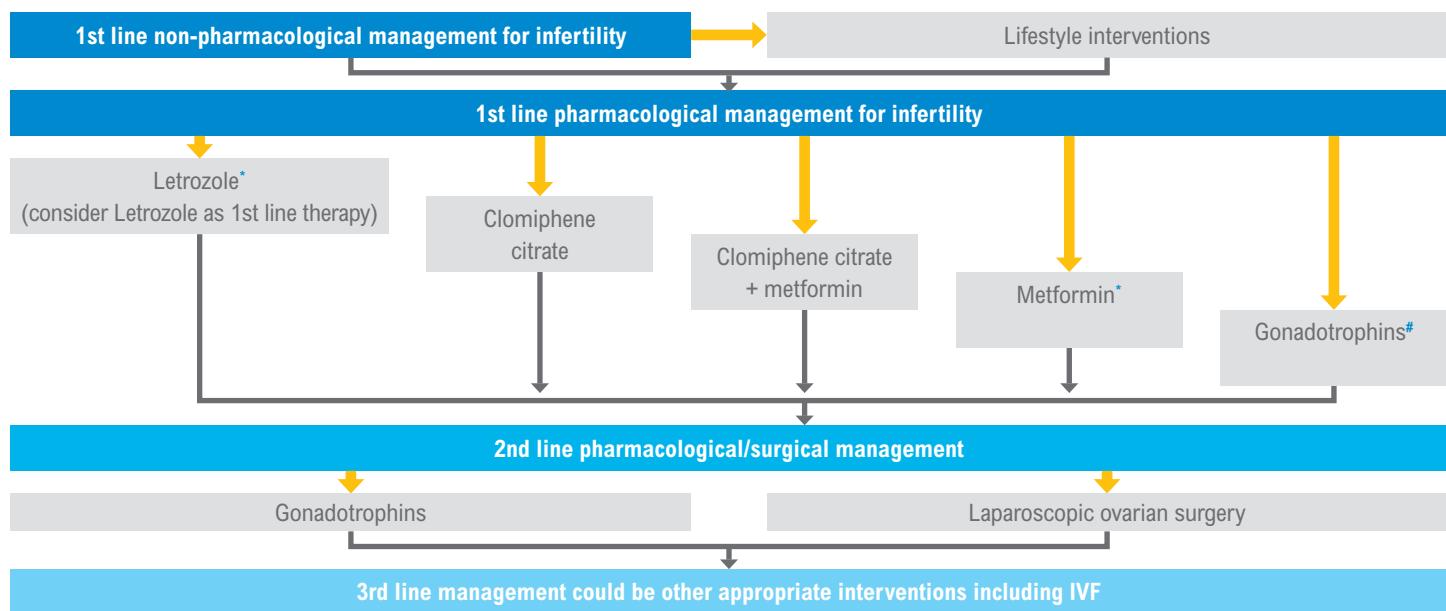

Consider starting low dose, with 500mg increments 1-2 weekly.

Metformin appears safe long-term. Ongoing monitoring required and has been associated with low vitamin B12.

Anti-obesity medications can be considered with lifestyle as per general population guidelines, considering cost, contraindications, side effects, availability and regulatory status and avoiding pregnancy when on therapy.

Inositol (in any form) should currently be considered experimental in PCOS, with emerging evidence of efficacy highlighting the need for further research.

Algorithm 5: Assessment and treatment of infertility

* **Off label prescribing:** Letrozole, COCPs, metformin and other pharmacological treatments are generally off label in PCOS, as pharmaceutical companies have not applied for approval in PCOS. However, off label use is predominantly evidence-based and is allowed in many countries. Where it is allowed, health professionals should inform women and discuss the evidence, possible concerns and side effects of treatment.

Assessment and treatment of infertility

Assessment of factors that may affect fertility, treatment response or pregnancy outcomes

Factors such as blood glucose, weight, blood pressure, smoking, alcohol, diet, exercise, sleep and mental, emotional and sexual health should be optimised in women with PCOS, to improve reproductive and obstetric outcomes, aligned with recommendations in the general population.

Refer to the International evidence-based guideline for the assessment and management of polycystic ovary syndrome 2018 available at: www.monash.edu/medicine/sphpm/mchri/pcos

Monitoring during pregnancy is important for women with PCOS, given increased risk of adverse maternal and offspring outcomes.

For women with PCOS and infertility due to anovulation alone with normal semen analysis, the risks, benefits, costs and timing of tubal patency testing should be discussed on an individual basis.

Tubal patency testing should be considered prior to ovulation induction for women with PCOS where there is suspected tubal infertility.

Ovulation induction principles

The use of ovulation induction agents, including letrozole, metformin and clomiphene citrate is off label in many countries*.

Pregnancy should be excluded prior to ovulation induction.

Unsuccessful, prolonged use of ovulation induction agents should be avoided, due to poor success rates.

Letrozole

Letrozole should be considered first line pharmacological treatment for ovulation induction in women with PCOS with anovulatory infertility and no other infertility factors to improve ovulation, pregnancy and live birth rates.

Where letrozole is not available or use is not permitted or cost is prohibitive, health professionals should use other ovulation induction agents.

Health professionals and women should be aware that the risk of multiple pregnancy appears to be less with letrozole, compared to clomiphene citrate.

Clomiphene citrate and metformin

Clomiphene citrate could be used alone in women with PCOS with anovulatory infertility and no other infertility factors to improve ovulation and pregnancy rates.

Metformin could be used alone in women with PCOS, with anovulatory infertility and no other infertility factors, to improve ovulation, pregnancy and live birth rates, although women should be informed that there are more effective ovulation induction agents.

Clomiphene citrate could be used in preference, when considering clomiphene citrate or metformin for ovulation induction in women with PCOS who are obese ($BMI \geq 30 \text{ kg/m}^2$) with anovulatory infertility and no other infertility factors.

If metformin is being used for ovulation induction in women with PCOS who are obese ($BMI \geq 30 \text{ kg/m}^2$) with anovulatory infertility and no other infertility factors, clomiphene citrate could be added to improve ovulation, pregnancy and live birth rates.

Clomiphene citrate could be combined with metformin, rather than persisting with clomiphene citrate alone, in women with PCOS who are clomiphene citrate-resistant, with anovulatory infertility and no other infertility factors, to improve ovulation and pregnancy rates.

The risk of multiple pregnancy is increased with clomiphene citrate use and therefore monitoring needs to be considered.

Gonadotrophins

Gonadotrophins could be used as second line pharmacological agents in women with PCOS who have failed first line oral ovulation induction therapy and are anovulatory and infertile, with no other infertility factors.

Gonadotrophins could be considered as first line treatment, in the presence of ultrasound monitoring, following counselling on cost and potential risk of multiple pregnancy, in women with PCOS with anovulatory infertility and no other infertility factors.

Gonadotrophins, where available and affordable, should be used in preference to clomiphene citrate combined with metformin therapy for ovulation induction, in women with PCOS with anovulatory infertility, clomiphene citrate-resistance and no other infertility factors, to improve ovulation, pregnancy and live birth rates.

Gonadotrophins with the addition of metformin, could be used rather than gonadotrophins alone, in women with PCOS with anovulatory infertility, clomiphene citrate-resistance and no other infertility factors, to improve ovulation, pregnancy and live birth rates.

Either gonadotrophins or laparoscopic ovarian surgery could be used in women with PCOS with anovulatory infertility, clomiphene citrate-resistance and no other infertility factors, following counselling on benefits and risks of each therapy.

Where gonadotrophins are prescribed, the following should be considered:

- cost and availability
- expertise required for use in ovulation induction
- degree of intensive ultrasound monitoring required
- lack of difference in clinical efficacy of available gonadotrophin preparations
- low dose gonadotrophin protocols optimise monofollicular development
- risk and implications of potential multiple pregnancy

Gonadotrophin induced ovulation should only be triggered when there are fewer than three mature follicles and should be cancelled if there are more than two mature follicles with the patient advised to avoid unprotected intercourse.

Anti-obesity agents

Pharmacological anti-obesity agents should be considered an experimental therapy for women with PCOS for the purpose of improving fertility, with risk to benefit ratios currently too uncertain to advocate this as fertility therapy.

Laparoscopic ovarian surgery

Laparoscopic ovarian surgery could be second line therapy for women with PCOS, who are clomiphene citrate resistant, with anovulatory infertility and no other infertility factors.

Laparoscopic ovarian surgery could potentially be offered as first line treatment if laparoscopy is indicated for another reason in women with PCOS with anovulatory infertility and no other infertility factors.

Risks should be explained to all women with PCOS considering laparoscopic ovarian surgery.

Where laparoscopic ovarian surgery is to be recommended, the following should be considered:

- comparative cost
- expertise required for use in ovulation induction
- intra-operative and post-operative risks are higher in women who are overweight and obese
- there may be a small associated risk of lower ovarian reserve or loss of ovarian function
- periadnexal adhesion formation may be an associated risk

Bariatric Surgery

Bariatric surgery should be considered an experimental therapy in women with PCOS, for the purpose of having healthy baby, with risk to benefit ratios currently too uncertain to advocate this as fertility therapy.

If bariatric surgery is to be prescribed, the following should be considered:

- comparative cost
- the need for a structured weight management program involving diet, physical activity and interventions to improve psychological, musculoskeletal and cardiovascular health to continue post-operatively
- perinatal risks such as small for gestational age, premature delivery, possibly increased infant mortality
- potential benefits such as reduced incidence of large for gestational age fetus and gestational diabetes
- recommendations for pregnancy avoidance during periods of rapid weight loss and for at least 12 months after bariatric surgery with appropriate contraception

If pregnancy occurs, the following should be considered:

- awareness and preventative management of pre- and post-operative nutritional deficiencies is important, ideally in a specialist interdisciplinary care setting
- monitoring of fetal growth during pregnancy

In-vitro fertilisation (IVF)

In the absence of an absolute indication for IVF ± ICSI, women with PCOS and anovulatory infertility could be offered IVF third line where other ovulation induction therapies have failed.

In women with anovulatory PCOS, the use of IVF is effective and when elective single embryo transfer is used, multiple pregnancies can be minimised.

Women with PCOS undergoing IVF ± ICSI therapy should be counselled prior to starting treatment, including on:

- availability, cost and convenience
- increased risk of ovarian hyperstimulation syndrome
- options to reduce the risk of ovarian hyperstimulation

Urinary or recombinant follicle stimulation hormone can be used in women with PCOS undergoing controlled ovarian hyperstimulation for IVF ± ICSI, with insufficient evidence to recommend specific FSH preparations.

Exogenous recombinant luteinising hormone treatment should not be routinely used in combination with follicle stimulating hormone therapy in women with PCOS undergoing controlled ovarian hyperstimulation for IVF ± ICSI.

A gonadotrophin releasing hormone antagonist protocol is preferred in women with PCOS undergoing an IVF ± ICSI cycle, over a gonadotrophin releasing hormone agonist long protocol, to reduce the duration of stimulation, total gonadotrophin dose and incidence of ovarian hyperstimulation syndrome (OHSS).

Human chorionic gonadotrophins should be used at the lowest doses to trigger final oocyte maturation in women with PCOS undergoing an IVF ± ICSI cycle to reduce the incidence of OHSS.

Triggering final oocyte maturation with a GnRH agonist and freezing all suitable embryos could be considered in women with PCOS having an IVF/ICSI cycle with a GnRH antagonist protocol and at an increased risk of developing OHSS or where fresh embryo transfer is not planned.

In IVF ± ICSI cycles in women with PCOS, consideration should be given to an elective freeze of all embryos.

Adjunct metformin therapy could be used before and/or during follicle stimulating hormone ovarian stimulation in women with PCOS undergoing IVF ± ICSI therapy with a gonadotrophin releasing hormone agonist protocol, to improve the clinical pregnancy rate and reduce the risk of OHSS.

In a gonadotrophin releasing hormone agonist protocol with adjunct metformin therapy, in women with PCOS undergoing IVF ± ICSI treatment, the following could be considered:

- metformin commencement at the start of gonadotrophin releasing hormone agonist treatment
- metformin use at a dose of between 1000mg to 2550mg daily
- metformin cessation at the time of the pregnancy test or menses (unless the metformin therapy is otherwise indicated)
- metformin side-effects (refer to the International evidence-based guideline for the assessment and management of polycystic ovary syndrome 2018 available at: www.monash.edu/medicine/sphpm/mchri/pcos)

In IVF ± ICSI cycles, women with PCOS could be counselled on potential benefits of adjunct metformin in a gonadotrophin releasing hormone antagonist protocol to reduce risk of ovarian hyperstimulation syndrome (refer to the International evidence-based guideline for the assessment and management of polycystic ovary syndrome 2018 available at: www.monash.edu/medicine/sphpm/mchri/pcos).

The term in vitro maturation (IVM) treatment cycle should be applied to “the maturation in vitro of immature cumulus oocyte complexes collected from antral follicles” (encompassing both stimulated and unstimulated cycles, but without the use of a human gonadotrophin trigger).

In units with sufficient expertise, IVM could be offered to achieve pregnancy and live birth rates approaching those of standard IVF ± ICSI treatment without the risk of OHSS for women with PCOS, where an embryo is generated, then vitrified and thawed and transferred in a subsequent cycle.

Abstract: Polycystic ovary syndrome (PCOS) is increasingly recognized as a complex metabolic disorder that manifests in genetically susceptible women following a range of negative exposures to nutritional and environmental factors related to contemporary lifestyle. The hypothesis that PCOS phenotypes are derived from a mismatch between ancient genetic survival mechanisms and modern lifestyle practices is supported by a diversity of research findings. The proposed evolutionary model of the pathogenesis of PCOS incorporates evidence related to evolutionary theory, genetic studies, in-utero developmental epigenetic programming, transgenerational inheritance, metabolic features including insulin resistance, obesity and the apparent paradox of lean phenotypes, reproductive effects and subfertility, the impact of the microbiome and dysbiosis, endocrine disrupting chemical exposure, and the influence of lifestyle factors such as poor quality diet and physical inactivity. Based on these premises, the diverse lines of research are synthesized into a composite evolutionary model of the pathogenesis of PCOS. It is hoped that this model will assist clinicians and patients to understand the importance of lifestyle interventions in the prevention and management of PCOS and provide a conceptual framework for future research. It is appreciated that this theory represents a synthesis of the current evidence and that it is expected to evolve and change over time.

Keywords: polycystic ovary syndrome; evolution; insulin resistance; infertility; toxins, endocrine disrupting chemicals; environment; lifestyle; diet

1. Introduction

It is widely accepted that there is a global epidemic of lifestyle-related chronic diseases, such as obesity and diabetes, that are underpinned by reversible metabolic dysfunction in the majority of individuals affected (1–3). It is also recognized that many of these chronic diseases may share a similar pathogenesis involving the interaction of genetic and environmental factors that manifest in overlapping pathophysiological features (4–6). The revised International Guidelines for the assessment and management of women with PCOS, emphasise that the associated metabolic dysfunction and symptoms should initially be addressed via lifestyle interventions (7).

Evolutionary medicine is an emerging discipline involving the study of evolutionary processes that relate to human traits and diseases and the incorporation of these findings

into the practice of medicine (8). Evolutionary medicine brings together interdisciplinary research to inform clinical medicine based on the influence of evolutionary history on human health and disease (9). Previous utilization of the principles of evolutionary medicine has been limited to monogenetic diseases (cystic fibrosis, sickle cell anaemia, phenylketonuria and many others), drug resistance of microorganisms, tumour growth and chemoresistance (8). Future insights into the application of evolutionary research offers the potential to improve and personalize the established medical and scientific approaches to complex chronic diseases like type 2 diabetes, metabolic syndrome and PCOS (5,9).

The evolutionary origins of complex chronic diseases incorporate considerations of relative reproductive fitness, mismatch between our biological past and modern environment, trade-offs involving combinations of genetic traits, and evolutionary conflicts (8,10). These evolutionary factors are relevant when analysing the contributors to the pathogenesis of PCOS in modern and modernising societies, that result in a mismatch between our rapid cultural evolution with our slow biological evolution (11,12). The unique cultural evolution of humans does not have a plausible analogue in most other species and is increasingly recognised to play a significant role in the pathogenesis of metabolic diseases such as PCOS (5,13–17).

Polycystic ovary syndrome is a complex multisystem condition with metabolic, endocrine, psychological, fertility and pregnancy-related implications at all stages of life (7,18). The majority of women with PCOS manifest multiple metabolic features including obesity, insulin resistance (IR), hyperlipidaemia and hyperandrogenism (19,20). PCOS results in an increased risk of developing metabolic disease (type 2 diabetes, non-alcoholic fatty liver disease (NAFLD) and metabolic syndrome), cardiovascular disease, cancer, a wide array of pregnancy complications (deep venous thrombosis, pre-eclampsia, gestational diabetes, macrosomia, growth restriction, miscarriage, stillbirth and preterm labour) and psychological problems (anxiety, depression) (6,21–25). PCOS is part of a cluster of inter-related metabolic conditions and makes a significant contribution to the chronic disease epidemic.

Extensive research suggests that the aetiology of PCOS involves an interaction between environmental factors and gene variants, although it has been suggested that genetic factors contribute less than 10% to disease susceptibility (26–28). A large number of genetic and genome-wide association studies (GWAS) have identified common gene loci associated with PCOS phenotypes in different ethnic populations (29–31). These appear to be normal gene variants or polymorphisms, given the frequency and type of genes that have been identified. PCOS is therefore viewed as a polygenic trait that results from an interaction between susceptible genomic variants and the environment.

PCOS affects upward of 10% of reproductive-aged women, estimated at over 200 million women worldwide (32,33). PCOS is thought to be increasing in incidence in both developing and developed nations as a result of lifestyle-related changes in diet quality, reduced physical activity, ubiquitous environmental endocrine disrupting chemicals (EDC), altered light exposures, sleep disturbance, heightened levels of stress and other

environmental factors (11,34–38). These factors, and the high prevalence of PCOS, suggest that there could be an evolutionary basis for the syndrome (15,16,39). Evolutionary medicine has changed the paradigm for understanding PCOS, acknowledging many of the contributing lifestyle and environmental factors that facilitate the observed metabolic and clinical features and that are also shared with related metabolic diseases (8). These “mismatch disorders” are estimated to make a significant contribution to chronic disease in developed countries and a growing proportion of disability and death in developing nations (3). According to the Global Burden of Disease Study, the human diet is now the leading risk factor for morbidity and mortality worldwide (3). In keeping with these findings, diet is recognized as one of the major contributors to the growing prevalence of PCOS globally (7,40).

Dietary and environmental factors are hypothesized to have an impact on developmental programming of susceptible gene variants in women with PCOS (41–43). Extensive experimental evidence suggests that prenatal androgen exposure may play a role in the pathogenesis of PCOS-like syndromes in animal models (19,44–46). The discovery of naturally-occurring PCOS phenotypes in non-human primates supports a survival advantage of a hyperandrogenic, insulin resistant phenotype with delayed fertility (47). In humans, the origin of excess androgens may be from maternal, fetal or placental sources. In addition, emerging and concerning evidence suggests that EDC may contribute to altered fetal programming and play a role in the pathogenesis of PCOS (41,48).

In-utero genomic programming of metabolic and endocrine pathways can increase the susceptibility of offspring to develop PCOS following exposure to specific nutritional and environmental conditions (45). This view of the pathogenesis of PCOS is consistent with the Developmental Origins of Health and Disease (DOHaD) model proposed by Neel (49). Postnatal exposure to lifestyle and environmental factors, such as poor-quality diet and EDC, may activate epigenetically programmed pathways that further promote the observed features of PCOS. Dietary and lifestyle interventions have demonstrated that many of the clinical, metabolic and endocrine features of PCOS can be reversed (7,50,51).

Lifestyle-induced changes in the gastrointestinal tract microbiome are another significant factor in the aetiology of PCOS (52,53). Dysbiosis of the gut microbiota has been hypothesised to play a role in increased gastrointestinal permeability, initiating chronic inflammation, IR and hyperandrogenism (40). Numerous studies have reported reduced alpha diversity of the microbiome that has been associated with the metabolic, endocrine and clinical features observed in women with PCOS (54,55). The resulting dysbiosis has been shown to be reversible after interventions aimed at improving diet quality or treatment with probiotics or synbiotics (50,51,56–58).

A unified evolutionary theory of the pathogenesis of PCOS proposes that ancient genetic polymorphisms that were aligned with the environment of that era, resulted in an adaptive survival advantage in offspring in ancestral populations (14–16,28). When these same genetic variants are exposed to modern lifestyle and environmental influences, maladaptive physiological responses occur. The prior advantages of insulin resistance, hyperandrogenism, enhanced energy storage and reduced fertility in ancestral

populations become pathological and result in the observed features of PCOS in contemporary women (figure 1).

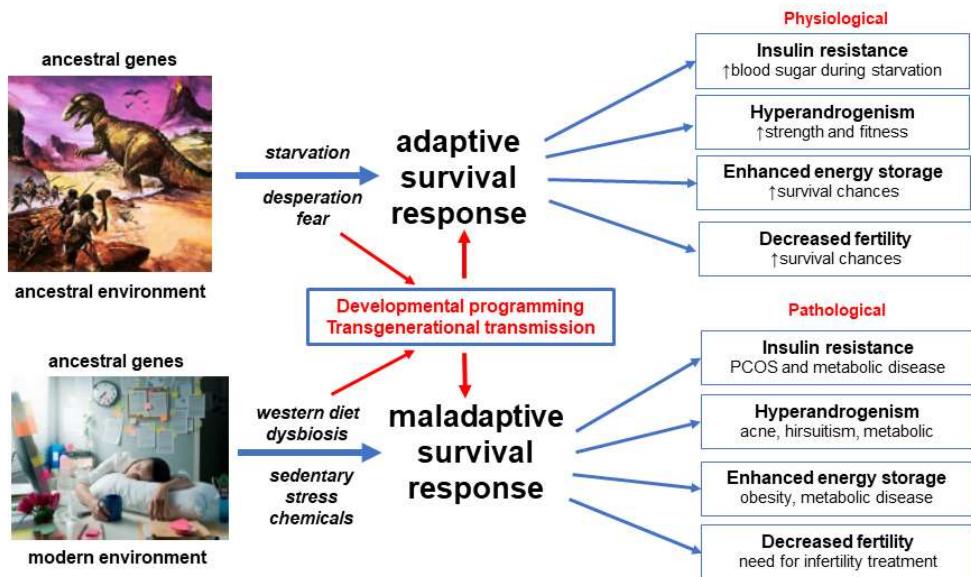

Figure 1. Evolutionary model of the pathogenesis of polycystic ovary syndrome

2. Materials and Methods

The literature search focused on research publications related to the pathogenesis of PCOS using the keywords listed above and related mesh terms for data on the evolutionary aspects of PCOS, genetic studies, in-utero developmental epigenetic programming, transgenerational inheritance, metabolic features including insulin resistance, obese and lean PCOS phenotypes, reproductive changes and subfertility, impact of the microbiome and dysbiosis, possible effects of endocrine disrupting chemical exposure and the influence of lifestyle factors such as diet and physical activity. The databases searched included PubMed, Scopus, Cochrane and Google Scholar. Relevant papers were selected and citation searches were performed.

The present manuscript synthesizes the findings into a unified evolutionary model. The following text is presented as a narrative review of factors involved in the pathogenesis of PCOS and is discussed in ten main subject areas that provide the rationale for the development of a unified model. 1. Evolution 2. Genetics 3. Developmental Epigenetic Programming 4. Microbiome and Dysbiosis 5. Insulin resistance 6. Obesity and the lean paradox 7. Environmental Chemical Exposure 8. Lifestyle Contributors to the Pathogenesis of PCOS 9. Conceptual Framework of a Unified Evolutionary Model 10. Explanation to women diagnosed with PCOS.

3. Pathogenesis of PCOS

3.1. Evolution

The description of PCOS phenotypes can be found in medical records from antiquity and the modern syndrome was described over 80 years ago (17,59). Nevertheless, there is ongoing debate regarding the evolutionary origins of PCOS (15–17,39,60–64). PCOS

susceptibility alleles may have arisen in our phylogenetic ancestors, in the Hunter-gatherer Paleolithic period of the Stone Age, after the Neolithic Agricultural Revolution or following the Industrial Revolution (16,17). From an evolutionary perspective, nearly all genetic variants that influence disease risk have human-specific origins, but the systems they relate to have ancient roots in our evolutionary ancestors (8). Regardless of the precise timing of the origin of PCOS in humans, the complex metabolic and reproductive gene variants identified in women with PCOS relate to ancient evolutionary-conserved metabolic and reproductive survival pathways (15,29). Although evolutionary hypotheses about disease vulnerability are impossible to prove they have the potential to frame medical thinking and direct scientific research for the proximate causes of disease (15,60).

Multiple hypotheses have been proposed regarding the evolutionary origins of PCOS and related metabolic diseases (8,60,63). These hypotheses are focused on the relative importance of metabolic survival adaptations versus improved reproductive success, or a combination of both. A detailed analysis of these hypotheses, and the complexities of the evolutionary considerations, have been reviewed elsewhere and is beyond the scope of the present review (8,60). One common theme is that PCOS may be viewed as a “conditional phenotype” where a specific set of conditions has unmasked normally unexpressed or partly expressed genetic pathways, which then provide a survival advantage under certain environmental conditions (14,16).

All organisms have physiological adaptive responses to deal with changing environmental conditions (starvation, fasting, physical threat, stress and infection) and the varying demands of internal physiological states (pregnancy, lactation and adolescence) (14,65). It has been proposed that the PCOS phenotype may have been invoked in specific environmental conditions in ancestral populations as a short, medium or even long-term adaptive survival mechanism (15–17). The view of PCOS as a conditional phenotype proposes that these physiological responses become pathological in our modern environment due to factors such as food abundance, reduced physical activity, circadian disruption, stress and environmental chemical exposure. The transgenerational evolutionary theory of the pathogenesis of PCOS encompasses all of the above ideas to explain the observed pathophysiological and clinical features of PCOS (28).

It is generally accepted that almost all pre-industrial societies and animal populations experienced seasonal or unpredictable episodes of food shortage that applied evolutionary pressure to develop metabolic and reproductive adaptive survival responses (17,49). It is also appreciated that metabolic and reproductive pathways are interconnected and involve reciprocal feedback control mechanisms (66–68). During periods of starvation, anorexia or excessive weight gain, reproduction is down-regulated and ovulation becomes irregular or ceases (69,70). Similarly, metabolic function is co-ordinated with the menstrual cycle to ensure optimal physiological conditions for fertilisation, implantation, pregnancy, parturition and lactation (71). Recent research has elaborated on the details of how some of these complex regulatory mechanisms interact by using specific hormonal, nutrient sensing and intracellular signalling networks (72–74).

Details of the mechanisms underlying the proposed adaptive survival advantages of IR, hyperandrogenism, enhanced energy storage and sub-fertility have been obtained from paleolithic records, animal models and human populations exposed to adverse environmental conditions such as war and famine-inflicted starvation (14,16,62,63). Multiple lines of evidence support the maladaptive response of human populations to rapidly changing nutritional, physical, psychological and cultural environments, in the modern world (5,11,14,75). These “adaptations” result in pathological responses to IR, hyperandrogenism, enhanced energy storage and ovulation (figure 1).

Theories of evolutionary mismatch have also been advanced to explain all of the cluster of metabolic diseases associated with PCOS (type 2 diabetes, metabolic syndrome, NAFLD and cardiovascular disease) and follow the same set of basic principles and explanations (14,76). This common body of evolutionary evidence is supported by the increasing incidence of metabolic-related disease, such as diabetes and obesity, in developed countries and in developing nations adopting a Western diet and lifestyle (11,77). In addition, the demonstrated reversibility of PCOS and related metabolic and biochemical features following changes in diet, increased physical activity and other lifestyle interventions, adds further support to a transgenerational evolutionary model (50,51).

3.2. Genetics

The heritable nature of PCOS has been proposed since the 1960’s following a range of familial, twin and chromosomal studies (78–80). Cytogenetic studies failed to identify karyotypic abnormalities and genetic studies did not show a monogenic inheritance pattern following examination of candidate genes (81,82). In addition, two or more phenotypes can be present in the same family suggesting that some of the phenotypic differences could be accounted for by variable expression of the same shared genes (81,83).

The mapping of the human genome in 2003 (84) and the publication of the human haplotype map (more than one million single nucleotide polymorphisms of common genetic variants) in 2005 (85), lead to the realisation that most DNA variation is shared by all humans and is inherited as blocks of linked genes (linkage disequilibrium) (86). These advances enabled a revolution in case-control studies and the development of GWAS which map the entire human genome looking for susceptibility genes for complex traits such as obesity, type 2 diabetes and PCOS (81).

The first PCOS GWAS was published in 2010 and demonstrated 11 gene loci associated with PCOS (87). Additional loci have subsequently been found in a number of different ethnic groups (86,88). The first GWAS analysis of quantitative traits was published in 2015 and showed that a variant (rs11031006) was associated with luteinizing hormone levels (88). The largest GWAS included a meta-analysis of 10,074 PCOS cases and 103,164 controls and identified 19 loci that confer risk for PCOS (29). The genes associated with these loci involve gonadotrophin action, ovarian steroidogenesis, insulin resistance and type 2 diabetes susceptibility genes. The first GWAS using electronic health record-linked biobanks has introduced greater investigative power and identified 2 additional loci (89). These variants were associated with polycystic ovaries and hyperandrogenism

(rs17186366 near *SOD2*) and oligomenorrhoea and infertility (rs144248326 near *WWTR1*) (89). In addition to identifying common gene variants for PCOS phenotypes, finding the same signals (*THADA*, *YAP1* and *c9orf3*) in Chinese and European populations suggests that PCOS is an ancient trait that was present before humans migrated out of Africa (81).

More recently Mendelian randomization (MR) studies have been used to explore the potential causative association between gene variants identified in GWAS and PCOS (90,91). Many of the gene variants identified in GWAS are located in non-coding regions of DNA (92). The genes or functional DNA elements through which these variants exert their effects are often unknown. Mendelian randomization is a statistical methodology used to jointly analyse GWAS and quantitative gene loci to test for association between gene expression and a trait, due to a shared or potentially causal variant at a specific locus (93). A detailed analysis of MR methodology and the limitations of this statistical tool is beyond the scope of the present review. Although MR studies have the potential to infer causation it is recognised that they also have limitations in PCOS research (90). Nevertheless, preliminary evidence suggests that a number of genes related to obesity, metabolic and reproductive function, may play a causal role in the pathogenesis of PCOS (90,91).

Decades of genetic research has therefore characterised PCOS as a polygenic trait that results from interactions between the environment and susceptible genomic traits (27,29,79,88). The failure to identify a qualitative or monogenic inheritance pattern and the findings from GWAS, MR, familial and twin studies, suggests that the heritability of PCOS is likely to be due to the combination of multiple genes having small effect size, as has been found with obesity and type 2 diabetes (79,80,94–96). Polygenic traits are the result of gene variants that represent one end of the bell-shaped normal distribution curve of continuous variation in a population (97). From an evolutionary perspective, women with PCOS may represent the “metabolic elite” end of the normal distribution curve, being able to efficiently store energy in periods of food abundance and down-regulate fertility in times of food scarcity, or even in anticipation of reduced seasonal food availability as a predictive adaptive response (16,17,60).

The realisation that PCOS is a quantitative trait (phenotype determined by multiple genes and environmental factors) has far-reaching implications for the diagnosis, treatment and prevention of symptoms and pathology associated with PCOS. The implications require a shift in thinking about PCOS as a “disease” to a variation of normal metabolic and reproductive function. This shift invites a change in vocabulary from talking about “disorder” and “risk” to talking about “expression” and “variability” (97). This new understanding supports and reinforces an evolutionary model of the pathogenesis of PCOS. In keeping with this model, multiple lines of evidence suggest that inherited PCOS gene variants are developmentally programmed in a way that primes them for activation by nutritional and environmental factors in postnatal life (41,42,98).

3.3. Developmental epigenetic programming

The developmental programming of PCOS represents changes in gene expression that occur during critical periods of fetal development (99). Following fertilisation, most

parental epigenetic programming is erased and dramatic epigenomic reprogramming occurs (100). This results in transformation of the parental epigenome to the zygote epigenome and determines personalised gene function. Compelling evidence shows that a wide range of maternal, nutritional and environmental factors can effect fetal development during these critical periods of programming (44,98,99,101,102). These include hormones, vitamins, diet-derived metabolites and environmental chemicals (48,98,103,104). In addition, epigenetic reprogramming of germ-line cells can lead to transgenerational inheritance resulting in phenotypic variation or pathology in the absence of continued direct exposure (98).

Experimental studies in primates, sheep, rats and mice show that PCOS-like syndromes can be induced by a range of treatments including androgens, anti-Mullerian hormone and letrozole (19,44,46). Nevertheless, there is significant debate regarding when an animal model qualifies as PCOS-like (105). The model used and the method of induction of PCOS phenotypes therefore needs to be carefully scrutinised when generalising findings from animal research to women with PCOS. The vast majority of animal and human research on the developmental origins of PCOS has focussed on the role of prenatal androgen exposure. This has been extensively reviewed in numerous previous publications (41,46). This research has resulted in a proposed “two hit” hypothesis for the development of PCOS phenotypes (43,45). The “first hit” involves developmental programming of inherited susceptibility genes and the “second hit” arises due to lifestyle and environmental influences in childhood, adolescence and adulthood (41,106).

If PCOS is a quantitative trait involving normal gene variants, as suggested by the evolutionary considerations and findings from genetic research, then the “first hit” may result from normal developmental programming events as occurs with other gene variants (102). According to this hypothesis, the polygenic susceptibility genes would be normally “activated” and “primed” to respond to future maternal and environmental conditions and exposures, as would be the case with many other normal genes (28). In addition, the susceptibility alleles may be “activated” or “functionally enhanced” by a range of maternal and environmental factors, as is usually presumed to be the case in PCOS (5,14,102). This developmental plasticity would provide a mechanism for a predictive adaptive response, based on inputs from the maternal environment that could be used to programme metabolic and reproductive survival pathways, to better prepare the offspring for the future world in which they may be expected to live (107).

Parental lifestyle factors including diet, obesity, smoking and endocrine disrupting chemicals, have all been shown to modulate disease risk later in life (104,108,109). The original description of the fetal origin’s hypothesis proposed that poor maternal nutrition would increase fetal susceptibility to the effects of a Western-style diet later in life (49). Subsequent studies have confirmed that maternal exposure to either nutrient excess or deficit, can have long-term consequences for the health of the progeny (104). Evidence from human and animal studies suggests that maternal obesity programs the offspring for increased risk of developing obesity, hyperglycaemia, diabetes, hypertension and metabolic syndrome (108).

The developmental origins of PCOS may have been due to different factors in ancestral and modern populations (17,60). It has been hypothesised that environmental stress, infection, nutrient deprivation, fetal growth restriction and stress hormone responses may have resulted in maternally-mediated modulation of gene expression in ancestral offspring (17,110). Some of these factors have been investigated and confirmed in modern populations subject to starvation and extreme environmental conditions (111). In contrast, altered fetal programming in modern societies may be secondary to maternal overnutrition, sedentary behaviour, obesity, emotional stress, circadian rhythm disruption, poor gut health or environmental chemical exposure (35,101,112,113). The preconception and pregnancy periods therefore provide a unique opportunity for lifestyle interventions that promote optimal future health for both the mother and the offspring (figure 2).

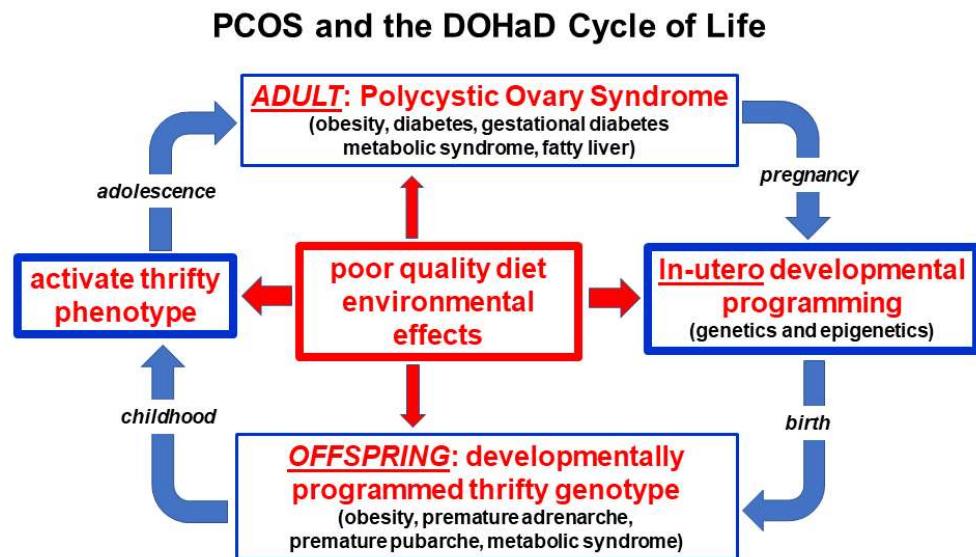

Figure 2. Nutritional and environmental influences throughout the life course and the perpetuation of the transgenerational inheritance of polycystic ovary syndrome

3.4. Microbiome and Dysbiosis

The gastrointestinal microbiome is now appreciated to play a central role in human health and disease (114,115). The microbiome is known to co-regulate many physiological functions involving the immune, neuroendocrine and metabolic systems via complex reciprocal feedback mechanisms that operate between the microbial ecosystem and the host (116,117). Evidence from studies in Western populations, Hunter-gatherer societies and phylogenetic studies in other species, have attempted to place the human microbiome into an evolutionary context (118). Although microbes clearly impact host physiology and have changed along branches of the evolutionary tree, there is ongoing debate regarding whether the microbiome can evolve according to the usual evolutionary forces (119,120). Nevertheless, it has been argued that focusing on functional pathways and metabolic roles of microbial communities, rather than on specific microbes, provides a better model for

understanding evolutionary fitness (118). The co-evolution of the microbiome and human physiology may therefore be important in understanding the differences between ancient adaptive physiological survival mechanisms and modern lifestyle-related pathological responses, in women with PCOS (figure 1).

Twin studies and GWAS show that host genetics can influence the microbiome composition, and microbes can exert effects on the host genome, although the environment has an important role (121,122). Humans are constantly adapting to the gut microbiome to try to determine which microorganisms are beneficial or harmful. Immune genes involved in this process are the most rapidly evolving protein-encoding genes in the mammalian genome (123,124). Diversification of microbes allows humans to access dietary niches and nutritional components they otherwise wouldn't be able to access, which may be beneficial and ultimately lead to the integration of specific microbes into the ecosystem (125). Although no living population today carries an ancestral microbiome, comparison studies of non-Western and Western populations show significant differences in the relative abundances of common phyla and a much greater species diversity in non-Western populations (126,127). A review of non-human primate and human gut microbiome datasets, revealed a changing microbiome in response to host habitat, season and diet, although there appear to be common species-specific symbiotic communities (118).

Rapid human cultural changes have resulted in significant dietary modifications in urban-industrialised communities and shifted the microbiome at an unprecedented rate. The result has been the development of a mismatch between human metabolic genes and bacteria that enhance fat storage (128). In our evolutionary past, when nutrients were scarce, it has been theorized that host selection led to the maintenance of microbes that enhance nutrient uptake or host energy storage. However, in the modern environment where a high fat, high sugar, low fibre diet has become common and easily accessible, integration of these microbes leads to maladaptive physiological responses (40). For metabolically thrifty individuals with PCOS, harbouring microbes that enhance energy storage escalates the evolutionary conflict, furthering the development of insulin resistance and thereby progression to obesity and type 2 diabetes (12,129). Further compounding this maladaptive response is the loss of microbes that are required to access other dietary niches. One example is the loss of symbiotic species of *Treponema* in individuals living in urban-industrialised communities (130). A change from the ancestral hunter-gatherer diet, where foods consumed changed seasonally and a wide variety of food components were eaten, to a diet that is similar across seasons and significantly less varied, is another likely contributor to reduced diversity of the microbiomes of individuals living in urbanised-industrialised communities (131).

The majority of women with PCOS are overweight or obese and evidence indicates that the microbiome of obese individuals is capable of extracting more energy from the host diet compared with the microbiome of lean individuals (132). This is thought to be driven by an expansion in pro-inflammatory species of bacteria, such as *E. coli*, and a depletion of anti-inflammatory bacteria such as *Faecalibacterium prausnitzii* (133,134).

Chronic low-grade ‘metabolic’ inflammation, or meta-inflammation, is a result of an imbalanced gut microbiome that promotes the development of insulin resistance and type 2 diabetes (135–137).

The dysbiosis of gut microbiota theory of PCOS, proposed by Tremellen in 2012, accounts for the development of all of the components of PCOS (multiple ovarian follicles, anovulation or menstrual irregularity and hyperandrogenism) (40). The theory proposes that a poor-quality diet and resulting imbalanced microbiome, induces intestinal permeability and endotoxaemia, exacerbating hyperinsulinaemia. Increased insulin levels promotes higher androgen production by the ovaries and disrupts normal follicle development. Metabolic, endocrine and environmental factors associated with PCOS are not mutually exclusive, and therefore their relative contributions to dysbiosis in PCOS remains uncertain (138). Consuming a balanced diet that is low in fat and high in fibre, can also restore balance to the ecosystem (termed eubiosis) (50). A recent study showed that dietary intake of fibre and vitamin D was significantly decreased in both lean and obese women with PCOS, compared to healthy controls, and correlated with lower diversity of the gut microbiome (139). Dysbiosis is reversible with improvement in diet quality augmented by the addition of probiotics or synbiotics (51,56–58).

Dysbiosis is a consistent finding when looking at the microbiome of women with PCOS (140–143). Although most studies are small, dysbiosis has consistently been found to correlate with different physiological parameters, such as obesity, sex hormones and metabolic defects (140,141,143). Similar to microbiomes associated with obesity, the microbiomes of individuals with PCOS have generally been found to have lower alpha diversity (lower numbers of bacterial taxa) than controls, and most studies describe an altered composition of taxa relative to controls (140,143). However, the bacterial taxa observed to be either increased, depleted or absent in PCOS differs from study to study. This is likely due to both the immense inter-individual variation in microbiotas, as well the fact that PCOS is a quantitative trait with women having various degrees and levels of obesity and sex hormones.

In keeping with the developmental origins hypothesis previously discussed, maternal androgens may alter the composition and function of the microbiome, thereby facilitating the pathogenesis of PCOS (140). One study showed that beta diversity, which is used to measure differences between groups, was negatively correlated with hyperandrogenism, suggesting that androgens play a significant role in dysbiosis (140). The ‘first hit’ in utero may therefore combine with vertical transmission of a dysbiotic microbiome from a mother with PCOS, resulting in dysbiosis in the offspring. Preconception and pregnancy provide a unique opportunities for lifestyle and dietary interventions aimed at restoring eubiosis, to enable the transference of a balanced ecosystem to the offspring, via vertical transmission (118).

The accumulating scientific evidence strongly supports the significant role played by the microbiome in the pathogenesis and maintenance of PCOS, consistent with research in other related metabolic conditions. Dysbiosis is a significant factor in the pathogenesis of PCOS and an important component of a unified evolutionary model. Dysbiosis represents

a maladaptive response of the microbiome to modern lifestyle influences and is a modifiable factor in the treatment of women with PCOS.

3.5. *Insulin Resistance*

There are a number of dilemmas when assessing the role of IR in women with PCOS. There is no consensus on the definition of IR (144,145), measurement is difficult (146,147), whole-body IR is usually measured although it is recognized that IR can be selective being either tissue-specific or pathway-specific within cells (148–150), normal values are categorical and determined by arbitrary cut-offs (4.45 mg/kg/min) (144), testing is not recommended in clinical practice (38), reported prevalence rates in obese and lean women vary widely (146,151), and the significance of IR as a pathognomonic component of PCOS is an area of debate (152–154).

Despite these limitations, it is hypothesised that IR is a significant proximate cause of PCOS and is intrinsic to the underlying pathophysiology (44,155). In addition, it is recognized that IR plays a major role in the pathophysiology of all of the metabolic diseases, cardiovascular disease, some neurodegenerative diseases, and selected cancers (22,156). Insulin resistance is therefore considered to be the main driver for many diseases and makes a significant contribution to the chronic disease epidemic (157). Nevertheless, being able to vary the sensitivity and physiological action of insulin is thought to have conferred a significant adaptive survival role in many animals throughout evolutionary history (145,158). It has been proposed that IR may have evolved as a switch in reproductive and metabolic strategies, since the development of IR can result in anovulation and reduced fertility, in addition to differential energy repartitioning to specific tissues (158).

Insulin receptors are located on the cell membranes of most tissues in the body (159). Ligand binding to the alpha-subunit induces autophosphorylation of specific tyrosine residues on the cytoplasmic side of the membrane (159,160). The activated insulin receptor initiates signal transduction via the phosphatidylinositol-3 kinase (PI-3K) metabolic pathway and the mitogen-activated protein kinase pathway (MAPK) which is involved in cell growth and proliferation (160). Insulin is an anabolic hormone that facilitates glucose removal from the blood, enhances fat storage and inhibits lipolysis in adipose tissue, stimulates glycogen synthesis in muscle and liver and inhibits hepatic glucose output (160). IR can be defined as a state where higher circulating insulin levels are necessary to achieve an integrated glucose-lowering response (145). IR results from alterations to cellular membrane insulin-receptor function or intracellular signaling, enzyme, metabolic or gene function (145,159,160).

Insulin resistance can be caused by a wide variety of mechanisms that have the ability to disrupt any part of this metabolic signaling system (53,160). These include autoantibodies, receptor agonists and antagonists, hormones, inflammatory cytokines, oxidative stress, nutrient sensors and metabolic intermediates (159–162). Physiological regulation of insulin function can be viewed as an adaptive mechanism to regulate the metabolic pathway of insulin signaling (PI-3K), in response to changing environmental conditions (starvation, fear, stress) (163,164) or during normal alterations of internal states (pregnancy, lactation, adolescence) (65,145,151).

The physiological activation of IR allows the organism to switch from an anabolic energy storage state to a catabolic or energy mobilizing state. This allows free fatty acids to be mobilized from adipose tissue, which are then converted to glucose in the liver and released into the circulation (160). As a result of this metabolic change, blood sugar levels are maintained for vital metabolic processes and brain function (14). This adaptive protective mechanism can be pathway specific during periods of growth, such as pregnancy, lactation and adolescence, so that only the metabolic signaling (PI-3K) is inhibited and not the mitogenic pathway (MAPK), which may even be upregulated (30,65,159).

When the physiology of insulin function is considered as a quantitative or continuous variable from an evolutionary perspective, it is likely that all women with PCOS, whether obese or lean, have reduced insulin sensitivity (151,154,165). A systematic review and meta-analysis of euglycemic-hyperinsulinaemic clamp studies found that women with PCOS have a 27% reduction in insulin sensitivity compared to body mass index (BMI) and age-matched controls (154). In evolutionary terms, women with a PCOS metabolic phenotype would have increased survival chances during times of environmental or physiological demand for altered energy metabolism, but be more vulnerable to the pathological effects of IR when exposed to modern lifestyle factors (14,17,158). In particular, a poor-quality, high glycaemic, high fat, low fibre diet has been shown to cause IR (40,166). As discussed in the dysbiosis section, diet-related changes in the gastrointestinal microbiome have also been shown to cause IR in women with PCOS (53,55). Numerous studies have shown that dietary modification (167–169), or treatment with probiotics or synbiotics, has the potential to restore normal insulin function (57,170).

Consumption of a high glycaemic load diet results in rapid increases in blood sugar levels that cause compensatory hyperinsulinaemia (166,171). Excessive dietary intake of glucose and fructose are converted to fatty acids by de novo lipogenesis in the liver, transported to adipocytes via lipoproteins, released as fatty acids to adipocytes and stored in fat globules as triglycerides (160). As a result of nutrient overload, diacylglycerol, the penultimate molecule in the synthesis of triglyceride, accumulates in the cytoplasm and binds with the threonine amino acid in the 1160 position of the insulin receptor. This inhibits autophosphorylation and down-regulates the metabolic PI-3K pathway and causes IR (160). This process has the potential to be reversible following changes in diet quantity and quality, as has been shown to occur with calorie restriction, fasting, time-restricted eating, gastric bypass surgery, low saturated fat and low glycaemic diets (167,169,172). Diets high in animal protein or saturated fat can also cause IR independent of BMI (173,174). These mechanisms provide the rationale for the principal recommendation of the International Guidelines, that women with PCOS should be advised about dietary modification as the first-line of management in all symptom presentations (38).

3.6. Obesity and the lean PCOS paradox

Insight can be obtained into the role of obesity in women with PCOS by examining the evolutionary history, genetic studies and pathological disorders of adipose tissue

(150,175,176). The ability to store energy is a basic function of life beginning with unicellular organisms (175). In multicellular organisms, from yeast to humans, the largest source of stored energy is as triglycerides in lipid droplets in order to provide energy during periods when energy demands exceed caloric intake (175). Understanding the biological functions of adipose tissue has progressed from energy storage and thermal insulation to that of a complex endocrine organ with immune and inflammatory effects and important reproductive and metabolic implications (175,177).

Adipose tissue is organized into brown adipose tissue (BAT) and white adipose tissue (WAT), both with different functions (177). While the evolutionary origins of BAT and WAT are the subject of ongoing debate (175), BAT is located in the supraclavicular and thoracic prevertebral areas and is primarily involved in cold thermogenesis and regulation of basal metabolic rate (178). WAT is distributed in multiple anatomical areas such as visceral adipose tissue (VAT) and subcutaneous adipose tissue (SAT) and functions as a fat storage depot and an endocrine organ (177,178). An additional layer of SAT is thought to have evolved as insulation against cool night temperatures in the Pleistocene open Savanah (179). The lower body distribution of SAT in women is hypothesised to have evolved to provide additional calorie storage for pregnancy and lactation and is unique to human females (14). Lower body SAT has a metabolic programme that makes it less readily available for every-day energy needs, but it can be mobilized during pregnancy and lactation (14). In addition, excess accumulation of SAT is much less likely to cause IR and metabolic dysfunction and explains why IR is not observed in all obese individuals (150,180). Visceral WAT is associated with IR in women with PCOS leading to both metabolic and reproductive problems (181).

Multiple lines of evidence from evolutionary history, genetic and twin studies, support a genetic basis for obesity and differences in obese and lean phenotypes in women with PCOS (182–185). The majority of women with PCOS are overweight or obese, with reports ranging from 38–88% (151,185). Studies comparing obese and lean women with PCOS have a number of methodological problems including small sample size, overlap of PCOS characteristics with normal pubertal changes, non-standardized diagnostic criteria, and limited generalizability to the entire population due to a focus on a specific ethnic group (165,181). In addition, most of the studies examining body composition in PCOS have relied on anthropomorphic measurements (BMI, waist circumference, waist-to-hip ratio) which are considered inaccurate compared with the current gold-standard of magnetic resonance imaging (181). Consequently, there is wide heterogeneity in reports examining the relationship between body composition measures, including extent of VAT and metabolic changes such as IR (185).

In humans, there is large individual variation in the fat storage capability and expandability of different adipose tissue depots (150). It has been hypothesised that once the genetically determined limit of expandability of SAT is reached, there is expansion of VAT and excess lipid accumulation in muscle, liver and other organs, resulting in IR, inflammation and metabolic dysregulation (150). We hypothesize that lean women with PCOS have a genetically determined limited ability to store excess lipid in SAT, but

develop increased lipid deposition in VAT and organs such as the liver, resulting in metabolic dysregulation and IR in a similar manner to what occurs in obese women with PCOS. The wide variation in the genetic limitation of SAT expansion is also supported by studies in individuals with lipodystrophy.

Lipodystrophies are a heterogenous group of rare inherited and acquired disorders characterized by a selective loss of adipose tissue (176,186). They are classified on the basis of the extent of fat loss as generalized, partial or localized (186). Patients with congenital generalised lipodystrophy have a generalized deficiency of fat from birth, usually have severe IR and develop diabetes at puberty. As a consequence of genetically limited ability for SCT lipid storage, lipids can only be stored ectopically in non-adipocytes resulting in major health consequences including IR, fatty liver, diabetes and PCOS (187). In contrast to generalised lipodystrophy, patients with familial partial lipodystrophy have normal fat distribution at birth but loose SAT in the limbs, buttocks and hips, at puberty. Fifty percent of women develop diabetes and 20-35% develop irregular periods and polycystic ovaries (176) . Despite the rare nature of these syndromes much has been learned about the underlying genetic variants involved (186).

Elucidation of clinical subtypes and the genetic background of patients with lipodystrophies may pave the way to new insights into the role of fat partitioning and obesity, and has implications for understanding the pathogenesis of insulin resistance, diabetes and PCOS (176). Lean women with PCOS may have a genetic predisposition for limited SCT fat storage, coupled with underlying metabolic predispositions, that result in deposition of excess lipid in VAT and liver and the observed metabolic features of IR, fatty liver and diabetes. If the extent of IR and ectopic fat deposition is excessive, the resulting hormonal changes may be sufficient to cause oligomenorrhoea and sub-fertility as occurs with secondary familial partial lipodystrophy type 2 (187,188). If this underlying mechanism is confirmed in future studies, the main difference between women with lean or obese PCOS may be the combined effects of metabolic programming and the genetically-determined extent of SCT fat deposition. This would explain why lean women have all the same clinical, biochemical and endocrine features, although possibly less severe, than overweight and obese women with PCOS (185).

3.7. Environmental chemical exposure

Anthropomorphic chemical exposure is ubiquitous in the environment and has possible effects on many aspects related to women's health (36,189–191). Historically, many environmental chemicals have resulted in large-scale health disasters in human populations including diethylstilbestrol (DES), dichlorodiphenyltrichloroethane (DDT), asbestos, lead, mercury and nicotine (191). There over 191 million organic and inorganic chemicals registered on the Chemical Abstract Service Registry (192). Detailed analysis of risks is extremely limited and regulation relies on animal toxicology, in-vitro assays, and epidemiological studies that retrospectively examine adverse effects after population exposure (193,194). More recently, toxogenetic testing of chemical-gene interactions have been employed to identify molecular pathways involved in causing toxicity (193). These

studies have concluded that the majority of endocrine and metabolic pathways are sensitive to the effects of environmental chemicals (193).

The identification of more than 1000 EDC in food, air, water, pesticides, plastics, personal care products, and other consumer goods, raises specific concerns for pregnant women and women with increased susceptibility to metabolic diseases like PCOS (36,171,191,195,196). Endocrine disrupting chemicals may be involved in the pathogenesis of PCOS given their known and potential hormonal and metabolic effects (36,189,197). This includes many of the areas that have been considered in the unified evolutionary model, such as developmental epigenetic programming, microbiome composition and function, metabolic processes such IR, and regulation of body weight.

3.7.1. EDC and DOHaD

Many observational studies have demonstrated the presence of EDC in maternal and fetal serum and urine, amniotic fluid, cord blood and breast milk (198–200). Six classes of EDC have been shown to cross the placenta confirming that the fetus is exposed at all stages of development (109,198). Although it is impossible to perform experimental studies in humans, evidence from epidemiological, molecular toxicology and animal studies provide compelling evidence of adverse developmental effects and transgenerational toxicity (171,189,191,201,202). The realisation of the tragic effects of DES in the 1970's was first example of an in-utero exposure causing serious transgenerational health effects (191). This was followed by increasing interest in identifying the properties of environmental oestrogens (36).

Several oestrogenic EDC have been associated with birth outcomes that are thought to be associated with the development of PCOS (189). These include decreased birthweight (perfluoroalkyl substances [PFAS], perfluorooctanoic acid) and preterm birth (di-2-ethylhexyl phthalate) (201). Prenatal exposure to androgenic EDC (triclosan, glyphosate, tributyltin, nicotine) is of increasing concern, given the suspected epigenetic role of in-utero androgen exposure in the pathogenesis of PCOS (48,203,204). EDC can act at any stage of the human lifespan, including preconception and prenatally, and are increasingly becoming a priority in PCOS research (205).

3.7.2. EDC and the microbiome

As discussed above, the microbiome is increasingly considered to make a significant contribution to many human diseases, including PCOS (40,206). EDC that disrupts the composition or function of the microbiome have been termed "microbiota disrupting chemicals" (207). In turn, any disruption of the microbiome from EDC can impact crucial metabolic and endocrine physiology and homeostasis (36,208). A number of studies have reviewed the effect of EDC in invertebrate and vertebrate species, animal models and humans. These studies have found that BPA, phthalates, artificial sweeteners, heavy metals, fungicides, pesticides and microplastics can all affect the gut microbiome, and have metabolic and obesogenic effects (202,209,210). They have concluded that EDC exert their effects in a variety of species via a range of mechanisms, including modification of

epigenetic, cell signalling and metabolomic pathways, in addition to their effects on the microbiome.

Human exposure to the herbicide glyphosate, through diet and drinking water, has also been reported to alter gut microbial communities (211). Glyphosate-mediated inhibition of 5-enolpyruvylshikimate-3-phosphate synthase in intestinal microbiota has been shown to alter composition and enrich potentially pathogenic bacteria (212–214). In addition, microbiota exposure to glyphosate has been shown to alter mucosal-associated T-cells and promote a pro-inflammatory immune response (211). Taken together, EDC have been found to alter microbial composition and diversity (207,213), disrupt gastrointestinal barrier integrity (202,215), increase systemic endotoxin levels and inflammatory cytokines (216,217), alter the production of metabolites and influence metabolomic patterns (210), all of which have been proposed to be involved in the pathogenesis of PCOS (40).

3.7.3. EDC, insulin resistance and diabetes

Kahn et al reviewed six cohort studies and 2 case-control studies that raise concerns about exposure to PFAS in pregnancy and increased risk of impaired glucose tolerance and gestational diabetes in different ethnic groups (189). They also identified 4 studies showing similar increased risk with phthalate exposure during pregnancy, and one study that did not identify an association with gestational diabetes. Animal studies have found that some EDC target alpha and beta cells in the pancreas, adipose cells and hepatocytes, and contribute to insulin resistance (218). As a result of these and many other concerning studies the Endocrine Society issued a scientific statement cautioning that emerging evidence ties EDC exposure to two of the biggest public health threats facing society, diabetes and obesity (219,220).

3.7.4. EDC and obesity

A large number of EDC are now classified as “obesogens” due to their suspected role in promoting weight-gain and contributing to the global rise in obesity (202,203,221). So far, about 50 obesogens have been recognized including tributyltin, parabins, DDT, cadmium, persistent organic pollutants and many others (202,222,223). Three of the most studied compounds are BPA, phthalates and PFAS (200,201,221). Evidence from multiple birth cohort studies have shown an association between prenatal exposure to PFAS and childhood obesity (200,201). A number of reports have suggested that exposure to PFAS and phthalates also contribute to weight gain in adults (224). Two trials have identified an association between weight gain (Diabetes Prevention Trial Program Lifestyle Trial) (225) and reduced resting metabolic rate (the POUNDS Lost trial) (226), with serum PFAS concentrations. In recognition of the suspected significant risk, the International Federation of Obstetrics and Gynecology (FIGO) recommended a full global phase out of PFAS (227).

3.7.5. EDC and PCOS

A large number of cross-sectional studies have identified associations between EDC and PCOS, including PFAS, phthalates, bisphenol-A, triclosan and nicotine (196,208,228,229). Experimental animal studies have shown that exposure to androgenic EDC in pregnancy can result in significantly increased androgen levels in female offspring (36,48). Other androgenic EDC have been found to alter surrogate markers of developmental programming, such as anogenital distance (224). Although there are no specific toxicogenetic studies in women with PCOS, many EDC have been found to activate signalling pathways thought to be involved in the pathogenesis of PCOS (193,208). Taken together, the available evidence suggests EDC are likely to have a role in the pathogenesis of PCOS.

3.7.6. EDC recommendations

There is a significant global imperative to implement a multifaceted global programme to address the effects of EDC on human health using a hazard-based approach in preference to the current risk-based regulatory framework (230). As a result, implementation of the precautionary principle is a high priority in counselling women with PCOS (231). International professional bodies (The Royal College of Obstetricians and Gynaecologists, Endocrine Society, FIGO) have recommended that all pregnant women should be advised of the possible risks of EDC and that education programmes be developed to inform health professionals (220,232,233). An explanation of the pathogenesis of PCOS (discussed below), should include reference to environmental chemical exposure and open the way for more detailed discussion of specific personalised advice and lifestyle recommendations.

3.8. *Lifestyle Contributors to the Pathogenesis of PCOS*

It has been recognized that a variety of lifestyle factors contribute to the pathogenesis of PCOS for many decades (234,235). As a result, a number of lifestyle factors have been investigated for their role in the pathogenesis of PCOS. These include diet, exercise, stress, sleep disturbance and exposure to environmental chemicals (28,41,236). A large number of animal studies have provided experimental evidence supporting a causative role for many of these factors either individually, or in combination (44). Human research investigating causation is limited to observational and epidemiological studies, as many experimental protocols would be unethical. As a result, proving causation in humans will be extremely difficult. In addition, proving causation in evolutionary models also has a number of significant challenges (8,9,60). Nevertheless, developing a unified evolutionary model based on the large number of available human and animal studies may provide a useful evidenced-based framework for counselling women and informing future research.

Despite the limitations in proving causation, recent advances in genomics, epigenetics, metabolomics, nutrigenomics, evolutionary biology, computer technology and artificial intelligence, are providing many insights into the mechanisms of how lifestyle factors impact the pathogenesis of PCOS (9,90,235,237). We have attempted to integrate the research findings supporting an evolutionary model into the respective sections outlined

in this paper. It has not been our aim to comprehensively review all aspects of the role of lifestyle in the pathogenesis of PCOS. We have tried to highlight the evolutionary aspects of how diet in particular, may impact the pathogenesis of PCOS, as components of the human diet have effects on many areas of the proposed unified evolutionary model. A large body of evidence from studies in women with PCOS, and a range of other metabolic diseases, supports the view that a Western-style high glycaemic, high saturated fat, high calorie, low nutrient-dense, and low fibre diet that contains a high proportion of processed rather than whole food, contributes to the pathogenesis of PCOS (28,40,235). This is likely to be exacerbated by the additional adverse effects of multiple other lifestyle factors such as EDC, stress, circadian disruption and reduced physical activity.

The dysbiosis theory of the pathogenesis of PCOS highlights the role of a poor-quality diet in the pathogenesis of PCOS and is supported by over 30 proof-of-concept studies (40,238). International Guidelines for the assessment and management of PCOS recommend lifestyle management, with diet and exercise as first-line treatment for all women with PCOS, and provide a comprehensive review of the literature (7). Nutritional studies based on diet indices, diet composition and metabolomics have identified dietary components that contribute to a healthy eating pattern (51,237,239,240). Healthy diet patterns, or wholefood diets, have been found to be effective in controlling and reversing many of the symptoms and metabolic alterations associated with PCOS, and have also previously been reviewed (50). Two components of a healthy wholefood diet that appear to be important from an evolutionary perspective, in addition to the requirement for fundamental macronutrients (protein, fat and carbohydrate) and essential micronutrients (vitamins and minerals), are dietary fibre and polyphenols.

Throughout evolutionary history, humans have obtained nutrients from a wide variety of plant and animal food sources (241). These foods provided macronutrients, micronutrients and contingent nutrient factors that contain a range of bioactive components. Contingent nutrients include a variety of compounds that are not essential but may be beneficial to human health (242). Polyphenols are an important contingent nutrient, and comprise a large collection of plant-derived secondary metabolites that have been found to have beneficial biological and metabolic effects when consumed (243). Dietary polyphenols improve microbiota diversity and undergo extensive biotransformation by a variety of microbial species (244). It is estimated that less than 5% of ingested polyphenols reach the circulation intact (245). A large number of microbially-derived polyphenol metabolites can be detected in plasma compared with low levels of the parent compounds (246). Polyphenols have potent anti-inflammatory and antioxidant effects and are the most abundant antioxidant in the human diet (246). Not surprisingly, there has been significant interest in investigating the possible beneficial effects of polyphenols in PCOS, since the pathophysiology involves oxidative stress, chronic inflammation and alterations in the microbiome (247–250).

Polyphenol-rich foods have historically made up a considerable proportion of the dietary intake in many Hunter-gatherer societies and post-agricultural communities, and until recently, in Western nations (251–253). Polyphenols are present in fruits, vegetables,

legumes, nuts, and whole grains, as well as plant-derived foods and drinks like green tea, red wine, and chocolate (50). Women with PCOS have been noted to consume diets lower in polyphenol-containing foods (236). Consumption of polyphenols and polyphenol-rich foods and drinks have been found to improve a number of important outcome measures in women with PCOS, such as body weight, metabolic abnormalities, and serum androgen levels (50). Some polyphenols can act as selective oestrogen receptor modulators and may provide unique benefits to women with PCOS due to estrogen-related effects (254). Polyphenols are therefore an important part of a healthy diet and have been investigated for their potential role in the pathogenesis of PCOS (50). A healthy wholefood diet contains a wide variety of polyphenols coupled with the necessary dietary fibre required for optimal microbiome and metabolic function.

As previously discussed, the modern Western diet and lifestyle is at odds with our evolutionary background. In general, our traditional hunter-gatherer ancestors consumed significantly more fibre than modern populations. Studies that have investigated the dietary patterns of remaining contemporary Hunter-gatherer societies, have found their dietary fibre intake to be around 80-150 grams per day (255). This contrasts with the contemporary Western diet, where the average fibre intake is 18.2 grams per day in children and 20.7 grams per day in adults (256). Adequate dietary fibre consumption is important as it has a number of benefits, such as improved insulin sensitivity, reduced blood glucose levels, decreased systemic inflammation, lower serum levels of androgens and LPS, all of which have been linked to the pathogenesis of PCOS (257-260).

Recent systematic reviews of observational studies and randomized controlled trials have found dietary fibre consumption to be inversely related to risk of obesity, type 2 diabetes, and cardiovascular disease (261,262). A recent cohort study from Canada found that obese women with PCOS consumed significantly less dietary fibre than normal weight women without PCOS (263). In addition, fibre intake of women with PCOS was negatively correlated with IR, fasting insulin, glucose tolerance and serum androgens (263). Hence, the mismatch between the amount of fibre traditionally consumed and the fibre content of Western diets, may be an important dietary component contributing to the increased rates of PCOS seen in developed and developing nations.

The current low level of fibre consumption in Western nations also contributes to a lack of microbial diversity in the microbiota. The amount and variety of fibre in the diet is one of the main determinants of ecosystem diversity (264). Lack of microbial diversity has been associated with obesity, IR, and systemic inflammation (136,265,266). As previously discussed, low diversity is one of the key microbiota patterns observed in women with PCOS, and has been positively associated with hyperandrogenism, total testosterone levels, and hirsutism in this population (267). Conversely, ecosystem diversity and richness are hallmarks of Hunter-gatherer microbiotas who consume a high-fibre, more diverse plant-based diet (255,268). A shift towards a more wholefood diet therefore provides a variety of phytonutrients, polyphenols and fibre, in addition to the other essential macronutrients and micronutrients, and is likely to make a significant difference to metabolic and symptomatic outcomes in women with PCOS.

Although discussion of specific details related to lifestyle counselling are beyond the scope of this review, it is clear that improving outcomes in PCOS will require a multifaceted population-based approach that includes public health measures (269,270), improved compliance-aiding strategies, inclusion of nutrition training in medical education (271), implementation of current best-practice management strategies, and further development of the International Guidelines for the Assessment and Management of PCOS (7).

3.9. Conceptual framework of the unified evolutionary theory

Comprehensive International Guidelines have made 166 recommendations for the assessment and management of PCOS (38). We believe the current unified evolutionary theory of the pathogenesis of PCOS provides a conceptual framework that may help practitioners and patients understand the development of PCOS symptoms and pathology in the context of our modern lifestyle and environment. It will hopefully contribute to improved communication, result in improved feelings of empowerment over the personal manifestations of PCOS, improve compliance, reduce morbidity, increase quality of life and inform future research (figure 3).

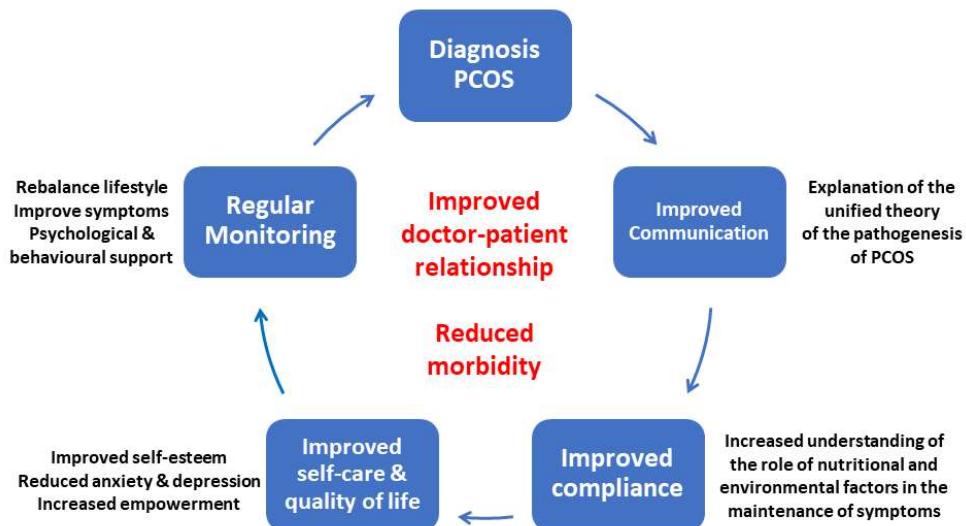

Figure 3. Impact of the unified theory on the management of polycystic ovary syndrome

3.10. Explanation to Women Diagnosed with PCOS

"Polycystic ovary syndrome is a problem that is inherited from both of your parents. The inherited genes are activated by a range of dietary and environmental factors that can cause a number of symptoms. These include weight gain, irregular periods, acne, excess hair growth, hair loss, anxiety and depression. Women with PCOS are also at risk of developing a range of other problems throughout their lifetime if they are not adequately treated. These include gestational diabetes, type 2 diabetes, heart disease and fertility problems. All of these symptoms and problems can be treated, controlled and reversed with appropriate lifestyle changes. These include a healthy

diet, exercise, avoiding environmental chemicals, stress management techniques, sleep and support from friends, family and health professionals. In addition, there are a range of medical and natural treatments that can also be used. Women with PCOS can have healthy, active lives with normal fertility”.

4. Conclusions

Substantial evidence and discussion support an evolutionary basis for the pathogenesis of polycystic ovary syndrome, although many of the mechanistic details are yet to be determined. Nevertheless, multiple lines of evidence from evolutionary theory, comparative biology, genetics, epigenetics, metabolism research, and cell biology, provide supportive evidence and hypothesis-generating data. The ability of animals to synchronize internal physiology, metabolism and reproductive function, with our changing external environment and habitat, are a necessary requirement for individual and species survival. The co-operative and sometimes competitive evolution of metabolism and reproduction provided adaptive survival mechanisms in ancestral environments that appear to be maladaptive in modern environments.

Lifestyle and environmental influences such as food abundance, altered food quality, chemical exposure, circadian disruption, chronic stress and sedentary behaviour, combine to redirect previously beneficial adaptations into adverse symptoms and disease. A unified evolutionary model provides a conceptual framework that considers the role of genetics, developmental programming, the microbiome, dysbiosis, environmental chemical exposure, metabolism, reproduction, and lifestyle factors that are involved in the initiation, treatment and prevention of PCOS. Mechanistic studies of the relative contributions of these and other ultimate and proximate causes are the subject of ongoing research and discussion. An evolutionary model therefore provides a framework to enhance practitioner and patient understanding, improve compliance with lifestyle interventions, reduce morbidity, improve quality of life and will evolve and change over time.

Author Contributions: JP conceptualized, designed and wrote the original draft of the manuscript; COB conceptualization, writing, reviewed and edited the manuscript; JH conceptualization, writing, reviewed and edited the manuscript; FLG conceptualized, reviewed, edited and significantly improved the manuscript. All authors critically revised the manuscript and approved the final submitted version of the manuscript.

Review

Polycystic Ovarian Syndrome: Diagnosis and Management

Michael T. Sheehan, MD, *Department of Endocrinology, Marshfield Clinic-Wausau Center, Wausau, Wisconsin*

ABSTRACT

Polycystic ovarian syndrome (PCOS) affects 4% to 12% of women of reproductive age. The lack of well-defined diagnostic criteria makes identification of this common disease confusing to many clinicians. Also, with the varied manifestations of the disorder a patient may present to any one of several providers: an internist, family practitioner, nurse practitioner, pediatrician, gynecologist, dermatologist, or endocrinologist. Furthermore, the most distressing aspect of PCOS for any given patient may change over time, from hirsutism as a teenager to infertility as a young adult—potentially requiring several different providers along the way. It is important, therefore, that those caring for these patients understand not only the management issues pertinent to their specialty, but also appreciate the other potential health risks in these women. Recent insights into the pathophysiology of PCOS have shown insulin resistance to play a substantial role and as such have brought the long-term issues of type 2 diabetes mellitus and its resultant increased risk of coronary artery disease to the forefront. No longer can irregular menses and/or hirsutism be thought of as benign nuisances.

This review will focus on the two most confusing aspects of PCOS for the practicing provider—diagnosis/differential diagnosis and treatment options. Special attention is given to the role of insulin resistance and the potential utility of insulin sensitizers in management. The benefit and utmost importance of lifestyle modification for the long-term health of these women is stressed as well. It is hoped that some clarity in this regard will allow more women to not only be diagnosed and managed properly for their presenting symptoms (hirsutism, irregular menses, etc.), but also to be educated and managed for the continuing health risk of insulin resistance throughout their lives.

Polycystic ovarian syndrome; Hirsutism; Infertility; Irregular menses; Obesity; Insulin resistance; Insulin sensitizers; Women's health

INTRODUCTION

Polycystic ovarian syndrome (PCOS) is an extremely common disorder affecting 4% to 12% of women of reproductive age.^{1,2} Despite being heterogeneous in nature, the hallmarks of the disease are hyperandrogenism and chronic anovulation. Since its description in 1935 by Stein and Leventhal,³ much has been learned about the pathophysiology of PCOS from its neuroendocrine underpinnings⁴ to an ever-growing understanding of the link between obesity, insulin resistance (IR) and PCOS.⁵ Based on this current understanding of PCOS, it is important that the patient and medical provider approach management not only toward improving the often troublesome hirsutism and infertility but also toward the long-term risks associated with IR. Indeed, the management of the PCOS patient often will vary over time as the patient enters different stages of life with different goals. In contrast, because of the long-term health implications of IR, the importance of lifestyle modification toward weight management and maintaining adequate physical activity should be the one constant in the management of these patients.

Despite the high prevalence of PCOS, the diagnosis and differential diagnosis remains confusing. This is in part due to the lack of a specific diagnostic test for the disorder. Oftentimes the clinical history and a few laboratory tests are enough to make the diagnosis and exclude other entities that may present in much the same way. Once the diagnosis is made, the management options can seem daunting at first. This has become especially true since the link between PCOS and IR has been made (i.e., adding the issue of if/when insulin sensitizers should be used). However, if approached from the standpoint of what the patient and/or medical provider is concerned about at any given time, the options seem more manageable. Generally there are but four issues which arise in the management of PCOS patients: regulation of menses, control of hirsutism, fertility issues, and the management of the IR syndrome and its associated risks (type 2 diabetes mellitus, dyslipidemia, and cardiovascular disease). This review aims to not only clarify the diagnosis of PCOS and the management of its manifestations, but also to stress the importance of taking a life-long approach to the management of the IR syndrome in these often young patients.

CLINICAL FEATURES AND HISTORY

Often the first step in the diagnosis of any disorder lies in the recognition of historical and physical manifestations of the disease process. These clues may be brought to the attention of the medical provider by the patient (i.e., the complaint of hair growth under the chin) or during a routine history and physical examination (i.e., a history of irregular menstrual cycles or the discovery of acanthosis nigricans). No matter how these issues come to light, the crucial next step is to further pursue the findings through a more detailed history and examination targeted at the diagnosis and differential diagnosis. This is extremely important in the evaluation of PCOS because, again, there is not one specific test that makes the diagnosis.

PCOS is most simply defined as the presence of hyperandrogenism (clinically and/or biochemically) and/or chronic anovulation in the absence of specific adrenal and/or pituitary disease.⁶ Table 1 outlines the clinical features of PCOS. Hyperandrogenism may present clinically as hirsutism, acne, and/or male pattern alopecia. Hirsutism can be defined as the growth of coarse hair on a woman in a male pattern (upper lip, chin, chest, upper abdomen, back etc.). This is to be distinguished from hypertrichosis that involves a more uniform, whole body distribution of fine hair. Acne related to hyperandrogenism may be difficult to distinguish from normal pubertal acne in an adolescent with PCOS though pubertal acne in general is twice as prevalent in adolescent males versus females and males are more likely to have severe disease.⁷ Thus, an adolescent female with moderate to severe acne should be investigated for PCOS. Furthermore, the development or persistence of acne into adulthood is unusual and should raise attention. The severity of any of these manifestations is highly variable and may depend on genetic and ethnic differences in the sensitivity to the effects of androgens. The presence of virilization (clitoromegaly, deepening voice, increased musculature, or rapidly progressive hirsutism or alopecia), however, is not a feature of PCOS, but instead of more severe hyperandrogenism. Chronic anovulation often presents as oligomenorrhea, amenorrhea, dysfunctional uterine bleeding, and/or infertility. Interestingly, however, around 20% of patients with PCOS may describe normal menstrual cycles.⁸ Often, but not always, menstrual abnormalities are long-standing, even since menarche. Other women may only develop menstrual problems later in life, perhaps after significant weight gain. Furthermore, primary amenorrhea is possible although not common.

When clinically evaluating a patient for the possibility of PCOS, it is also important to search for signs of IR. Upper-body obesity is a key component of the IR syndrome.⁹ However, obesity is not required for the diagnosis of PCOS with perhaps only 35% to 50% of these patients being obese.^{1,10} Acanthosis nigricans on physical examination is a sign of IR. A personal or family history of type 2 diabetes mellitus or gestational diabetes mellitus, or the presence of hypertension should also be sought in the evaluation. Overall, the criteria for diagnosis of the IR syndrome in women should be evaluated in all patients (table 2).

DIAGNOSIS AND DIFFERENTIAL DIAGNOSES

As noted previously, the diagnosis of PCOS is based on hyperandrogenism or chronic anovulation in the absence of specific pituitary and/or adrenal disease. The differential diagnoses of PCOS are listed in table 3 along with the tests needed to adequately assess for these possibilities. As is apparent, these disorders may cause some, but not all, features of PCOS. For instance, pregnancy, hypothyroidism, and hyperprolactinemia may all cause secondary amenorrhea but do not cause hirsutism; however, they need to be ruled-out.

A careful history and physical examination, looking for other signs of those disorders that may not be a part of PCOS, must be performed. Symptoms of cold intolerance, dry skin, and increased fatigue (among others) may signify hypothyroidism, as would the presence of a goiter. Galactorrhea may or may not be present in women with hyperprolactinemia. Signs of virilization signify more significantly elevated androgen levels than those seen in PCOS (see below) and may indicate an ovarian or adrenal tumor. Patients with Cushing's syndrome may be more apt to have hypertension, purple abdominal striae, prominent dorsal cervical fat pads, and a rounded, plethoric face.

Late-onset congenital adrenal hyperplasia, even though relatively rare, deserves mention as it can mimic PCOS in all regards clinically. Congenital adrenal hyperplasia is due to one of a variety of enzymatic defects in adrenal steroidogenesis (which leads to increased levels of precursor hormones that have androgenic properties). The classic forms of these disorders involve complete enzymatic defects and present in newborn girls as ambiguous genitalia. More recently partial enzymatic defects in these same pathways have been shown to not present until menarche and then with irregular menses and hirsutism mimicking PCOS. Measurement of the hormone preceding the enzymatic block is used to definitively diagnose these disorders. The most common form of late-onset congenital adrenal hyperplasia is due to

Table 2. Diagnostic criteria for the insulin resistance syndrome in women.

Any three or more of the following:

Waist circumference >88 cm

Triglycerides \geq 150 mg/dL^a

HDL-cholesterol <50 mg/dL^b

Blood pressure \geq 130/85

Fasting glucose \geq 110 mg/dL^c

^a To convert triglycerides to mmol/L multiply by 0.0112.

^b To convert HDL-cholesterol to mmol/L multiply by 0.0256.

^c To convert glucose to mmol/L multiply by 0.055.

HDL, high density lipoprotein. Adapted from reference 9.

21-hydroxylase deficiency and, as such, is often the only type tested for in the differential diagnosis of PCOS. The interested reader is referred to the review by Azziz and colleagues for a more complete discussion of these disorders.¹¹

LABORATORY EVALUATION

Biochemical evaluations should look for supporting evidence of PCOS (hyperandrogenism and IR) and rule out the other disorders described above. All of the tests in table 3 (with the exception of the 24-hour urine free cortisol) should be performed in every patient. Tests helpful in evaluating for IR are listed in table 4. It should be noted that direct testing for IR is fraught with difficulties and there are many methods in use.¹² Only the simplest, fasting glucose-to-insulin ratio is mentioned for simplicity. It should be noted that the use of the fasting glucose-to-insulin ratio to measure IR has been studied primarily in obese and lean euglycemic, non-Hispanic white adult women and in obese and lean euglycemic, Hispanic adolescents.¹³⁻¹⁵ It is likely not a valid marker in patients with impaired fasting glucose or impaired glucose tolerance, and assessing for IR in patients who are not euglycemic is likely a moot point. Furthermore, none of the tests for IR are extremely sensitive or specific, and the argument can be made that none are needed. On the contrary, assessment of fasting lipids and glucose may be enough (table 2). Lastly, a 2-hour oral glucose tolerance test may be a better predictor of IR than fasting glucose,¹⁶ and it is extremely useful in categorizing patients' risk of type 2 diabetes mellitus, which may affect therapeutic decisions.

There are a variety of nuances in the interpretation of these laboratory tests that can greatly affect further decision-making:

Table 3. Differential diagnoses and screening tests.

Diagnosis	Laboratory test
Pregnancy	Pregnancy test
Hypothyroidism	TSH
Hyperprolactinemia	Prolactin
Late-onset CAH	17-hydroxyprogesterone ^a
Ovarian tumor	Total testosterone ^b
Hyperthecosis	Total testosterone
Adrenal tumor	DHEA-S ^b
Cushing's syndrome	24-hour urine free cortisol

^a Only assesses for 21-hydroxylase deficiency (most common form of CAH).

^b Degree of elevation helpful.

TSH, thyroid stimulating hormone; CAH, congenital adrenal hyperplasia; DHEA-S, dehydroepiandrosterone-sulfate.

Testosterone

- A total testosterone is likely to be more reliable than a free testosterone given the difficulties seen with many of the assays used for the latter.¹⁷
- Testosterone values may be normal in PCOS.
- Oral contraceptives will lower total testosterone, and interpretation in this setting is difficult (3 months off oral contraceptives is best to get a “true” testosterone value).
- Most testosterone values in PCOS will be ≤ 150 ng/dL (≤ 5.2 nmol/L).
- Testosterone values of ≥ 200 ng/dL (≥ 6.9 nmol/L) warrant consideration of an ovarian or adrenal tumor.¹⁸

Dehydroepiandrosterone-sulfate (DHEA-S)

- DHEA-S values may be normal or slightly elevated in PCOS.
- DHEA-S values ≥ 800 $\mu\text{g}/\text{dL}$ (21.7 $\mu\text{mol}/\text{L}$) warrant consideration of an adrenal tumor.¹⁸

Prolactin

- Mild hyperprolactinemia has been reported in 5% to 30% of patients with PCOS.^{19,20} Prolactin is generally only 50% above the upper limit of normal.²¹ Furthermore, hyperprolactinemia is most often transient, with perhaps only 3% to 7% of hyperprolactinemic PCOS patients having persistently elevated prolactin levels.²² Thus, it is now felt that PCOS and hyperprolactinemia are independent disorders. If normalization on re-sampling does not occur, then an assessment for other causes should be undertaken (including pituitary magnetic resonance imaging).
- Patients with prolactinomas may have polycystic ovaries on ultrasound.²³

17-hydroxyprogesterone

- A morning, fasting, unstimulated level of <200 ng/dL (<6 nmol/L) in the follicular phase reliably excludes late-onset 21-hydroxylase deficiency.
- Further evaluation of levels ≥ 200 ng/dL involves adrenocorticotrophic hormone (ACTH)-stimulation with an intravenous 250 μg dose and a 30 minute value (stimulated values $\geq 1,000$ ng/dL (≥ 30 nmol/L) confirm the diagnosis).¹¹
- Oral contraceptives and glucocorticoids can affect values.

24-hour urine free cortisol

- Mild elevations can be seen in PCOS with values ≥ 2 times the upper limit of normal more consistent with Cushing's syndrome.
- For mild elevations a dexamethasone-suppression, corticotropin-releasing hormone stimulation test is needed to distinguish mild Cushing's syndrome from pseudo-Cushing's.²⁴
- Interpretation of serum (but not urine) cortisol levels in patients on oral contraceptives is problematic as cortisol-binding globulin may be increased falsely elevating the values (it is especially important that oral contraceptives be discontinued before dynamic testing is performed).

Luteinizing hormone/follicle stimulating hormone (LH/FSH) ratio

- A ratio ≥ 2.0 is suggestive of PCOS but is not highly sensitive or specific.
- Gonadotropin levels are affected by oral contraceptives.

Pelvic ultrasonography may be very helpful in the evaluation as well, but polycystic ovaries are not specific for PCOS with over 20% of “normal” women having this finding.²⁵ The number of follicles and ovary volume are both important in the ultrasound evaluation. The criteria for PCOS put forth by Adams et al. are the most often cited: the presence of ≥ 10 cysts measuring 2-8 mm around a dense core of stroma or scattered within an increased amount of stroma.²⁶ A recent proposal to modify these criteria has been put forth by Jonard et al.: “increased ovarian area ($>5.5\text{cm}^2$) or volume (>11 mL) and/or presence of ≥ 12 follicles measuring 2 to 9 mm in diameter (mean of both ovaries).”²⁷ These criteria had a specificity of 99% and a sensitivity of 75% for the diagnosis of PCOS.

The approach to laboratory and ultrasound evaluations in the diagnosis of PCOS varies widely without any consensus even among experts in the field. Indeed, the diagnosis of PCOS in Europe does not require any hormonal testing, with great importance placed on the finding of polycystic ovaries on ultrasound.²⁸ This is in stark contrast to the National Institute of Health conference in 1990 which did not include ultrasound evidence of polycystic ovaries in the diagnostic criteria.⁶ What is needed is a simple consensus that is easy to implement for the clinician trying to diagnose this highly prevalent disorder with important health consequences.

Table 4. Laboratory evaluation for insulin resistance/glucose intolerance.

Test	Interpretation
Fasting glucose/insulin ratio	<4.5 in obese, euglycemic, non-Hispanic white adult polycystic ovarian syndrome patients ¹⁴ (<7.0 in adolescents ¹³) consistent with insulin resistance
75 g oral glucose tolerance test	Normal: 2 hour glucose <140 mg/dL Impaired glucose tolerance: 2 hour glucose 140-199 mg/dL Diabetes: 2 hour glucose ≥ 200 mg/dL

Perhaps this 'clinical' consensus should be different than that used in the research setting. An extremely practical proposal has recently been put forth for the diagnosis of PCOS by Homburg.²⁸ In this proposal any one of four classic symptoms of PCOS (menstrual disturbance, hirsutism, acne or anovulatory infertility) should lead to an ultrasound evaluation of the ovaries. If polycystic ovaries are found, the diagnosis is confirmed. If the ovarian morphology is normal, then biochemical testing is undertaken. If any one or more of the following are noted, the diagnosis is confirmed: elevated LH, fasting glucose/insulin <4.5, and/or elevated testosterone or free androgen index (in the absence of late-onset congenital adrenal hyperplasia). The argument could be made, however, that the exclusion of the other conditions listed in table 3 should be a part of such guidelines. That said, proposals such as the one put forward by Homburg are the first steps toward a much needed, simple, and unified set of diagnostic guidelines for the clinician.

MANAGEMENT FOR PCOS

The medical management of PCOS can be broken down into four components, three of which are "acute" issues (control of irregular menses, treatment of hirsutism and management of infertility) and one that is more "chronic." This latter issue may be the most important but least remembered by patients and providers alike—management of the IR syndrome. "Acute" issues that need management may change, however, a continuous life-long management approach is important for the IR of PCOS.

CONTROL OF IRREGULAR MENSES

This cardinal feature of PCOS can be both a nuisance and a significant health risk to patients. Irregular menses can be embarrassing because of unpredictability and painful because the infrequent occurrence often leads to increased cramping with the heavier flow. Infrequent menstrual cycles also carry a 3-fold increased risk of endometrial carcinoma.²⁹ In general, four menses per year are required to control this increased risk. Four common management options in this regard are listed in table 5.

The mainstay for decades has been oral contraceptives, which are nearly always effective at normalizing menstrual cycles. The newer formulations are generally safer than those of years past, although recently their use in PCOS is coming under greater scrutiny in regard to their potentially detrimental effect on insulin sensitivity.³⁰ Oral contraceptives should not be used in those with a history of hypercoagulable state or deep venous thrombosis or in women over the age of 35 who smoke. A fasting lipid profile should be assessed before initiating therapy as oral contraceptives can worsen hypertriglyceridemia. For those women who might prefer not to cycle every month, periodic progesterone withdrawal is an option. A 7- to 10-day course of medroxyprogesterone 10 mg daily every 3 months will often result in four menses annually. One appealing aspect of this is that women can often plan their menses to avoid vacations, etc. A cycle should occur a week after the course of therapy has been completed.

Because of the central role IR plays in PCOS, it is understandable that improving insulin sensitivity can restore normal menstrual function. This might be looked at as treating the "root cause" of the problem rather than simply using oral contraceptives to regulate the cycles. Weight loss itself can result in improvement in menses. Kiddy et al. showed improvement in menstrual function in 9 of 11 patients (82%) with oligomenorrhea who lost >5% initial body weight (range 5.9 to 22%) on a 1000 kcal/day, low-fat diet over 6 to 7 months, whereas only 1 of 11 patients (9%) losing <5% body weight demonstrated such improvement.³¹ Metformin therapy has been shown to induce resumption of normal, ovulatory menstrual cycles in 40% to 90% of patients studied.³²⁻³⁵ Doses used varied from 500 to 1000 mg twice daily. Table 6 lists dosing/titration information, as well as safety issues with metformin use. The response to metformin is predictable based on higher levels of testosterone^{33,36,37} and in those patients with less severe menstrual irregularities at baseline.³⁷ The degree of hyperinsulinemia may³⁷ or may not^{33,36} be predictive. It is not clear how long metformin should be tried before it is deemed ineffective at improving menstrual function. However, a 6 month trial seems reasonable.

Overall, the option chosen at present to regulate menses should depend on factors such as the degree of weight excess or IR/glucose intolerance, the presence of other PCOS issues requiring management (hirsutism or infertility), and patient and/or physician preferences based on a careful discussion. Insulin sensitizers and/or weight loss may be most effective in patients in which this is a greater problem. However, recent data have shown that lean PCOS patients also respond to metformin.³⁸ In the future perhaps certain patient characteristics and/or laboratory parameters will be found to be predictive of the response to various interventions that will help guide the clinician.

TREATMENT OF HIRsutISM

Hirsutism can be measured and quantified by a variety of methods. However, the decision of if and when to treat should be based on the patient's perception of the excess terminal hair growth. A similar degree of hirsutism in two different patients may result in vastly different degrees of distress. When thought of simply, hirsutism can be managed in two ways: through medical means by decreasing the amount or blocking the action of androgens or by mechanical means (i.e., shaving, etc.). These options are summarized in table 5.

Table 5. Management options for polycystic ovarian syndrome.

Control of irregular menses
Oral contraceptives
Periodic progesterone withdrawal
Lifestyle modification/weight loss
Metformin
Treatment of hirsutism
Biochemical
Decreasing testosterone production
Oral contraceptives
Lifestyle modification/weight loss
Metformin
Decreasing testosterone action
Anti-androgens (spironolactone)
Lifestyle modification/weight loss
Metformin
Mechanical
Plucking/shaving/electrolysis/laser
Vaniqa cream (eflornithine hydrochloride 13.9%) (Bristol Myers-Squibb/Gillette Co, Princeton, NJ)
Management of infertility
Clomiphene citrate
Lifestyle modification/weight loss
Metformin
Thiazolidinediones
Management of insulin resistance/type 2 diabetes mellitus risk
Lifestyle modification/weight loss
Metformin

Table 6. Dose titration and safety issues with the use of metformin.

Dose titration example		
Breakfast	Supper	Duration
X	500 mg	1 week
500 mg	500 mg	1 week
500 mg	1000 mg	1 week
1000 mg	1000 mg	Thereafter
Side effects	Gastrointestinal intolerance in 30% (nausea, abdominal pain and/or diarrhea)	
Precautions	Hold for 48 hours prior to and after surgery and/or administration of radiocontrast materials	
Contraindications	Creatinine ≥ 1.4 mg/dL (for women) Liver disease (or risk thereof: alcohol abuse/binge drinking) Other risks for lactic acidosis: pulmonary disease, congestive heart failure	

MEDICAL

Decreasing testosterone production

Excess testosterone production is predominantly ovarian in nature and is caused by both increased luteinizing hormone stimulation from the pituitary and the effect of hyperinsulinemia at the ovary. By decreasing gonadotropin production and increasing sex hormone binding globulin (SHBG), oral contraceptives generally decrease bioavailable testosterone levels by 40% to 60%.³⁹ By improving insulin sensitivity (and thus lowering insulin levels), both metformin and lifestyle modification/weight loss also lower testosterone, although to a lesser degree.⁴⁰ Overall hirsutism scores improve by approximately 33% with the use of second or third generation oral contraceptives.⁴¹ Only 50% of patients respond to oral contraceptives, however.⁴² Targeting IR seems to have less pronounced improvements on hirsutism scores: metformin (3% to 13%)⁴³⁻⁴⁵ and troglitazone (17%).⁴⁶ Insulin sensitizers are not yet well studied in this area, however, and as such should not be the initial therapeutic option for the management of hirsutism unless there are contraindications to more established therapies.

Decreasing testosterone action

As none of the above therapies will fully suppress testosterone levels, the additional method of blocking testosterone action is useful. There are several anti-androgens available, but only spironolactone will be discussed further since many of the others have poor side effect profiles, are expensive, or are unavailable in the United States. Spironolactone is an aldosterone antagonist that was initially introduced as an antihypertensive agent. It also, however, has a 67% relative affinity for the testosterone receptor (versus dihydrotestosterone).⁴⁷ Spironolactone reduces hirsutism scores by ~40%^{48,49} and is effective in ~50% of patients when used alone.⁵⁰ When combined with oral contraceptives, the response rate increases to 75%⁵⁰ with a reduction in hirsutism scores of about 45%.⁵¹ Fifty milligrams twice daily is a reasonable starting dose working up to 100 mg twice daily if needed after 6 to 12 months. The most common side effect is menstrual irregularity, but nausea may also occur. Due to its effect on menses, its unknown safety during pregnancy, and the theoretical risk of preventing normal masculinization of a male fetus, the use of spironolactone in combination with oral contraceptives may be preferred. For monitoring, potassium can be checked 1 to 2 weeks after initiation or after a dose increase.

The effect of metformin and lifestyle modification/weight loss on testosterone action involves the increase in SHBG that occurs with improvement in insulin sensitivity. With an increase in SHBG, bioavailable (free) testosterone decreases, thus lowering testosterone action. The effect of these treatments on hirsutism, then, is due in part to decreased testosterone action (in addition to lowering testosterone as noted earlier). In the previously mentioned study by Kiddy et al., >5% weight loss resulted in a 40% reduction in hirsutism.³¹

Whatever biochemical option is used for hirsutism, the patient should be informed that a trial of 6 to 12 months is needed before any given therapy and/or dose can be deemed ineffective. Also, as noted, not all patients will respond to treatment, and any response is likely to be incomplete. Thus, mechanical measures will often be needed, although at a lesser frequency than would otherwise be required.

MECHANICAL

Plucking/shaving/electrolysis/laser

Many women have already used one or a combination of these methods to control hirsutism by the time they present for medical evaluation. Others have and may continue to avoid them for fear of worsening hair growth, although this does not occur.⁵² Plucking is best avoided, as it can lead to folliculitis and scarring in some women. Shaving is likely to be the cheapest and simplest way to remove unwanted hair but may not be acceptable to some women. Electrolysis involves electrocoagulation of the hair follicle, which may or may not be permanent and generally does not result in scarring.²¹ Laser treatment of hirsutism involves causing selective thermal damage to the hair follicle while avoiding surrounding tissue and thus works best in fair-skinned patients with darker unwanted hairs.⁵³ Laser treatment may lead to erythema, edema, blistering and/or temporary hyper- or hypopigmentation.⁵⁴

Eflornithine hydrochloride 13.9% cream

Vaniqa (Bristol Myers-Squibb/Gillette Co., San Diego, CA) is approved for the treatment of unwanted facial hair. Its mechanism of action is to inhibit the enzyme L-ornithine decarboxylase, which is involved in hair growth. Through this mechanism, Vaniqa slows the growth of, but does not remove hair. In a 24-week trial, 58% of treated subjects had some improvement in facial hirsutism versus 34% in the placebo group, while 32% and 8%, respectively were deemed to have marked improvement.⁵⁵ Continued use is required, however, as hair growth rates returned to baseline after 8 weeks off therapy. Adverse events more common than in the placebo group were limited to skin irritation (burning, stinging, and/or tingling). Because Vaniqa is often not covered by insurance, it may be less appealing.

MANAGEMENT OF INFERTILITY

PCOS accounts for 75% of anovulatory infertility. Additionally, if/when pregnancies do occur, the first trimester miscarriage rate is as high as 30% to 50%.⁵⁶ Successful medical management of infertility in these patients can be extremely rewarding to patients and physicians alike. Management of infertility can be difficult, however, and a team approach between the endocrinologist, gynecologist and, perhaps, reproductive endocrinologist should be stressed. An extensive review of the intricacies of infertility management of the patient with PCOS is beyond the scope of this review. Instead, a brief discussion of the relative resistance to clomiphene therapy in PCOS will be

undertaken followed by a more in depth look at the potential utility of methods aimed at improving insulin sensitivity (with a focus on metformin).

CLOMIPHENE CITRATE

Obese women with PCOS often do not respond to low doses of clomiphene, with only a 20% ovulation rate at the 50 mg dose seen in women weighing more than 91 kg.⁵⁷ Indeed, the degree of obesity correlates with the dose of clomiphene needed to induce ovulation.⁵⁸ The higher doses of clomiphene often required may cause side effects and can increase the rate of multiple gestations.⁵⁹ Clomiphene has been extensively studied in combination with metformin (see below).

LIFESTYLE MODIFICATION/WEIGHT LOSS

As mentioned in previous discussions, weight loss reduces hyperinsulinemia and subsequently hyperandrogenism. In the study by Kiddy et al. discussed earlier, about 40% of obese women with PCOS (mean body mass index [BMI] ~34 kg/m²) who lost >5% of initial body weight with caloric restriction achieved spontaneous pregnancy.³¹ A more recent trial compared the effects of an energy-restricted diet (~1400 kcal/day) through either a low or high protein diet in 28 obese (mean BMI ~ 37 kg/m²) PCOS subjects over 12 weeks.⁶⁰ Subjects were also advised to increase exercise to a minimum of 3 times weekly though no information was reported as to the actual duration and/or intensity achieved. Average weight loss was 7.5% (with abdominal fat decreasing 12.5%), and 3 of the 20 subjects actively trying to conceive did so (two in the high and one in the low-protein group) for a rate of 15%. Thus, lifestyle modification needs to be stressed in the treatment of infertility. A 3 to 6 month trial of aggressive lifestyle modification may be a prudent first step before considering an insulin sensitizer. However, many patients will have difficulty in achieving weight loss (see later).

METFORMIN

The initial report of metformin in the treatment of PCOS by Velazquez et al. in 1994 described three spontaneous pregnancies (~11% of subjects).⁶¹ Since that time, a number of other studies have been completed assessing metformin's role in the treatment of PCOS. The primary outcomes of these studies were the effects on parameters of IR, hyperandrogenemia, and improvements in menstrual function and ovulation. Many of these studies were small, involving approximately 20 patients each, but in the five trials describing spontaneous pregnancies, the rate was between 5% and 18%.^{33,62-65} A recent study by Heard et al. involved 48 anovulatory PCOS patients (mean age of 29.9 years and BMI of 28.7 kg/m²) enrolled for 15 months.³⁴ Metformin was started at 500 mg twice daily and increased to three times daily if ovulation did not occur by 6 weeks, and clomiphene was added 6 weeks later as needed.

Normalization of menstrual cycles and ovulation occurred in 19/48 subjects (40%) on metformin alone, and 15 of them (79%) became pregnant. Nearly 75% of these pregnancies

on metformin alone occurred within 3 months of starting the medication. The addition of low dose clomiphene (50 mg) resulted in five additional pregnancies.³⁴ Similar rates of ovulation (40%) were seen with metformin alone in obese subjects (mean BMI ~32 kg/m²), while the addition of clomiphene increased that rate to 89%.³² The use of clomiphene alone resulted in only an 11.5% ovulation rate. Pregnancies were not reported. Lastly, in clomiphene-resistant PCOS patients, metformin pre-treatment increased conception rates from 7% to 55%.⁶⁶ The use of metformin also improves the outcome of more advanced infertility therapies. When used for 1 month prior to ovulation induction with FSH, metformin reduced the risk of ovarian hyperstimulation.⁶⁷ As well, metformin improves fertilization and pregnancy rates in women with PCOS undergoing *in vitro* fertilization.⁶⁸ Thus, in the setting of infertility, metformin therapy should likely be continued for as long as fertility efforts are ongoing, even if it "fails" initially.

As mentioned, once pregnancy is achieved in PCOS patients, the first-trimester miscarriage rate is 3-fold higher than that of normal women.⁵⁶ Recently, metformin therapy continued throughout pregnancy has been shown to reduce this risk of early pregnancy loss. In a retrospective study of women who became pregnant on metformin and continued it throughout pregnancy, the rate of early pregnancy loss was 8.8% compared to 41.9% of women who were not on the drug.⁶⁹ In a prospective pilot study, Glueck et al. have reported on 19 women receiving metformin during their pregnancy to date.⁷⁰ Fifty-eight percent have had normal live births, 32% have ongoing pregnancies beyond the first trimester, and 10.5% had first-trimester miscarriages. No birth defects occurred.⁷⁰ This study will eventually include 125 women with PCOS. However, metformin is not approved for use in ovulation induction or during pregnancy. It is pregnancy category B.

THIAZOLIDINEDIONES (TZDs)

Several studies evaluating ovulation induction with troglitazone were completed before it was removed from the market in 2000.^{46,71,72} Troglitazone alone resulted in ovulatory rates of >40%, and the success rate of clomiphene increased from 35% to 75% with troglitazone pretreatment.⁷¹ Also, the use of troglitazone in clomiphene-resistant patients resulted in ovulation and pregnancy rates of 83% and 39%, respectively.⁷² In the largest trial involving a TZD, Azziz et al. evaluated the effect of troglitazone in 305 obese PCOS patients.⁴⁶ At the highest dose of troglitazone (600 mg daily), 57% of the patients ovulated >50% of the time compared with just 12% of the placebo group. Although pregnancy was not an outcome measure of the study, troglitazone-treated subjects had a 4-fold greater fertility rate compared to the placebo group (18% versus 4%).⁴⁶ Recently, data using the currently available TZDs was published. Pre-treatment with rosiglitazone 4 mg twice daily was used with placebo or clomiphene on cycle days 5-9 in 25 PCOS patients previously resistant to clomiphene (mean BMI >35 kg/m²).⁷³ Rosiglitazone alone resulted in ovulation

in 33% of subjects versus 77% in the combination group. One patient in the rosiglitazone-only group (8%) and two in the rosiglitazone-clomiphene group (15%) conceived.⁷³ TZDs are not approved for use in ovulation induction or during pregnancy. They are pregnancy category C.

DIABETES RISK AND LONG-TERM MANAGEMENT OF IR IN PCOS

Most PCOS patients are inherently IR with the obesity seen in many, only adding to this problem. Perhaps not surprisingly then a substantial proportion of PCOS patients have abnormalities on the oral glucose tolerance testing at the time of diagnosis. When assessed overall (obese and lean together), PCOS patients had a 31% rate of impaired glucose tolerance and 7.5% met the criteria for type 2 diabetes mellitus.⁷⁴ These results were confirmed in another United States study,⁷⁵ but a European study found only a 6.4% rate of impaired glucose tolerance and no cases of type 2 diabetes mellitus.⁷⁶ This discrepancy may be related to a significant difference in the severity of obesity between studies.⁷⁷ In the United States, even non-obese PCOS patients have a prevalence of these disorders 3 times that of the general population (10.3% impaired glucose tolerance and 1.5% type 2 diabetes mellitus).⁷⁴ Also, Norman et al. followed 67 women with PCOS (54 with normal glucose tolerance and 13 with impaired glucose tolerance) for a mean of 6.2 years.⁷⁸ In those with normal glucose tolerance at baseline 17% had developed impaired glucose tolerance or type 2 diabetes mellitus over time, while 54% of those with impaired glucose tolerance at baseline had progressed to type 2 diabetes mellitus. Further support for the high prevalence of abnormal glucose tolerance in PCOS is the 10-fold increased risk of developing gestational diabetes mellitus compared to the general population (baseline risk ~3%).⁷⁹ Lastly, Cibula et al. noted a 4-fold increased prevalence of type 2 diabetes mellitus in women with PCOS who had undergone ovarian wedge resection for polycystic ovaries some 20 to 40 years earlier compared to a closely matched control population.⁸⁰

With the high prevalence of abnormalities in glucose tolerance in PCOS and the significant impact this might have on patients' health, much has been done to evaluate the effects of insulin sensitizers in this regard. Metformin is perhaps the most widely studied agent thus far and most,^{62,64,81} but not all⁸² uncontrolled studies have shown a significant improvement in insulin sensitivity. A review of controlled trials showed similar findings with 5 of 7 studies showing improvements in insulin sensitivity.⁴⁰ Troglitazone has similar effects in PCOS patients.^{83,84} Also, metformin use throughout pregnancy in women with PCOS decreases the rate of gestational diabetes mellitus from ~30% to ~3%.⁷⁹

With these results, there may be potential utility in using insulin sensitizers to prevent or delay the onset of type 2 diabetes mellitus in PCOS patients. Perhaps the closest data available to deal with such an issue comes from the Diabetes Prevention Program where the effect of metformin or

lifestyle modification was compared to placebo in obese patients with impaired glucose tolerance (68% of whom were women). Metformin resulted in a 31% reduction in the development of type 2 diabetes mellitus over 2.8 years versus placebo, while lifestyle modification reduced the risk to a greater extent (58%).⁸⁵ It is important to note that the lifestyle intervention was modest involving approximately a 7% weight loss and 20 minutes of brisk walking daily. Metformin plus lifestyle modification was not studied. It is apparent that a strong emphasis needs to be placed on lifestyle modification in the management of the long-term health risks of PCOS. The results of the Diabetes Prevention Program should be discussed at length with all PCOS patients. If metformin is used for the prevention of type 2 diabetes mellitus, it is unclear how long it should be continued, as the risk is lifelong and the effectiveness of this agent wanes after it is discontinued. Further research is needed in this area.

Information on the effectiveness of various therapies on two of the cornerstones of 'acute' PCOS management (hirsutism and irregular menses) and their effect on testosterone levels is spread throughout this discussion. Therefore, table 7 is included as a concise summary.

OTHER ISSUES

Cardiovascular Risk Factors and Disease in PCOS

Aside from the increased risk of type 2 diabetes mellitus in PCOS patients, there are multiple other metabolic abnormalities that put them at higher risk for cardiovascular disease. Many,⁸⁶⁻⁸⁹ but not all^{90,91} studies have shown either a greater prevalence of diagnosed hypertension or higher ambulatory blood pressure in PCOS. The pattern of dyslipidemia in PCOS is in keeping with IR, increased triglycerides, and low HDL-cholesterol.⁹²⁻⁹⁵ Women with PCOS may also have higher levels of small, dense LDL-cholesterol,⁹⁶ homocysteine,⁹⁷ plasminogen activator inhibitor type 1,⁸¹ decreased insulin-induced vascular relaxation,⁹⁸ and endothelial dysfunction.⁹⁹ As an extension of these data on risk factors, two retrospective studies of patients undergoing coronary angiography found women with a significant history of hirsutism to be more likely to have coronary artery disease.^{100,101} Also, women with polycystic ovaries on ultrasound had more extensive coronary artery disease at catheterization than those without such ultrasound findings.¹⁰¹ Lastly, PCOS patients have been shown to have increased carotid intimal media thickness¹⁰² and an almost 6-fold increased prevalence of coronary artery calcification¹⁰³ versus age-matched control subjects.

Based on the increased prevalence of risk factors in patients with PCOS, Dahlgren and colleagues estimated a 7-fold increased risk of myocardial infarction in these women.¹⁰⁴ While there is evidence emerging showing increased cardiovascular and cerebrovascular event rates in these patients, the burden of disease does not seem to be as great as initially predicted. The Nurses' Health Study cohort revealed that women with "usually irregular" or "very irregular"

Table 7. Effects of various therapies on serum testosterone, hirsutism, and menstrual function in PCOS.

Intervention	Hirsutism			
	Decreased T	Response rate	Degree of improvement	Rate of improved menses/ovulation
Weight loss ($\geq 5\%$)	31% ³¹	50% ¹²⁶	40% ³¹	40% to 81% ^{31,126,127}
Metformin ^a	16% to 70% ^{38,40,63,128}	50% ¹²⁹	3% to 25% ^{43-45,129}	40% to 90% ³²⁻³⁵
TZD	25% to 35% ¹²⁸	Not reported	17% ⁴⁶	33% to 83% ^{46,71,73,130}
OCP	40% to 60% ³⁹	50% ⁴²	33% ⁴¹	Not applicable
Spironolactone	Not applicable	50% ⁵⁰	40% ^{48,49}	Not applicable ^b
OCP + spironolactone	Not applicable	75% ⁵⁰	45% ⁵¹	Not applicable
Clomiphene	Not applicable	Not applicable	Not applicable	11% to 48% ^{32,66,131}
Metformin + clomiphene	Not applicable	Not applicable	Not applicable	75% to 89% ^{32,66}
TZD + clomiphene	Not applicable	Not applicable	Not applicable	72% to 75% ^{71,73,131}

^a Includes data from lean and obese patients with regard to decreased T and menses/ovulation (see references for details).

^b Spironolactone alone may cause/worsen menstrual irregularities.

T, total or free testosterone (see specific reference for details); TZD, thiazolidinediones; OCP, oral contraceptive pills.

menstrual cycles had an increased risk of coronary artery disease events of approximately 20% and 60%, respectively versus those with “very regular” cycles.¹⁰⁵ There was a non-significant increased risk of cerebrovascular events of ~30%. Wild et al. found a significantly increased risk of stroke (odds ratio, 2.8) but no difference in coronary artery disease in a retrospective cohort of PCOS patients followed for 30 years,¹⁰⁶ while Cibula et al. reported a 4-fold increased risk of coronary artery disease in PCOS patients followed 20 to 40 years.⁸⁰ Further study into this crucial aspect of long-term risk/care of PCOS patients is desperately needed.

PCOS in Adolescents

Premature pubarche (appearance of pubic hair before age 8) may be an early expression of PCOS and is associated with ovarian hyperandrogenism¹⁰⁷ and the development of chronic anovulation.¹⁰⁸ Increased awareness of PCOS by physicians has and will continue to lead to diagnosis at an earlier age. Many previously mentioned diagnostic and therapeutic issues apply to adolescents with PCOS. Perhaps most alarming is the aspect of IR. It is well known that the increase in type 2 diabetes mellitus in the United States has paralleled the increase in overweight individuals and obesity.¹⁰⁹ Furthermore, the incidence of type 2 diabetes mellitus in children is increasing dramatically.¹¹⁰ Palment and colleagues performed oral glucose tolerance tests in adolescents with PCOS (mean age 16.7 years) and found the prevalence of impaired glucose tolerance to be 30% and that of type 2 diabetes mellitus 3.7%.¹¹¹ A glucose-to-insulin ratio may also be used in adolescents to help determine IR¹³ (see table 4).

Several small studies have been completed using metformin in adolescents with PCOS. Similar to the results in adult women, these studies have shown benefits in hirsutism,¹¹² dyslipidemia,¹¹² hyperandrogenism,¹¹²⁻¹¹⁴ menstrual function,^{112,113} and glucose intolerance.¹¹⁴ Overall, experience is very limited, however, and many questions are as yet unanswered. More data are needed before metformin can be routinely used in the management of adolescents with PCOS.

PCOS, Seizure Disorders, and Valproic Acid

There is an increased prevalence of reproductive endocrine disorders in patients with epilepsy. The reason for this overrepresentation is debatable but likely multifactorial, ranging from the influence of epilepsy itself on the hypothalamic-pituitary axis to various effects of anti-epileptic drugs on hormone secretion and action both directly and indirectly through changes in weight and body composition.^{115,116} Valproic acid has received particular attention in this regard. Some evidence suggests that some women on this therapy have higher levels of insulin, testosterone, and triglycerides than those on another agent (lamotrigine), although few actually had a clear biochemical suggestion of PCOS.¹¹⁷ Further study into this complex issue is needed, but in the meantime women with seizure disorders, perhaps especially those on valproic acid, deserve careful monitoring of their menstrual function clinically and potentially biochemically (i.e., assessment for hyperandrogenism).

Difficulties in Lifestyle Modification/Weight Loss

Mention has been made earlier as to the effectiveness of weight loss as an intervention to every aspect of PCOS. Weight loss, however, is difficult to achieve and maintain as is evidenced by the millions of overweight/obese children and adults. While a complete discussion of the options/strategies to attain and maintain weight loss is beyond the scope of this article, several basic points deserve mention. For summaries on the effect and role of lifestyle modification in PCOS, the interested reader is referred to the excellent reviews by Hoeger¹¹⁸ and Norman et al.,¹¹⁹ respectively.

Increased physical activity and dietary modification are the cornerstones to successful weight loss and cardiovascular risk reduction. Unfortunately, few patients attempting to lose weight are actually implementing both of these strategies simultaneously. Indeed, one report demonstrated only ~20% of men and women actively trying to lose weight were employing both.¹²⁰ One misconception that perhaps limits many patients' ability to achieve and maintain weight loss is that increased physical activity means vigorous exercise. On the contrary, moderate exercise is as efficacious as vigorous exercise.¹²¹ Also, moderate-intensity lifestyle activity has proven equal to structured aerobic exercise with regard to weight loss in obese women.¹²² Lastly, reducing sedentary behaviors may be extremely important in weight loss efforts. In a 1997 survey, adult women spent an average of 34 hours per week watching television.¹²³ In one study, each 2 hour/day increment in television watching was associated with a 23% increase in obesity and a 14% increase in the risk of type 2 diabetes mellitus over 6 years.¹²⁴ Clinicians should be stressing a 3 point approach to increasing physical activity: decreasing sedentary behaviors, increasing lifestyle activity and initiating moderate exercise.

The National Institutes of Health clinical guidelines for the treatment of overweight and obesity¹²⁵ should be followed in the management of PCOS patients who require weight loss. These guidelines focus not only on diet and activity, but also on the importance of behavior modification, reduction of psychosocial stressors, social support from family and peers, and smoking cessation.^{119,125}

SUMMARY

Much has been learned of the pathophysiology of PCOS since its first description in 1935. Yet, despite a better understanding of the disease itself (and the passage of nearly 70 years), it still lacks specific diagnostic criteria making identification of patients difficult. With appreciation of the role IR plays in PCOS, proper identification has become more important than ever before. There are several other disease states that may present in much the same way as PCOS, and evaluation to rule out these is crucial to apply appropriate management options. Further research into proper identification of patients with PCOS and perhaps updated diagnostic criteria are needed.

Management of any three "acute" concerns of the PCOS patient (control of irregular menses and/or hirsutism and/or infertility management) can be a challenge, and some guidance is offered in this review. Treatment for PCOS will change over time based on what issue is most important to the patient at that stage of her life. That said, it is imperative to not lose sight of the crucial, life-long importance of managing the IR syndrome. There are several approaches to quantifying the degree of IR (glucose to insulin ratio, etc.), but just simply evaluating for the presence of dyslipidemia and impaired glucose tolerance test or type 2 diabetes mellitus may be a better approach.

If diagnosed early and managed properly with lifestyle modification (and/or insulin sensitizers), the onset of type 2 diabetes mellitus and its resultant risk of coronary artery disease may be delayed or prevented. PCOS is a varied and complex entity requiring much knowledge and skill both for proper diagnosis and management over time. It is hoped that this review will add to the growing knowledge base that providers in many areas of medicine seek in regard to the management of these challenging patients.

Abstract: Polycystic ovary syndrome (PCOS) is increasingly recognized as a complex metabolic disorder that manifests in genetically susceptible women following a range of negative exposures to nutritional and environmental factors related to contemporary lifestyle. The hypothesis that PCOS phenotypes are derived from a mismatch between ancient genetic survival mechanisms and modern lifestyle practices is supported by a diversity of research findings. The proposed evolutionary model of the pathogenesis of PCOS incorporates evidence related to evolutionary theory, genetic studies, in-utero developmental epigenetic programming, transgenerational inheritance, metabolic features including insulin resistance, obesity and the apparent paradox of lean phenotypes, reproductive effects and subfertility, the impact of the microbiome and dysbiosis, endocrine disrupting chemical exposure, and the influence of lifestyle factors such as poor quality diet and physical inactivity. Based on these premises, the diverse lines of research are synthesized into a composite evolutionary model of the pathogenesis of PCOS. It is hoped that this model will assist clinicians and patients to understand the importance of lifestyle interventions in the prevention and management of PCOS and provide a conceptual framework for future research. It is appreciated that this theory represents a synthesis of the current evidence and that it is expected to evolve and change over time.

Keywords: polycystic ovary syndrome; evolution; insulin resistance; infertility; toxins, endocrine disrupting chemicals; environment; lifestyle; diet

1. Introduction

It is widely accepted that there is a global epidemic of lifestyle-related chronic diseases, such as obesity and diabetes, that are underpinned by reversible metabolic dysfunction in the majority of individuals affected (1–3). It is also recognized that many of these chronic diseases may share a similar pathogenesis involving the interaction of genetic and environmental factors that manifest in overlapping pathophysiological features (4–6). The revised International Guidelines for the assessment and management of women with PCOS, emphasise that the associated metabolic dysfunction and symptoms should initially be addressed via lifestyle interventions (7).

Evolutionary medicine is an emerging discipline involving the study of evolutionary processes that relate to human traits and diseases and the incorporation of these findings

into the practice of medicine (8). Evolutionary medicine brings together interdisciplinary research to inform clinical medicine based on the influence of evolutionary history on human health and disease (9). Previous utilization of the principles of evolutionary medicine has been limited to monogenetic diseases (cystic fibrosis, sickle cell anaemia, phenylketonuria and many others), drug resistance of microorganisms, tumour growth and chemoresistance (8). Future insights into the application of evolutionary research offers the potential to improve and personalize the established medical and scientific approaches to complex chronic diseases like type 2 diabetes, metabolic syndrome and PCOS (5,9).

The evolutionary origins of complex chronic diseases incorporate considerations of relative reproductive fitness, mismatch between our biological past and modern environment, trade-offs involving combinations of genetic traits, and evolutionary conflicts (8,10). These evolutionary factors are relevant when analysing the contributors to the pathogenesis of PCOS in modern and modernising societies, that result in a mismatch between our rapid cultural evolution with our slow biological evolution (11,12). The unique cultural evolution of humans does not have a plausible analogue in most other species and is increasingly recognised to play a significant role in the pathogenesis of metabolic diseases such as PCOS (5,13–17).

Polycystic ovary syndrome is a complex multisystem condition with metabolic, endocrine, psychological, fertility and pregnancy-related implications at all stages of life (7,18). The majority of women with PCOS manifest multiple metabolic features including obesity, insulin resistance (IR), hyperlipidaemia and hyperandrogenism (19,20). PCOS results in an increased risk of developing metabolic disease (type 2 diabetes, non-alcoholic fatty liver disease (NAFLD) and metabolic syndrome), cardiovascular disease, cancer, a wide array of pregnancy complications (deep venous thrombosis, pre-eclampsia, gestational diabetes, macrosomia, growth restriction, miscarriage, stillbirth and preterm labour) and psychological problems (anxiety, depression) (6,21–25). PCOS is part of a cluster of inter-related metabolic conditions and makes a significant contribution to the chronic disease epidemic.

Extensive research suggests that the aetiology of PCOS involves an interaction between environmental factors and gene variants, although it has been suggested that genetic factors contribute less than 10% to disease susceptibility (26–28). A large number of genetic and genome-wide association studies (GWAS) have identified common gene loci associated with PCOS phenotypes in different ethnic populations (29–31). These appear to be normal gene variants or polymorphisms, given the frequency and type of genes that have been identified. PCOS is therefore viewed as a polygenic trait that results from an interaction between susceptible genomic variants and the environment.

PCOS affects upward of 10% of reproductive-aged women, estimated at over 200 million women worldwide (32,33). PCOS is thought to be increasing in incidence in both developing and developed nations as a result of lifestyle-related changes in diet quality, reduced physical activity, ubiquitous environmental endocrine disrupting chemicals (EDC), altered light exposures, sleep disturbance, heightened levels of stress and other

environmental factors (11,34–38). These factors, and the high prevalence of PCOS, suggest that there could be an evolutionary basis for the syndrome (15,16,39). Evolutionary medicine has changed the paradigm for understanding PCOS, acknowledging many of the contributing lifestyle and environmental factors that facilitate the observed metabolic and clinical features and that are also shared with related metabolic diseases (8). These “mismatch disorders” are estimated to make a significant contribution to chronic disease in developed countries and a growing proportion of disability and death in developing nations (3). According to the Global Burden of Disease Study, the human diet is now the leading risk factor for morbidity and mortality worldwide (3). In keeping with these findings, diet is recognized as one of the major contributors to the growing prevalence of PCOS globally (7,40).

Dietary and environmental factors are hypothesized to have an impact on developmental programming of susceptible gene variants in women with PCOS (41–43). Extensive experimental evidence suggests that prenatal androgen exposure may play a role in the pathogenesis of PCOS-like syndromes in animal models (19,44–46). The discovery of naturally-occurring PCOS phenotypes in non-human primates supports a survival advantage of a hyperandrogenic, insulin resistant phenotype with delayed fertility (47). In humans, the origin of excess androgens may be from maternal, fetal or placental sources. In addition, emerging and concerning evidence suggests that EDC may contribute to altered fetal programming and play a role in the pathogenesis of PCOS (41,48).

In-utero genomic programming of metabolic and endocrine pathways can increase the susceptibility of offspring to develop PCOS following exposure to specific nutritional and environmental conditions (45). This view of the pathogenesis of PCOS is consistent with the Developmental Origins of Health and Disease (DOHaD) model proposed by Neel (49). Postnatal exposure to lifestyle and environmental factors, such as poor-quality diet and EDC, may activate epigenetically programmed pathways that further promote the observed features of PCOS. Dietary and lifestyle interventions have demonstrated that many of the clinical, metabolic and endocrine features of PCOS can be reversed (7,50,51).

Lifestyle-induced changes in the gastrointestinal tract microbiome are another significant factor in the aetiology of PCOS (52,53). Dysbiosis of the gut microbiota has been hypothesised to play a role in increased gastrointestinal permeability, initiating chronic inflammation, IR and hyperandrogenism (40). Numerous studies have reported reduced alpha diversity of the microbiome that has been associated with the metabolic, endocrine and clinical features observed in women with PCOS (54,55). The resulting dysbiosis has been shown to be reversible after interventions aimed at improving diet quality or treatment with probiotics or synbiotics (50,51,56–58).

A unified evolutionary theory of the pathogenesis of PCOS proposes that ancient genetic polymorphisms that were aligned with the environment of that era, resulted in an adaptive survival advantage in offspring in ancestral populations (14–16,28). When these same genetic variants are exposed to modern lifestyle and environmental influences, maladaptive physiological responses occur. The prior advantages of insulin resistance, hyperandrogenism, enhanced energy storage and reduced fertility in ancestral

populations become pathological and result in the observed features of PCOS in contemporary women (figure 1).

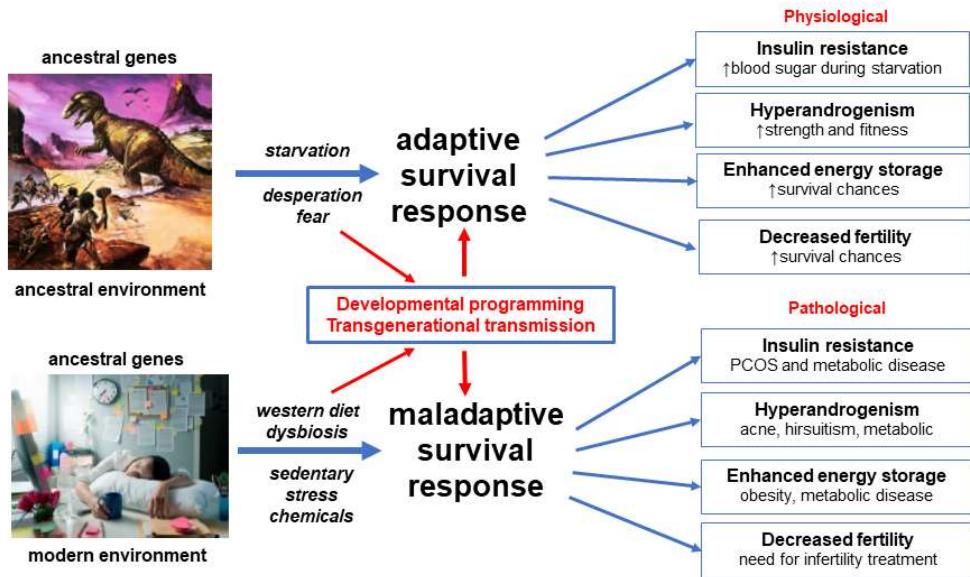

Figure 1. Evolutionary model of the pathogenesis of polycystic ovary syndrome

2. Materials and Methods

The literature search focused on research publications related to the pathogenesis of PCOS using the keywords listed above and related mesh terms for data on the evolutionary aspects of PCOS, genetic studies, in-utero developmental epigenetic programming, transgenerational inheritance, metabolic features including insulin resistance, obese and lean PCOS phenotypes, reproductive changes and subfertility, impact of the microbiome and dysbiosis, possible effects of endocrine disrupting chemical exposure and the influence of lifestyle factors such as diet and physical activity. The databases searched included PubMed, Scopus, Cochrane and Google Scholar. Relevant papers were selected and citation searches were performed.

The present manuscript synthesizes the findings into a unified evolutionary model. The following text is presented as a narrative review of factors involved in the pathogenesis of PCOS and is discussed in ten main subject areas that provide the rationale for the development of a unified model. 1. Evolution 2. Genetics 3. Developmental Epigenetic Programming 4. Microbiome and Dysbiosis 5. Insulin resistance 6. Obesity and the lean paradox 7. Environmental Chemical Exposure 8. Lifestyle Contributors to the Pathogenesis of PCOS 9. Conceptual Framework of a Unified Evolutionary Model 10. Explanation to women diagnosed with PCOS.

3. Pathogenesis of PCOS

3.1. Evolution

The description of PCOS phenotypes can be found in medical records from antiquity and the modern syndrome was described over 80 years ago (17,59). Nevertheless, there is ongoing debate regarding the evolutionary origins of PCOS (15–17,39,60–64). PCOS

susceptibility alleles may have arisen in our phylogenetic ancestors, in the Hunter-gatherer Paleolithic period of the Stone Age, after the Neolithic Agricultural Revolution or following the Industrial Revolution (16,17). From an evolutionary perspective, nearly all genetic variants that influence disease risk have human-specific origins, but the systems they relate to have ancient roots in our evolutionary ancestors (8). Regardless of the precise timing of the origin of PCOS in humans, the complex metabolic and reproductive gene variants identified in women with PCOS relate to ancient evolutionary-conserved metabolic and reproductive survival pathways (15,29). Although evolutionary hypotheses about disease vulnerability are impossible to prove they have the potential to frame medical thinking and direct scientific research for the proximate causes of disease (15,60).

Multiple hypotheses have been proposed regarding the evolutionary origins of PCOS and related metabolic diseases (8,60,63). These hypotheses are focused on the relative importance of metabolic survival adaptations versus improved reproductive success, or a combination of both. A detailed analysis of these hypotheses, and the complexities of the evolutionary considerations, have been reviewed elsewhere and is beyond the scope of the present review (8,60). One common theme is that PCOS may be viewed as a “conditional phenotype” where a specific set of conditions has unmasked normally unexpressed or partly expressed genetic pathways, which then provide a survival advantage under certain environmental conditions (14,16).

All organisms have physiological adaptive responses to deal with changing environmental conditions (starvation, fasting, physical threat, stress and infection) and the varying demands of internal physiological states (pregnancy, lactation and adolescence) (14,65). It has been proposed that the PCOS phenotype may have been invoked in specific environmental conditions in ancestral populations as a short, medium or even long-term adaptive survival mechanism (15–17). The view of PCOS as a conditional phenotype proposes that these physiological responses become pathological in our modern environment due to factors such as food abundance, reduced physical activity, circadian disruption, stress and environmental chemical exposure. The transgenerational evolutionary theory of the pathogenesis of PCOS encompasses all of the above ideas to explain the observed pathophysiological and clinical features of PCOS (28).

It is generally accepted that almost all pre-industrial societies and animal populations experienced seasonal or unpredictable episodes of food shortage that applied evolutionary pressure to develop metabolic and reproductive adaptive survival responses (17,49). It is also appreciated that metabolic and reproductive pathways are interconnected and involve reciprocal feedback control mechanisms (66–68). During periods of starvation, anorexia or excessive weight gain, reproduction is down-regulated and ovulation becomes irregular or ceases (69,70). Similarly, metabolic function is co-ordinated with the menstrual cycle to ensure optimal physiological conditions for fertilisation, implantation, pregnancy, parturition and lactation (71). Recent research has elaborated on the details of how some of these complex regulatory mechanisms interact by using specific hormonal, nutrient sensing and intracellular signalling networks (72–74).

Details of the mechanisms underlying the proposed adaptive survival advantages of IR, hyperandrogenism, enhanced energy storage and sub-fertility have been obtained from paleolithic records, animal models and human populations exposed to adverse environmental conditions such as war and famine-inflicted starvation (14,16,62,63). Multiple lines of evidence support the maladaptive response of human populations to rapidly changing nutritional, physical, psychological and cultural environments, in the modern world (5,11,14,75). These “adaptations” result in pathological responses to IR, hyperandrogenism, enhanced energy storage and ovulation (figure 1).

Theories of evolutionary mismatch have also been advanced to explain all of the cluster of metabolic diseases associated with PCOS (type 2 diabetes, metabolic syndrome, NAFLD and cardiovascular disease) and follow the same set of basic principles and explanations (14,76). This common body of evolutionary evidence is supported by the increasing incidence of metabolic-related disease, such as diabetes and obesity, in developed countries and in developing nations adopting a Western diet and lifestyle (11,77). In addition, the demonstrated reversibility of PCOS and related metabolic and biochemical features following changes in diet, increased physical activity and other lifestyle interventions, adds further support to a transgenerational evolutionary model (50,51).

3.2. Genetics

The heritable nature of PCOS has been proposed since the 1960’s following a range of familial, twin and chromosomal studies (78–80). Cytogenetic studies failed to identify karyotypic abnormalities and genetic studies did not show a monogenic inheritance pattern following examination of candidate genes (81,82). In addition, two or more phenotypes can be present in the same family suggesting that some of the phenotypic differences could be accounted for by variable expression of the same shared genes (81,83).

The mapping of the human genome in 2003 (84) and the publication of the human haplotype map (more than one million single nucleotide polymorphisms of common genetic variants) in 2005 (85), lead to the realisation that most DNA variation is shared by all humans and is inherited as blocks of linked genes (linkage disequilibrium) (86). These advances enabled a revolution in case-control studies and the development of GWAS which map the entire human genome looking for susceptibility genes for complex traits such as obesity, type 2 diabetes and PCOS (81).

The first PCOS GWAS was published in 2010 and demonstrated 11 gene loci associated with PCOS (87). Additional loci have subsequently been found in a number of different ethnic groups (86,88). The first GWAS analysis of quantitative traits was published in 2015 and showed that a variant (rs11031006) was associated with luteinizing hormone levels (88). The largest GWAS included a meta-analysis of 10,074 PCOS cases and 103,164 controls and identified 19 loci that confer risk for PCOS (29). The genes associated with these loci involve gonadotrophin action, ovarian steroidogenesis, insulin resistance and type 2 diabetes susceptibility genes. The first GWAS using electronic health record-linked biobanks has introduced greater investigative power and identified 2 additional loci (89). These variants were associated with polycystic ovaries and hyperandrogenism

(rs17186366 near *SOD2*) and oligomenorrhoea and infertility (rs144248326 near *WWTR1*) (89). In addition to identifying common gene variants for PCOS phenotypes, finding the same signals (*THADA*, *YAP1* and *c9orf3*) in Chinese and European populations suggests that PCOS is an ancient trait that was present before humans migrated out of Africa (81).

More recently Mendelian randomization (MR) studies have been used to explore the potential causative association between gene variants identified in GWAS and PCOS (90,91). Many of the gene variants identified in GWAS are located in non-coding regions of DNA (92). The genes or functional DNA elements through which these variants exert their effects are often unknown. Mendelian randomization is a statistical methodology used to jointly analyse GWAS and quantitative gene loci to test for association between gene expression and a trait, due to a shared or potentially causal variant at a specific locus (93). A detailed analysis of MR methodology and the limitations of this statistical tool is beyond the scope of the present review. Although MR studies have the potential to infer causation it is recognised that they also have limitations in PCOS research (90). Nevertheless, preliminary evidence suggests that a number of genes related to obesity, metabolic and reproductive function, may play a causal role in the pathogenesis of PCOS (90,91).

Decades of genetic research has therefore characterised PCOS as a polygenic trait that results from interactions between the environment and susceptible genomic traits (27,29,79,88). The failure to identify a qualitative or monogenic inheritance pattern and the findings from GWAS, MR, familial and twin studies, suggests that the heritability of PCOS is likely to be due to the combination of multiple genes having small effect size, as has been found with obesity and type 2 diabetes (79,80,94–96). Polygenic traits are the result of gene variants that represent one end of the bell-shaped normal distribution curve of continuous variation in a population (97). From an evolutionary perspective, women with PCOS may represent the “metabolic elite” end of the normal distribution curve, being able to efficiently store energy in periods of food abundance and down-regulate fertility in times of food scarcity, or even in anticipation of reduced seasonal food availability as a predictive adaptive response (16,17,60).

The realisation that PCOS is a quantitative trait (phenotype determined by multiple genes and environmental factors) has far-reaching implications for the diagnosis, treatment and prevention of symptoms and pathology associated with PCOS. The implications require a shift in thinking about PCOS as a “disease” to a variation of normal metabolic and reproductive function. This shift invites a change in vocabulary from talking about “disorder” and “risk” to talking about “expression” and “variability” (97). This new understanding supports and reinforces an evolutionary model of the pathogenesis of PCOS. In keeping with this model, multiple lines of evidence suggest that inherited PCOS gene variants are developmentally programmed in a way that primes them for activation by nutritional and environmental factors in postnatal life (41,42,98).

3.3. Developmental epigenetic programming

The developmental programming of PCOS represents changes in gene expression that occur during critical periods of fetal development (99). Following fertilisation, most

parental epigenetic programming is erased and dramatic epigenomic reprogramming occurs (100). This results in transformation of the parental epigenome to the zygote epigenome and determines personalised gene function. Compelling evidence shows that a wide range of maternal, nutritional and environmental factors can effect fetal development during these critical periods of programming (44,98,99,101,102). These include hormones, vitamins, diet-derived metabolites and environmental chemicals (48,98,103,104). In addition, epigenetic reprogramming of germ-line cells can lead to transgenerational inheritance resulting in phenotypic variation or pathology in the absence of continued direct exposure (98).

Experimental studies in primates, sheep, rats and mice show that PCOS-like syndromes can be induced by a range of treatments including androgens, anti-Mullerian hormone and letrozole (19,44,46). Nevertheless, there is significant debate regarding when an animal model qualifies as PCOS-like (105). The model used and the method of induction of PCOS phenotypes therefore needs to be carefully scrutinised when generalising findings from animal research to women with PCOS. The vast majority of animal and human research on the developmental origins of PCOS has focussed on the role of prenatal androgen exposure. This has been extensively reviewed in numerous previous publications (41,46). This research has resulted in a proposed “two hit” hypothesis for the development of PCOS phenotypes (43,45). The “first hit” involves developmental programming of inherited susceptibility genes and the “second hit” arises due to lifestyle and environmental influences in childhood, adolescence and adulthood (41,106).

If PCOS is a quantitative trait involving normal gene variants, as suggested by the evolutionary considerations and findings from genetic research, then the “first hit” may result from normal developmental programming events as occurs with other gene variants (102). According to this hypothesis, the polygenic susceptibility genes would be normally “activated” and “primed” to respond to future maternal and environmental conditions and exposures, as would be the case with many other normal genes (28). In addition, the susceptibility alleles may be “activated” or “functionally enhanced” by a range of maternal and environmental factors, as is usually presumed to be the case in PCOS (5,14,102). This developmental plasticity would provide a mechanism for a predictive adaptive response, based on inputs from the maternal environment that could be used to programme metabolic and reproductive survival pathways, to better prepare the offspring for the future world in which they may be expected to live (107).

Parental lifestyle factors including diet, obesity, smoking and endocrine disrupting chemicals, have all been shown to modulate disease risk later in life (104,108,109). The original description of the fetal origin’s hypothesis proposed that poor maternal nutrition would increase fetal susceptibility to the effects of a Western-style diet later in life (49). Subsequent studies have confirmed that maternal exposure to either nutrient excess or deficit, can have long-term consequences for the health of the progeny (104). Evidence from human and animal studies suggests that maternal obesity programs the offspring for increased risk of developing obesity, hyperglycaemia, diabetes, hypertension and metabolic syndrome (108).

The developmental origins of PCOS may have been due to different factors in ancestral and modern populations (17,60). It has been hypothesised that environmental stress, infection, nutrient deprivation, fetal growth restriction and stress hormone responses may have resulted in maternally-mediated modulation of gene expression in ancestral offspring (17,110). Some of these factors have been investigated and confirmed in modern populations subject to starvation and extreme environmental conditions (111). In contrast, altered fetal programming in modern societies may be secondary to maternal overnutrition, sedentary behaviour, obesity, emotional stress, circadian rhythm disruption, poor gut health or environmental chemical exposure (35,101,112,113). The preconception and pregnancy periods therefore provide a unique opportunity for lifestyle interventions that promote optimal future health for both the mother and the offspring (figure 2).

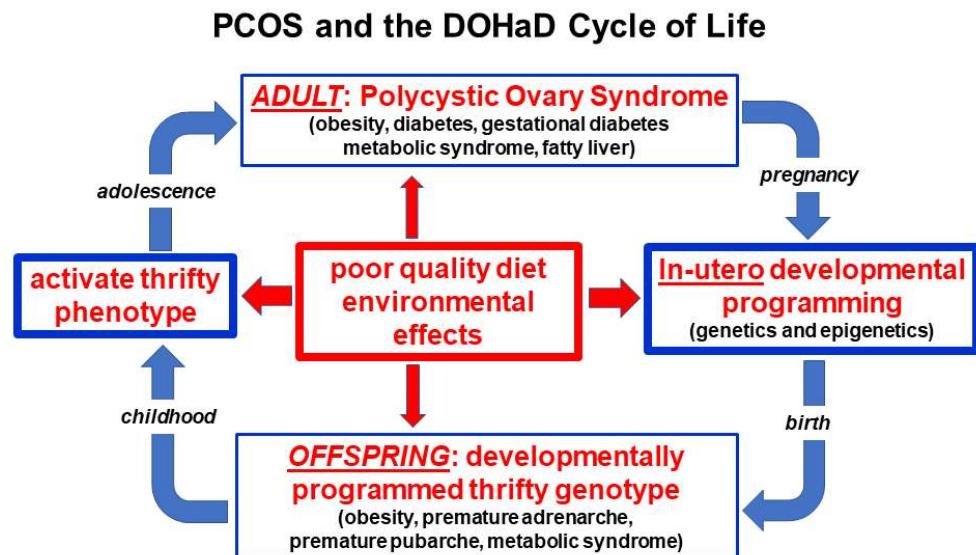

Figure 2. Nutritional and environmental influences throughout the life course and the perpetuation of the transgenerational inheritance of polycystic ovary syndrome

3.4. Microbiome and Dysbiosis

The gastrointestinal microbiome is now appreciated to play a central role in human health and disease (114,115). The microbiome is known to co-regulate many physiological functions involving the immune, neuroendocrine and metabolic systems via complex reciprocal feedback mechanisms that operate between the microbial ecosystem and the host (116,117). Evidence from studies in Western populations, Hunter-gatherer societies and phylogenetic studies in other species, have attempted to place the human microbiome into an evolutionary context (118). Although microbes clearly impact host physiology and have changed along branches of the evolutionary tree, there is ongoing debate regarding whether the microbiome can evolve according to the usual evolutionary forces (119,120). Nevertheless, it has been argued that focusing on functional pathways and metabolic roles of microbial communities, rather than on specific microbes, provides a better model for

understanding evolutionary fitness (118). The co-evolution of the microbiome and human physiology may therefore be important in understanding the differences between ancient adaptive physiological survival mechanisms and modern lifestyle-related pathological responses, in women with PCOS (figure 1).

Twin studies and GWAS show that host genetics can influence the microbiome composition, and microbes can exert effects on the host genome, although the environment has an important role (121,122). Humans are constantly adapting to the gut microbiome to try to determine which microorganisms are beneficial or harmful. Immune genes involved in this process are the most rapidly evolving protein-encoding genes in the mammalian genome (123,124). Diversification of microbes allows humans to access dietary niches and nutritional components they otherwise wouldn't be able to access, which may be beneficial and ultimately lead to the integration of specific microbes into the ecosystem (125). Although no living population today carries an ancestral microbiome, comparison studies of non-Western and Western populations show significant differences in the relative abundances of common phyla and a much greater species diversity in non-Western populations (126,127). A review of non-human primate and human gut microbiome datasets, revealed a changing microbiome in response to host habitat, season and diet, although there appear to be common species-specific symbiotic communities (118).

Rapid human cultural changes have resulted in significant dietary modifications in urban-industrialised communities and shifted the microbiome at an unprecedented rate. The result has been the development of a mismatch between human metabolic genes and bacteria that enhance fat storage (128). In our evolutionary past, when nutrients were scarce, it has been theorized that host selection led to the maintenance of microbes that enhance nutrient uptake or host energy storage. However, in the modern environment where a high fat, high sugar, low fibre diet has become common and easily accessible, integration of these microbes leads to maladaptive physiological responses (40). For metabolically thrifty individuals with PCOS, harbouring microbes that enhance energy storage escalates the evolutionary conflict, furthering the development of insulin resistance and thereby progression to obesity and type 2 diabetes (12,129). Further compounding this maladaptive response is the loss of microbes that are required to access other dietary niches. One example is the loss of symbiotic species of *Treponema* in individuals living in urban-industrialised communities (130). A change from the ancestral hunter-gatherer diet, where foods consumed changed seasonally and a wide variety of food components were eaten, to a diet that is similar across seasons and significantly less varied, is another likely contributor to reduced diversity of the microbiomes of individuals living in urbanised-industrialised communities (131).

The majority of women with PCOS are overweight or obese and evidence indicates that the microbiome of obese individuals is capable of extracting more energy from the host diet compared with the microbiome of lean individuals (132). This is thought to be driven by an expansion in pro-inflammatory species of bacteria, such as *E. coli*, and a depletion of anti-inflammatory bacteria such as *Faecalibacterium prausnitzii* (133,134).

Chronic low-grade ‘metabolic’ inflammation, or meta-inflammation, is a result of an imbalanced gut microbiome that promotes the development of insulin resistance and type 2 diabetes (135–137).

The dysbiosis of gut microbiota theory of PCOS, proposed by Tremellen in 2012, accounts for the development of all of the components of PCOS (multiple ovarian follicles, anovulation or menstrual irregularity and hyperandrogenism) (40). The theory proposes that a poor-quality diet and resulting imbalanced microbiome, induces intestinal permeability and endotoxaemia, exacerbating hyperinsulinaemia. Increased insulin levels promotes higher androgen production by the ovaries and disrupts normal follicle development. Metabolic, endocrine and environmental factors associated with PCOS are not mutually exclusive, and therefore their relative contributions to dysbiosis in PCOS remains uncertain (138). Consuming a balanced diet that is low in fat and high in fibre, can also restore balance to the ecosystem (termed eubiosis) (50). A recent study showed that dietary intake of fibre and vitamin D was significantly decreased in both lean and obese women with PCOS, compared to healthy controls, and correlated with lower diversity of the gut microbiome (139). Dysbiosis is reversible with improvement in diet quality augmented by the addition of probiotics or synbiotics (51,56–58).

Dysbiosis is a consistent finding when looking at the microbiome of women with PCOS (140–143). Although most studies are small, dysbiosis has consistently been found to correlate with different physiological parameters, such as obesity, sex hormones and metabolic defects (140,141,143). Similar to microbiomes associated with obesity, the microbiomes of individuals with PCOS have generally been found to have lower alpha diversity (lower numbers of bacterial taxa) than controls, and most studies describe an altered composition of taxa relative to controls (140,143). However, the bacterial taxa observed to be either increased, depleted or absent in PCOS differs from study to study. This is likely due to both the immense inter-individual variation in microbiotas, as well the fact that PCOS is a quantitative trait with women having various degrees and levels of obesity and sex hormones.

In keeping with the developmental origins hypothesis previously discussed, maternal androgens may alter the composition and function of the microbiome, thereby facilitating the pathogenesis of PCOS (140). One study showed that beta diversity, which is used to measure differences between groups, was negatively correlated with hyperandrogenism, suggesting that androgens play a significant role in dysbiosis (140). The ‘first hit’ in utero may therefore combine with vertical transmission of a dysbiotic microbiome from a mother with PCOS, resulting in dysbiosis in the offspring. Preconception and pregnancy provide a unique opportunities for lifestyle and dietary interventions aimed at restoring eubiosis, to enable the transference of a balanced ecosystem to the offspring, via vertical transmission (118).

The accumulating scientific evidence strongly supports the significant role played by the microbiome in the pathogenesis and maintenance of PCOS, consistent with research in other related metabolic conditions. Dysbiosis is a significant factor in the pathogenesis of PCOS and an important component of a unified evolutionary model. Dysbiosis represents

a maladaptive response of the microbiome to modern lifestyle influences and is a modifiable factor in the treatment of women with PCOS.

3.5. *Insulin Resistance*

There are a number of dilemmas when assessing the role of IR in women with PCOS. There is no consensus on the definition of IR (144,145), measurement is difficult (146,147), whole-body IR is usually measured although it is recognized that IR can be selective being either tissue-specific or pathway-specific within cells (148–150), normal values are categorical and determined by arbitrary cut-offs (4.45 mg/kg/min) (144), testing is not recommended in clinical practice (38), reported prevalence rates in obese and lean women vary widely (146,151), and the significance of IR as a pathognomonic component of PCOS is an area of debate (152–154).

Despite these limitations, it is hypothesised that IR is a significant proximate cause of PCOS and is intrinsic to the underlying pathophysiology (44,155). In addition, it is recognized that IR plays a major role in the pathophysiology of all of the metabolic diseases, cardiovascular disease, some neurodegenerative diseases, and selected cancers (22,156). Insulin resistance is therefore considered to be the main driver for many diseases and makes a significant contribution to the chronic disease epidemic (157). Nevertheless, being able to vary the sensitivity and physiological action of insulin is thought to have conferred a significant adaptive survival role in many animals throughout evolutionary history (145,158). It has been proposed that IR may have evolved as a switch in reproductive and metabolic strategies, since the development of IR can result in anovulation and reduced fertility, in addition to differential energy repartitioning to specific tissues (158).

Insulin receptors are located on the cell membranes of most tissues in the body (159). Ligand binding to the alpha-subunit induces autophosphorylation of specific tyrosine residues on the cytoplasmic side of the membrane (159,160). The activated insulin receptor initiates signal transduction via the phosphatidylinositol-3 kinase (PI-3K) metabolic pathway and the mitogen-activated protein kinase pathway (MAPK) which is involved in cell growth and proliferation (160). Insulin is an anabolic hormone that facilitates glucose removal from the blood, enhances fat storage and inhibits lipolysis in adipose tissue, stimulates glycogen synthesis in muscle and liver and inhibits hepatic glucose output (160). IR can be defined as a state where higher circulating insulin levels are necessary to achieve an integrated glucose-lowering response (145). IR results from alterations to cellular membrane insulin-receptor function or intracellular signaling, enzyme, metabolic or gene function (145,159,160).

Insulin resistance can be caused by a wide variety of mechanisms that have the ability to disrupt any part of this metabolic signaling system (53,160). These include autoantibodies, receptor agonists and antagonists, hormones, inflammatory cytokines, oxidative stress, nutrient sensors and metabolic intermediates (159–162). Physiological regulation of insulin function can be viewed as an adaptive mechanism to regulate the metabolic pathway of insulin signaling (PI-3K), in response to changing environmental conditions (starvation, fear, stress) (163,164) or during normal alterations of internal states (pregnancy, lactation, adolescence) (65,145,151).

The physiological activation of IR allows the organism to switch from an anabolic energy storage state to a catabolic or energy mobilizing state. This allows free fatty acids to be mobilized from adipose tissue, which are then converted to glucose in the liver and released into the circulation (160). As a result of this metabolic change, blood sugar levels are maintained for vital metabolic processes and brain function (14). This adaptive protective mechanism can be pathway specific during periods of growth, such as pregnancy, lactation and adolescence, so that only the metabolic signaling (PI-3K) is inhibited and not the mitogenic pathway (MAPK), which may even be upregulated (30,65,159).

When the physiology of insulin function is considered as a quantitative or continuous variable from an evolutionary perspective, it is likely that all women with PCOS, whether obese or lean, have reduced insulin sensitivity (151,154,165). A systematic review and meta-analysis of euglycemic-hyperinsulinaemic clamp studies found that women with PCOS have a 27% reduction in insulin sensitivity compared to body mass index (BMI) and age-matched controls (154). In evolutionary terms, women with a PCOS metabolic phenotype would have increased survival chances during times of environmental or physiological demand for altered energy metabolism, but be more vulnerable to the pathological effects of IR when exposed to modern lifestyle factors (14,17,158). In particular, a poor-quality, high glycaemic, high fat, low fibre diet has been shown to cause IR (40,166). As discussed in the dysbiosis section, diet-related changes in the gastrointestinal microbiome have also been shown to cause IR in women with PCOS (53,55). Numerous studies have shown that dietary modification (167–169), or treatment with probiotics or synbiotics, has the potential to restore normal insulin function (57,170).

Consumption of a high glycaemic load diet results in rapid increases in blood sugar levels that cause compensatory hyperinsulinaemia (166,171). Excessive dietary intake of glucose and fructose are converted to fatty acids by de novo lipogenesis in the liver, transported to adipocytes via lipoproteins, released as fatty acids to adipocytes and stored in fat globules as triglycerides (160). As a result of nutrient overload, diacylglycerol, the penultimate molecule in the synthesis of triglyceride, accumulates in the cytoplasm and binds with the threonine amino acid in the 1160 position of the insulin receptor. This inhibits autophosphorylation and down-regulates the metabolic PI-3K pathway and causes IR (160). This process has the potential to be reversible following changes in diet quantity and quality, as has been shown to occur with calorie restriction, fasting, time-restricted eating, gastric bypass surgery, low saturated fat and low glycaemic diets (167,169,172). Diets high in animal protein or saturated fat can also cause IR independent of BMI (173,174). These mechanisms provide the rationale for the principal recommendation of the International Guidelines, that women with PCOS should be advised about dietary modification as the first-line of management in all symptom presentations (38).

3.6. Obesity and the lean PCOS paradox

Insight can be obtained into the role of obesity in women with PCOS by examining the evolutionary history, genetic studies and pathological disorders of adipose tissue

(150,175,176). The ability to store energy is a basic function of life beginning with unicellular organisms (175). In multicellular organisms, from yeast to humans, the largest source of stored energy is as triglycerides in lipid droplets in order to provide energy during periods when energy demands exceed caloric intake (175). Understanding the biological functions of adipose tissue has progressed from energy storage and thermal insulation to that of a complex endocrine organ with immune and inflammatory effects and important reproductive and metabolic implications (175,177).

Adipose tissue is organized into brown adipose tissue (BAT) and white adipose tissue (WAT), both with different functions (177). While the evolutionary origins of BAT and WAT are the subject of ongoing debate (175), BAT is located in the supraclavicular and thoracic prevertebral areas and is primarily involved in cold thermogenesis and regulation of basal metabolic rate (178). WAT is distributed in multiple anatomical areas such as visceral adipose tissue (VAT) and subcutaneous adipose tissue (SAT) and functions as a fat storage depot and an endocrine organ (177,178). An additional layer of SAT is thought to have evolved as insulation against cool night temperatures in the Pleistocene open Savanah (179). The lower body distribution of SAT in women is hypothesised to have evolved to provide additional calorie storage for pregnancy and lactation and is unique to human females (14). Lower body SAT has a metabolic programme that makes it less readily available for every-day energy needs, but it can be mobilized during pregnancy and lactation (14). In addition, excess accumulation of SAT is much less likely to cause IR and metabolic dysfunction and explains why IR is not observed in all obese individuals (150,180). Visceral WAT is associated with IR in women with PCOS leading to both metabolic and reproductive problems (181).

Multiple lines of evidence from evolutionary history, genetic and twin studies, support a genetic basis for obesity and differences in obese and lean phenotypes in women with PCOS (182–185). The majority of women with PCOS are overweight or obese, with reports ranging from 38–88% (151,185). Studies comparing obese and lean women with PCOS have a number of methodological problems including small sample size, overlap of PCOS characteristics with normal pubertal changes, non-standardized diagnostic criteria, and limited generalizability to the entire population due to a focus on a specific ethnic group (165,181). In addition, most of the studies examining body composition in PCOS have relied on anthropomorphic measurements (BMI, waist circumference, waist-to-hip ratio) which are considered inaccurate compared with the current gold-standard of magnetic resonance imaging (181). Consequently, there is wide heterogeneity in reports examining the relationship between body composition measures, including extent of VAT and metabolic changes such as IR (185).

In humans, there is large individual variation in the fat storage capability and expandability of different adipose tissue depots (150). It has been hypothesised that once the genetically determined limit of expandability of SAT is reached, there is expansion of VAT and excess lipid accumulation in muscle, liver and other organs, resulting in IR, inflammation and metabolic dysregulation (150). We hypothesize that lean women with PCOS have a genetically determined limited ability to store excess lipid in SAT, but

develop increased lipid deposition in VAT and organs such as the liver, resulting in metabolic dysregulation and IR in a similar manner to what occurs in obese women with PCOS. The wide variation in the genetic limitation of SAT expansion is also supported by studies in individuals with lipodystrophy.

Lipodystrophies are a heterogenous group of rare inherited and acquired disorders characterized by a selective loss of adipose tissue (176,186). They are classified on the basis of the extent of fat loss as generalized, partial or localized (186). Patients with congenital generalised lipodystrophy have a generalized deficiency of fat from birth, usually have severe IR and develop diabetes at puberty. As a consequence of genetically limited ability for SCT lipid storage, lipids can only be stored ectopically in non-adipocytes resulting in major health consequences including IR, fatty liver, diabetes and PCOS (187). In contrast to generalised lipodystrophy, patients with familial partial lipodystrophy have normal fat distribution at birth but loose SAT in the limbs, buttocks and hips, at puberty. Fifty percent of women develop diabetes and 20-35% develop irregular periods and polycystic ovaries (176) . Despite the rare nature of these syndromes much has been learned about the underlying genetic variants involved (186).

Elucidation of clinical subtypes and the genetic background of patients with lipodystrophies may pave the way to new insights into the role of fat partitioning and obesity, and has implications for understanding the pathogenesis of insulin resistance, diabetes and PCOS (176). Lean women with PCOS may have a genetic predisposition for limited SCT fat storage, coupled with underlying metabolic predispositions, that result in deposition of excess lipid in VAT and liver and the observed metabolic features of IR, fatty liver and diabetes. If the extent of IR and ectopic fat deposition is excessive, the resulting hormonal changes may be sufficient to cause oligomenorrhoea and sub-fertility as occurs with secondary familial partial lipodystrophy type 2 (187,188). If this underlying mechanism is confirmed in future studies, the main difference between women with lean or obese PCOS may be the combined effects of metabolic programming and the genetically-determined extent of SCT fat deposition. This would explain why lean women have all the same clinical, biochemical and endocrine features, although possibly less severe, than overweight and obese women with PCOS (185).

3.7. Environmental chemical exposure

Anthropomorphic chemical exposure is ubiquitous in the environment and has possible effects on many aspects related to women's health (36,189–191). Historically, many environmental chemicals have resulted in large-scale health disasters in human populations including diethylstilbestrol (DES), dichlorodiphenyltrichloroethane (DDT), asbestos, lead, mercury and nicotine (191). There over 191 million organic and inorganic chemicals registered on the Chemical Abstract Service Registry (192). Detailed analysis of risks is extremely limited and regulation relies on animal toxicology, in-vitro assays, and epidemiological studies that retrospectively examine adverse effects after population exposure (193,194). More recently, toxogenetic testing of chemical-gene interactions have been employed to identify molecular pathways involved in causing toxicity (193). These

studies have concluded that the majority of endocrine and metabolic pathways are sensitive to the effects of environmental chemicals (193).

The identification of more than 1000 EDC in food, air, water, pesticides, plastics, personal care products, and other consumer goods, raises specific concerns for pregnant women and women with increased susceptibility to metabolic diseases like PCOS (36,171,191,195,196). Endocrine disrupting chemicals may be involved in the pathogenesis of PCOS given their known and potential hormonal and metabolic effects (36,189,197). This includes many of the areas that have been considered in the unified evolutionary model, such as developmental epigenetic programming, microbiome composition and function, metabolic processes such IR, and regulation of body weight.

3.7.1. EDC and DOHaD

Many observational studies have demonstrated the presence of EDC in maternal and fetal serum and urine, amniotic fluid, cord blood and breast milk (198–200). Six classes of EDC have been shown to cross the placenta confirming that the fetus is exposed at all stages of development (109,198). Although it is impossible to perform experimental studies in humans, evidence from epidemiological, molecular toxicology and animal studies provide compelling evidence of adverse developmental effects and transgenerational toxicity (171,189,191,201,202). The realisation of the tragic effects of DES in the 1970's was first example of an in-utero exposure causing serious transgenerational health effects (191). This was followed by increasing interest in identifying the properties of environmental oestrogens (36).

Several oestrogenic EDC have been associated with birth outcomes that are thought to be associated with the development of PCOS (189). These include decreased birthweight (perfluoroalkyl substances [PFAS], perfluorooctanoic acid) and preterm birth (di-2-ethylhexyl phthalate) (201). Prenatal exposure to androgenic EDC (triclosan, glyphosate, tributyltin, nicotine) is of increasing concern, given the suspected epigenetic role of in-utero androgen exposure in the pathogenesis of PCOS (48,203,204). EDC can act at any stage of the human lifespan, including preconception and prenatally, and are increasingly becoming a priority in PCOS research (205).

3.7.2. EDC and the microbiome

As discussed above, the microbiome is increasingly considered to make a significant contribution to many human diseases, including PCOS (40,206). EDC that disrupts the composition or function of the microbiome have been termed "microbiota disrupting chemicals" (207). In turn, any disruption of the microbiome from EDC can impact crucial metabolic and endocrine physiology and homeostasis (36,208). A number of studies have reviewed the effect of EDC in invertebrate and vertebrate species, animal models and humans. These studies have found that BPA, phthalates, artificial sweeteners, heavy metals, fungicides, pesticides and microplastics can all affect the gut microbiome, and have metabolic and obesogenic effects (202,209,210). They have concluded that EDC exert their effects in a variety of species via a range of mechanisms, including modification of

epigenetic, cell signalling and metabolomic pathways, in addition to their effects on the microbiome.

Human exposure to the herbicide glyphosate, through diet and drinking water, has also been reported to alter gut microbial communities (211). Glyphosate-mediated inhibition of 5-enolpyruvylshikimate-3-phosphate synthase in intestinal microbiota has been shown to alter composition and enrich potentially pathogenic bacteria (212–214). In addition, microbiota exposure to glyphosate has been shown to alter mucosal-associated T-cells and promote a pro-inflammatory immune response (211). Taken together, EDC have been found to alter microbial composition and diversity (207,213), disrupt gastrointestinal barrier integrity (202,215), increase systemic endotoxin levels and inflammatory cytokines (216,217), alter the production of metabolites and influence metabolomic patterns (210), all of which have been proposed to be involved in the pathogenesis of PCOS (40).

3.7.3. EDC, insulin resistance and diabetes

Kahn et al reviewed six cohort studies and 2 case-control studies that raise concerns about exposure to PFAS in pregnancy and increased risk of impaired glucose tolerance and gestational diabetes in different ethnic groups (189). They also identified 4 studies showing similar increased risk with phthalate exposure during pregnancy, and one study that did not identify an association with gestational diabetes. Animal studies have found that some EDC target alpha and beta cells in the pancreas, adipose cells and hepatocytes, and contribute to insulin resistance (218). As a result of these and many other concerning studies the Endocrine Society issued a scientific statement cautioning that emerging evidence ties EDC exposure to two of the biggest public health threats facing society, diabetes and obesity (219,220).

3.7.4. EDC and obesity

A large number of EDC are now classified as “obesogens” due to their suspected role in promoting weight-gain and contributing to the global rise in obesity (202,203,221). So far, about 50 obesogens have been recognized including tributyltin, parabins, DDT, cadmium, persistent organic pollutants and many others (202,222,223). Three of the most studied compounds are BPA, phthalates and PFAS (200,201,221). Evidence from multiple birth cohort studies have shown an association between prenatal exposure to PFAS and childhood obesity (200,201). A number of reports have suggested that exposure to PFAS and phthalates also contribute to weight gain in adults (224). Two trials have identified an association between weight gain (Diabetes Prevention Trial Program Lifestyle Trial) (225) and reduced resting metabolic rate (the POUNDS Lost trial) (226), with serum PFAS concentrations. In recognition of the suspected significant risk, the International Federation of Obstetrics and Gynecology (FIGO) recommended a full global phase out of PFAS (227).

3.7.5. EDC and PCOS

A large number of cross-sectional studies have identified associations between EDC and PCOS, including PFAS, phthalates, bisphenol-A, triclosan and nicotine (196,208,228,229). Experimental animal studies have shown that exposure to androgenic EDC in pregnancy can result in significantly increased androgen levels in female offspring (36,48). Other androgenic EDC have been found to alter surrogate markers of developmental programming, such as anogenital distance (224). Although there are no specific toxicogenetic studies in women with PCOS, many EDC have been found to activate signalling pathways thought to be involved in the pathogenesis of PCOS (193,208). Taken together, the available evidence suggests EDC are likely to have a role in the pathogenesis of PCOS.

3.7.6. EDC recommendations

There is a significant global imperative to implement a multifaceted global programme to address the effects of EDC on human health using a hazard-based approach in preference to the current risk-based regulatory framework (230). As a result, implementation of the precautionary principle is a high priority in counselling women with PCOS (231). International professional bodies (The Royal College of Obstetricians and Gynaecologists, Endocrine Society, FIGO) have recommended that all pregnant women should be advised of the possible risks of EDC and that education programmes be developed to inform health professionals (220,232,233). An explanation of the pathogenesis of PCOS (discussed below), should include reference to environmental chemical exposure and open the way for more detailed discussion of specific personalised advice and lifestyle recommendations.

3.8. *Lifestyle Contributors to the Pathogenesis of PCOS*

It has been recognized that a variety of lifestyle factors contribute to the pathogenesis of PCOS for many decades (234,235). As a result, a number of lifestyle factors have been investigated for their role in the pathogenesis of PCOS. These include diet, exercise, stress, sleep disturbance and exposure to environmental chemicals (28,41,236). A large number of animal studies have provided experimental evidence supporting a causative role for many of these factors either individually, or in combination (44). Human research investigating causation is limited to observational and epidemiological studies, as many experimental protocols would be unethical. As a result, proving causation in humans will be extremely difficult. In addition, proving causation in evolutionary models also has a number of significant challenges (8,9,60). Nevertheless, developing a unified evolutionary model based on the large number of available human and animal studies may provide a useful evidenced-based framework for counselling women and informing future research.

Despite the limitations in proving causation, recent advances in genomics, epigenetics, metabolomics, nutrigenomics, evolutionary biology, computer technology and artificial intelligence, are providing many insights into the mechanisms of how lifestyle factors impact the pathogenesis of PCOS (9,90,235,237). We have attempted to integrate the research findings supporting an evolutionary model into the respective sections outlined

in this paper. It has not been our aim to comprehensively review all aspects of the role of lifestyle in the pathogenesis of PCOS. We have tried to highlight the evolutionary aspects of how diet in particular, may impact the pathogenesis of PCOS, as components of the human diet have effects on many areas of the proposed unified evolutionary model. A large body of evidence from studies in women with PCOS, and a range of other metabolic diseases, supports the view that a Western-style high glycaemic, high saturated fat, high calorie, low nutrient-dense, and low fibre diet that contains a high proportion of processed rather than whole food, contributes to the pathogenesis of PCOS (28,40,235). This is likely to be exacerbated by the additional adverse effects of multiple other lifestyle factors such as EDC, stress, circadian disruption and reduced physical activity.

The dysbiosis theory of the pathogenesis of PCOS highlights the role of a poor-quality diet in the pathogenesis of PCOS and is supported by over 30 proof-of-concept studies (40,238). International Guidelines for the assessment and management of PCOS recommend lifestyle management, with diet and exercise as first-line treatment for all women with PCOS, and provide a comprehensive review of the literature (7). Nutritional studies based on diet indices, diet composition and metabolomics have identified dietary components that contribute to a healthy eating pattern (51,237,239,240). Healthy diet patterns, or wholefood diets, have been found to be effective in controlling and reversing many of the symptoms and metabolic alterations associated with PCOS, and have also previously been reviewed (50). Two components of a healthy wholefood diet that appear to be important from an evolutionary perspective, in addition to the requirement for fundamental macronutrients (protein, fat and carbohydrate) and essential micronutrients (vitamins and minerals), are dietary fibre and polyphenols.

Throughout evolutionary history, humans have obtained nutrients from a wide variety of plant and animal food sources (241). These foods provided macronutrients, micronutrients and contingent nutrient factors that contain a range of bioactive components. Contingent nutrients include a variety of compounds that are not essential but may be beneficial to human health (242). Polyphenols are an important contingent nutrient, and comprise a large collection of plant-derived secondary metabolites that have been found to have beneficial biological and metabolic effects when consumed (243). Dietary polyphenols improve microbiota diversity and undergo extensive biotransformation by a variety of microbial species (244). It is estimated that less than 5% of ingested polyphenols reach the circulation intact (245). A large number of microbially-derived polyphenol metabolites can be detected in plasma compared with low levels of the parent compounds (246). Polyphenols have potent anti-inflammatory and antioxidant effects and are the most abundant antioxidant in the human diet (246). Not surprisingly, there has been significant interest in investigating the possible beneficial effects of polyphenols in PCOS, since the pathophysiology involves oxidative stress, chronic inflammation and alterations in the microbiome (247–250).

Polyphenol-rich foods have historically made up a considerable proportion of the dietary intake in many Hunter-gatherer societies and post-agricultural communities, and until recently, in Western nations (251–253). Polyphenols are present in fruits, vegetables,

legumes, nuts, and whole grains, as well as plant-derived foods and drinks like green tea, red wine, and chocolate (50). Women with PCOS have been noted to consume diets lower in polyphenol-containing foods (236). Consumption of polyphenols and polyphenol-rich foods and drinks have been found to improve a number of important outcome measures in women with PCOS, such as body weight, metabolic abnormalities, and serum androgen levels (50). Some polyphenols can act as selective oestrogen receptor modulators and may provide unique benefits to women with PCOS due to estrogen-related effects (254). Polyphenols are therefore an important part of a healthy diet and have been investigated for their potential role in the pathogenesis of PCOS (50). A healthy wholefood diet contains a wide variety of polyphenols coupled with the necessary dietary fibre required for optimal microbiome and metabolic function.

As previously discussed, the modern Western diet and lifestyle is at odds with our evolutionary background. In general, our traditional hunter-gatherer ancestors consumed significantly more fibre than modern populations. Studies that have investigated the dietary patterns of remaining contemporary Hunter-gatherer societies, have found their dietary fibre intake to be around 80-150 grams per day (255). This contrasts with the contemporary Western diet, where the average fibre intake is 18.2 grams per day in children and 20.7 grams per day in adults (256). Adequate dietary fibre consumption is important as it has a number of benefits, such as improved insulin sensitivity, reduced blood glucose levels, decreased systemic inflammation, lower serum levels of androgens and LPS, all of which have been linked to the pathogenesis of PCOS (257-260).

Recent systematic reviews of observational studies and randomized controlled trials have found dietary fibre consumption to be inversely related to risk of obesity, type 2 diabetes, and cardiovascular disease (261,262). A recent cohort study from Canada found that obese women with PCOS consumed significantly less dietary fibre than normal weight women without PCOS (263). In addition, fibre intake of women with PCOS was negatively correlated with IR, fasting insulin, glucose tolerance and serum androgens (263). Hence, the mismatch between the amount of fibre traditionally consumed and the fibre content of Western diets, may be an important dietary component contributing to the increased rates of PCOS seen in developed and developing nations.

The current low level of fibre consumption in Western nations also contributes to a lack of microbial diversity in the microbiota. The amount and variety of fibre in the diet is one of the main determinants of ecosystem diversity (264). Lack of microbial diversity has been associated with obesity, IR, and systemic inflammation (136,265,266). As previously discussed, low diversity is one of the key microbiota patterns observed in women with PCOS, and has been positively associated with hyperandrogenism, total testosterone levels, and hirsutism in this population (267). Conversely, ecosystem diversity and richness are hallmarks of Hunter-gatherer microbiotas who consume a high-fibre, more diverse plant-based diet (255,268). A shift towards a more wholefood diet therefore provides a variety of phytonutrients, polyphenols and fibre, in addition to the other essential macronutrients and micronutrients, and is likely to make a significant difference to metabolic and symptomatic outcomes in women with PCOS.

Although discussion of specific details related to lifestyle counselling are beyond the scope of this review, it is clear that improving outcomes in PCOS will require a multifaceted population-based approach that includes public health measures (269,270), improved compliance-aiding strategies, inclusion of nutrition training in medical education (271), implementation of current best-practice management strategies, and further development of the International Guidelines for the Assessment and Management of PCOS (7).

3.9. Conceptual framework of the unified evolutionary theory

Comprehensive International Guidelines have made 166 recommendations for the assessment and management of PCOS (38). We believe the current unified evolutionary theory of the pathogenesis of PCOS provides a conceptual framework that may help practitioners and patients understand the development of PCOS symptoms and pathology in the context of our modern lifestyle and environment. It will hopefully contribute to improved communication, result in improved feelings of empowerment over the personal manifestations of PCOS, improve compliance, reduce morbidity, increase quality of life and inform future research (figure 3).

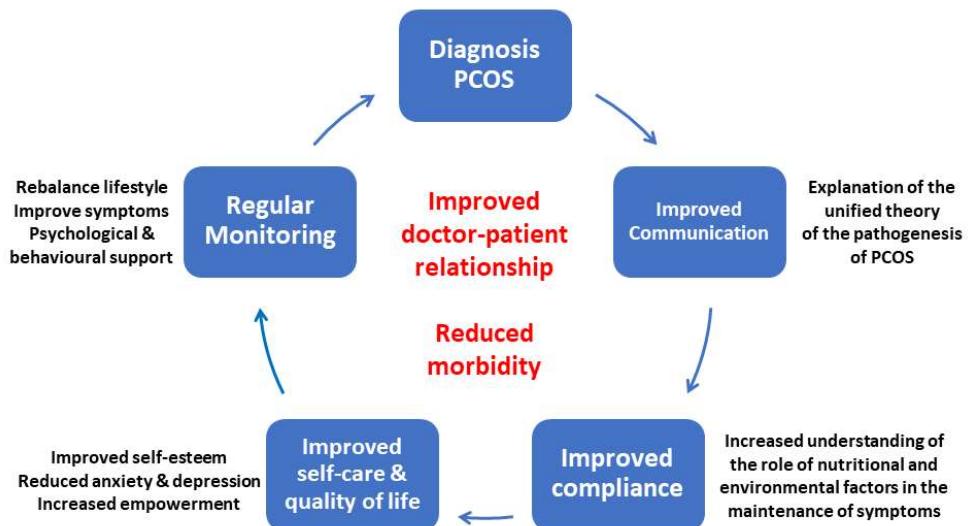

Figure 3. Impact of the unified theory on the management of polycystic ovary syndrome

3.10. Explanation to Women Diagnosed with PCOS

"Polycystic ovary syndrome is a problem that is inherited from both of your parents. The inherited genes are activated by a range of dietary and environmental factors that can cause a number of symptoms. These include weight gain, irregular periods, acne, excess hair growth, hair loss, anxiety and depression. Women with PCOS are also at risk of developing a range of other problems throughout their lifetime if they are not adequately treated. These include gestational diabetes, type 2 diabetes, heart disease and fertility problems. All of these symptoms and problems can be treated, controlled and reversed with appropriate lifestyle changes. These include a healthy

diet, exercise, avoiding environmental chemicals, stress management techniques, sleep and support from friends, family and health professionals. In addition, there are a range of medical and natural treatments that can also be used. Women with PCOS can have healthy, active lives with normal fertility”.

4. Conclusions

Substantial evidence and discussion support an evolutionary basis for the pathogenesis of polycystic ovary syndrome, although many of the mechanistic details are yet to be determined. Nevertheless, multiple lines of evidence from evolutionary theory, comparative biology, genetics, epigenetics, metabolism research, and cell biology, provide supportive evidence and hypothesis-generating data. The ability of animals to synchronize internal physiology, metabolism and reproductive function, with our changing external environment and habitat, are a necessary requirement for individual and species survival. The co-operative and sometimes competitive evolution of metabolism and reproduction provided adaptive survival mechanisms in ancestral environments that appear to be maladaptive in modern environments.

Lifestyle and environmental influences such as food abundance, altered food quality, chemical exposure, circadian disruption, chronic stress and sedentary behaviour, combine to redirect previously beneficial adaptations into adverse symptoms and disease. A unified evolutionary model provides a conceptual framework that considers the role of genetics, developmental programming, the microbiome, dysbiosis, environmental chemical exposure, metabolism, reproduction, and lifestyle factors that are involved in the initiation, treatment and prevention of PCOS. Mechanistic studies of the relative contributions of these and other ultimate and proximate causes are the subject of ongoing research and discussion. An evolutionary model therefore provides a framework to enhance practitioner and patient understanding, improve compliance with lifestyle interventions, reduce morbidity, improve quality of life and will evolve and change over time.

Author Contributions: JP conceptualized, designed and wrote the original draft of the manuscript; COB conceptualization, writing, reviewed and edited the manuscript; JH conceptualization, writing, reviewed and edited the manuscript; FLG conceptualized, reviewed, edited and significantly improved the manuscript. All authors critically revised the manuscript and approved the final submitted version of the manuscript.

Abstract: Polycystic ovary syndrome (PCOS) is increasingly recognized as a complex metabolic disorder that manifests in genetically susceptible women following a range of negative exposures to nutritional and environmental factors related to contemporary lifestyle. The hypothesis that PCOS phenotypes are derived from a mismatch between ancient genetic survival mechanisms and modern lifestyle practices is supported by a diversity of research findings. The proposed evolutionary model of the pathogenesis of PCOS incorporates evidence related to evolutionary theory, genetic studies, in utero developmental epigenetic programming, transgenerational inheritance, metabolic features including insulin resistance, obesity and the apparent paradox of lean phenotypes, reproductive effects and subfertility, the impact of the microbiome and dysbiosis, endocrine-disrupting chemical exposure, and the influence of lifestyle factors such as poor-quality diet and physical inactivity. Based on these premises, the diverse lines of research are synthesized into a composite evolutionary model of the pathogenesis of PCOS. It is hoped that this model will assist clinicians and patients to understand the importance of lifestyle interventions in the prevention and management of PCOS and provide a conceptual framework for future research. It is appreciated that this theory represents a synthesis of the current evidence and that it is expected to evolve and change over time.

1. Introduction

Polycystic ovary syndrome is a reversible metabolic condition that makes a significant contribution to the global epidemic of lifestyle-related chronic disease [1–3]. Many of these chronic diseases share a similar pathogenesis involving the interaction of genetic and environmental factors [4–6]. The revised International Guidelines for the assessment and management of women with PCOS emphasize that the associated metabolic dysfunction and symptoms should initially be addressed via lifestyle interventions [7]. A unified evolutionary model proposes that PCOS represents a mismatch between our ancient biology and modern lifestyle.

Evolutionary medicine is an emerging discipline involving the study of evolutionary processes that relate to human traits and diseases and the incorporation of these findings into the practice of medicine [8]. Evolutionary medicine brings together interdisciplinary research to inform clinical medicine based on the influence of evolutionary history on human health and disease [9]. Previous utilization of the principles of evolutionary medicine has been limited to monogenetic diseases (cystic fibrosis, sickle cell anemia, phenylketonuria and many others), drug resistance of microorganisms, tumor growth and chemoresistance [8]. Future insights into the application of evolutionary research offers the potential

to improve and personalize the established medical and scientific approaches to complex chronic diseases such as type 2 diabetes, metabolic syndrome and PCOS [5,9].

The evolutionary origins of complex chronic diseases incorporate considerations of relative reproductive fitness, mismatch between our biological past and modern environment, trade-offs involving combinations of genetic traits, and evolutionary conflicts [8,10]. These evolutionary factors are relevant when analyzing the contributors to the pathogenesis of PCOS in modern and modernizing societies that result in a mismatch between our rapid cultural evolution with our slow biological evolution [11,12]. The unique cultural evolution of humans does not have a plausible analogue in most other species and is increasingly recognized to play a significant role in the pathogenesis of metabolic diseases such as PCOS [5,13–17].

Polycystic ovary syndrome is a complex multisystem condition with metabolic, endocrine, psychological, fertility and pregnancy-related implications at all stages of life [7,18]. The majority of women with PCOS manifest multiple metabolic features including obesity, insulin resistance (IR), hyperlipidemia and hyperandrogenism [19,20]. PCOS results in an increased risk of developing metabolic disease (type 2 diabetes, non-alcoholic fatty liver disease [NAFLD] and metabolic syndrome), cardiovascular disease, cancer, a wide array of pregnancy complications (deep venous thrombosis, pre-eclampsia, gestational diabetes [GDM], macrosomia, growth restriction, miscarriage, stillbirth and preterm labor) and psychological problems (anxiety, depression) [6,21–25]. PCOS is part of a cluster of inter-related metabolic conditions and makes a significant contribution to the chronic disease epidemic.

Extensive research suggests that the etiology of PCOS involves an interaction between environmental factors and gene variants, although it has been suggested that genetic factors contribute less than 10% to disease susceptibility [26–28]. A large number of genetic and genome-wide association studies (GWAS) have identified common gene loci associated with PCOS phenotypes in different ethnic populations [29–31]. These appear to be normal gene variants or polymorphisms, given the frequency and type of genes that have been identified. PCOS is therefore viewed as a polygenic trait that results from an interaction between susceptible genomic variants and the environment.

PCOS affects upward of 10% of reproductive-aged women, estimated at over 200 million women worldwide [32,33]. PCOS is thought to be increasing in incidence in both developing and developed nations as a result of lifestyle-related changes in diet quality, reduced physical activity, ubiquitous environmental endocrine-disrupting chemicals (EDC), altered light exposures, sleep disturbance, heightened levels of stress and other environmental factors [11,34–38]. These factors, and the high prevalence of PCOS, suggest that there could be an evolutionary basis for the syndrome [15,16,39]. Evolutionary medicine has changed the paradigm for understanding PCOS, acknowledging many of the contributing lifestyle and environmental factors that facilitate the observed metabolic and clinical features and that are also shared with related metabolic diseases [8]. These “mismatch disorders” are estimated to make a significant contribution to chronic disease in developed countries and a growing proportion of disability and death in developing nations [3]. According to the Global Burden of Disease Study, the human diet is now the leading risk factor for morbidity and mortality worldwide [3]. In keeping with these findings, diet is recognized as one of the major contributors to the growing prevalence of PCOS globally [7,40].

Dietary and environmental factors are hypothesized to have an impact on developmental programming of susceptible gene variants in women with PCOS [41–43]. Extensive experimental evidence suggests that prenatal androgen exposure may play a role in the pathogenesis of PCOS-like syndromes in animal models [19,44–46]. The discovery of naturally occurring PCOS phenotypes in non-human primates supports a survival advantage of a hyperandrogenic, insulin resistant phenotype with delayed fertility [47]. In humans, the origin of excess androgens may be from maternal, fetal or placental sources. In addition, emerging and concerning evidence suggests that EDC may contribute to altered fetal programming and play a role in the pathogenesis of PCOS [41,48].

In utero genomic programming of metabolic and endocrine pathways can increase the susceptibility of offspring to develop PCOS following exposure to specific nutritional and environmental conditions [45]. This view of the pathogenesis of PCOS is consistent with the Developmental Origins of Health and Disease (DOHaD) model proposed by Neel [49]. Postnatal exposure to lifestyle and environmental factors, such as poor-quality diet and EDC, may activate epigenetically programmed pathways that further promote the observed features of PCOS. Dietary and lifestyle interventions have demonstrated that many of the clinical, metabolic and endocrine features of PCOS can be reversed [7,50,51].

Lifestyle-induced changes in the gastrointestinal tract microbiome are another significant factor in the etiology of PCOS [52,53]. Dysbiosis of the gut microbiota has been hypothesized to play a role in increased gastrointestinal permeability, initiating chronic inflammation, insulin resistance (IR) and hyperandrogenism [40]. Numerous studies have reported reduced alpha diversity of the microbiome that has been associated with the metabolic, endocrine and clinical features observed in women with PCOS [54,55]. The resulting dysbiosis has been shown to be reversible after interventions aimed at improving diet quality or treatment with probiotics or synbiotics [50,51,56–58].

A unified evolutionary theory of the pathogenesis of PCOS proposes that ancient genetic polymorphisms that were aligned with the environment of that era, resulted in an adaptive survival advantage in offspring in ancestral populations [14–16,28]. When these same genetic variants are exposed to modern lifestyle and environmental influences, maladaptive physiological responses occur. The prior advantages of insulin resistance, hyperandrogenism, enhanced energy storage and reduced fertility in ancestral populations become pathological and result in the observed features of PCOS in contemporary women (Figure 1).

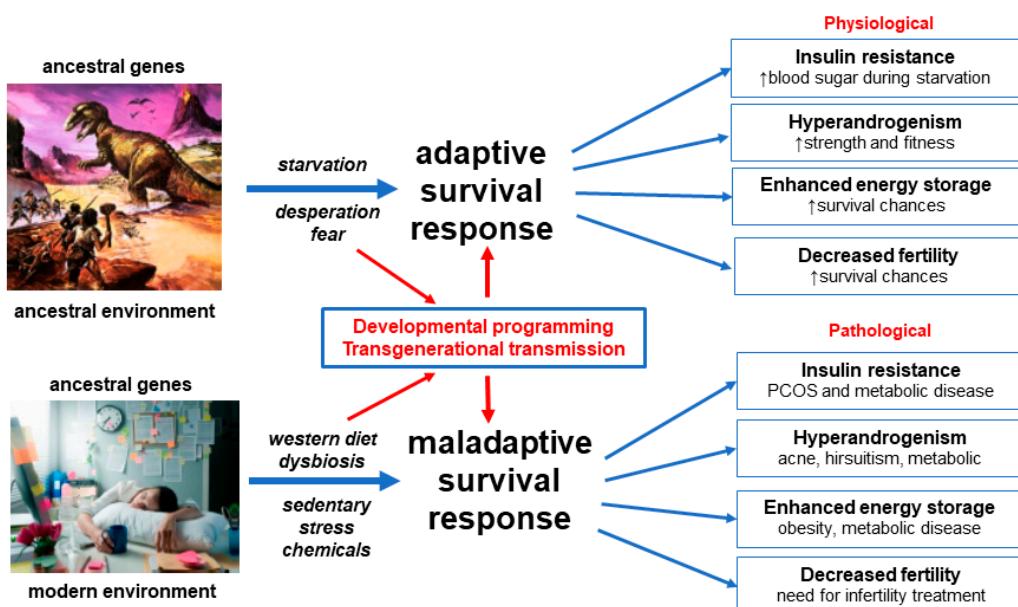

Figure 1. Evolutionary model of the pathogenesis of polycystic ovary syndrome. Adapted with permission from Ref. [12]. 2021 Journal of ACNEM.

2. Materials and Methods

The literature search focused on research publications related to the pathogenesis of PCOS using the keywords listed above and related mesh terms for data on the evolutionary aspects of PCOS, genetic studies, in utero developmental epigenetic programming, transgenerational inheritance, metabolic features including insulin resistance, obese and lean PCOS phenotypes, reproductive changes and subfertility, impact of the microbiome and dysbiosis, possible effects of endocrine-disrupting chemical exposure and the influence of lifestyle factors such as diet and physical activity. The databases searched included PubMed,

Scopus, Cochrane and Google Scholar. Relevant papers were selected, and citation searches were performed.

The present manuscript synthesizes the findings into a unified evolutionary model. The following text is presented as a narrative review of factors involved in the pathogenesis of PCOS and is discussed in ten main subject areas that provide the rationale for the development of a unified model. 1. Evolution 2. Genetics 3. Developmental Epigenetic Programming 4. Microbiome and Dysbiosis 5. Insulin resistance 6. Obesity and the lean paradox 7. Endocrine-Disrupting Chemical Exposure 8. Lifestyle contributors to the pathogenesis of PCOS 9. Circadian Rhythm Disruption and PCOS 10. Conceptual Framework and Summary of the Unified Evolutionary Model.

3. Pathogenesis of PCOS

3.1. Evolution

The description of PCOS phenotypes can be found in medical records from antiquity and the modern syndrome was described over 80 years ago [17,59]. Nevertheless, there is ongoing debate regarding the evolutionary origins of PCOS [15–17,39,60–64]. PCOS susceptibility alleles may have arisen in our phylogenetic ancestors, in the hunter-gatherer Paleolithic period of the Stone Age, after the Neolithic Agricultural Revolution or following the Industrial Revolution [16,17]. From an evolutionary perspective, nearly all genetic variants that influence disease risk have human-specific origins, but the systems they relate to have ancient roots in our evolutionary ancestors [8]. Regardless of the precise timing of the origin of PCOS in humans, the complex metabolic and reproductive gene variants identified in women with PCOS relate to ancient evolutionary-conserved metabolic and reproductive survival pathways [15,29]. Although evolutionary hypotheses about disease vulnerability are impossible to prove they have the potential to frame medical thinking and direct scientific research for the proximate causes of disease [15,60].

Multiple hypotheses have been proposed regarding the evolutionary origins of PCOS and related metabolic diseases [8,60,63]. These hypotheses are focused on the relative importance of metabolic survival adaptations versus improved reproductive success, or a combination of both. A detailed analysis of these hypotheses, and the complexities of the evolutionary considerations, have been reviewed elsewhere and is beyond the scope of the present review [8,60]. One common theme is that PCOS may be viewed as a “conditional phenotype” where a specific set of conditions has unmasked normally unexpressed or partly expressed genetic pathways, which then provide a survival advantage under certain environmental conditions [14,16].

All organisms have physiological adaptive responses to deal with changing environmental conditions (starvation, fasting, physical threat, stress and infection) and the varying demands of internal physiological states (pregnancy, lactation and adolescence) [14,65]. It has been proposed that the PCOS phenotype may have been invoked in specific environmental conditions in ancestral populations as a short, medium or even long-term adaptive survival mechanism [15–17]. The view of PCOS as a conditional phenotype proposes that these physiological responses become pathological in our modern environment due to factors such as food abundance, reduced physical activity, circadian disruption, stress and environmental chemical exposure. The transgenerational evolutionary theory of the pathogenesis of PCOS encompasses all of the above ideas to explain the observed pathophysiological and clinical features of PCOS [28].

It is generally accepted that almost all pre-industrial societies and animal populations experienced seasonal or unpredictable episodes of food shortage that applied evolutionary pressure to develop metabolic and reproductive adaptive survival responses [17,49]. It is also appreciated that metabolic and reproductive pathways are interconnected and involve reciprocal feedback control mechanisms [66–68]. During periods of starvation, anorexia or excessive weight gain, reproduction is down-regulated and ovulation becomes irregular or ceases [69,70]. Similarly, metabolic function is coordinated with the menstrual cycle to ensure optimal physiological conditions for fertilization, implantation, pregnancy,

parturition and lactation [71]. Recent research has elaborated on the details of how some of these complex regulatory mechanisms interact using specific hormonal, nutrient sensing and intracellular signaling networks [72–74].

Details of the mechanisms underlying the proposed adaptive survival advantages of IR, hyperandrogenism, enhanced energy storage and subfertility have been obtained from paleolithic records, animal models and human populations exposed to adverse environmental conditions such as war and famine-inflicted starvation [14,16,62,63]. Multiple lines of evidence support the maladaptive response of human populations to rapidly changing nutritional, physical, psychological and cultural environments, in the modern world [5,11,14,75]. These “adaptations” result in pathological responses to IR, hyperandrogenism, enhanced energy storage and ovulation (Figure 1).

Theories of evolutionary mismatch have also been advanced to explain all of the cluster of metabolic diseases associated with PCOS (type 2 diabetes, metabolic syndrome, NAFLD and cardiovascular disease) and follow the same set of basic principles and explanations [14,76]. This common body of evolutionary evidence is supported by the increasing incidence of metabolic-related disease, such as diabetes and obesity, in developed countries and in developing nations adopting a Western diet and lifestyle [11,77]. In addition, the demonstrated reversibility of PCOS and related metabolic and biochemical features following changes in diet, increased physical activity and other lifestyle interventions, adds further support to a transgenerational evolutionary model [50,51].

3.2. Genetics

The heritable nature of PCOS has been proposed since the 1960’s following a range of familial, twin and chromosomal studies [78–80]. Cytogenetic studies failed to identify karyotypic abnormalities and genetic studies did not show a monogenic inheritance pattern following examination of candidate genes [81,82]. In addition, two or more phenotypes can be present in the same family suggesting that some of the phenotypic differences could be accounted for by variable expression of the same shared genes [81,83].

The mapping of the human genome in 2003 [84] and the publication of the human haplotype map (more than one million single nucleotide polymorphisms of common genetic variants) in 2005 [85], lead to the realization that most DNA variation is shared by all humans and is inherited as blocks of linked genes (linkage disequilibrium) [86]. These advances enabled a revolution in case-control studies and the development of GWAS which map the entire human genome looking for susceptibility genes for complex traits such as obesity, type 2 diabetes and PCOS [81].

The first PCOS GWAS was published in 2010 and demonstrated 11 gene loci associated with PCOS [87]. Additional loci have subsequently been found in several different ethnic groups [86,88]. The first GWAS analysis of quantitative traits was published in 2015 and showed that a variant (rs11031006) was associated with luteinizing hormone levels [88]. The largest GWAS included a meta-analysis of 10,074 PCOS cases and 103,164 controls and identified 19 loci that confer risk for PCOS [29]. The genes associated with these loci involve gonadotrophin action, ovarian steroidogenesis, insulin resistance and type 2 diabetes susceptibility genes. The first GWAS using electronic health record-linked biobanks has introduced greater investigative power and identified 2 additional loci [89]. These variants were associated with polycystic ovaries and hyperandrogenism (rs17186366 near SOD2) and oligomenorrhoea and infertility (rs144248326 near WWTR1) [89]. In addition to identifying common gene variants for PCOS phenotypes, finding the same signals (THADA, YAP1 and c9orf3) in Chinese and European populations suggests that PCOS is an ancient trait that was present before humans migrated out of Africa [81].

More recently Mendelian randomization (MR) studies have been used to explore the potential causative association between gene variants identified in GWAS and PCOS [90,91]. Many of the gene variants identified in GWAS are located in non-coding regions of DNA [92]. The genes or functional DNA elements through which these variants exert their effects are often unknown. Mendelian randomization is a statistical methodology

used to jointly analyze GWAS and quantitative gene loci to test for association between gene expression and a trait, due to a shared or potentially causal variant at a specific locus [93]. A detailed analysis of MR methodology and the limitations of this statistical tool is beyond the scope of the present review. Although MR studies have the potential to infer causation it is recognized that they also have limitations in PCOS research [90]. Nevertheless, preliminary evidence suggests that several genes related to obesity, metabolic and reproductive function, may play a causal role in the pathogenesis of PCOS [90,91].

Decades of genetic research has therefore characterized PCOS as a polygenic trait that results from interactions between the environment and susceptible genomic traits [27,29,79,88]. The failure to identify a qualitative or monogenic inheritance pattern and the findings from GWAS, MR, familial and twin studies, suggests that the heritability of PCOS is likely to be due to the combination of multiple genes with small effect size, as has been found with obesity and type 2 diabetes [79,80,94–96]. Polygenic traits are the result of gene variants that represent one end of the bell-shaped normal distribution curve of continuous variation in a population [97]. From an evolutionary perspective, women with PCOS may represent the “metabolic elite” end of the normal distribution curve, being able to efficiently store energy in periods of food abundance and down-regulate fertility in times of food scarcity, or even in anticipation of reduced seasonal food availability as a predictive adaptive response [16,17,60].

The realization that PCOS is a quantitative trait (phenotype determined by multiple genes and environmental factors) has far-reaching implications for the diagnosis, treatment and prevention of symptoms and pathology associated with PCOS. The implications require a shift in thinking about PCOS as a “disease” to a variation of normal metabolic and reproductive function. This shift invites a change in vocabulary from talking about “disorder” and “risk” to talking about “expression” and “variability” [97]. This new understanding supports and reinforces an evolutionary model of the pathogenesis of PCOS. In keeping with this model, multiple lines of evidence suggest that inherited PCOS gene variants are developmentally programmed in a way that primes them for activation by nutritional and environmental factors in postnatal life [41,42,98].

3.3. Developmental Epigenetic Programming

The developmental programming of PCOS represents changes in gene expression that occur during critical periods of fetal development [99]. Following fertilization, most parental epigenetic programming is erased and dramatic epigenomic reprogramming occurs [100]. This results in transformation of the parental epigenome to the zygote epigenome and determines personalized gene function. Compelling evidence shows that a wide range of maternal, nutritional and environmental factors can effect fetal development during these critical periods of programming [44,98,99,101,102]. These include hormones, vitamins, diet-derived metabolites and environmental chemicals [48,98,103,104]. In addition, epigenetic reprogramming of germ-line cells can lead to transgenerational inheritance resulting in phenotypic variation or pathology in the absence of continued direct exposure [98].

Experimental studies in primates, sheep, rats and mice show that PCOS-like syndromes can be induced by a range of treatments including androgens, anti-Mullerian hormone and letrozole [19,44,46]. Nevertheless, there is significant debate regarding when an animal model qualifies as PCOS-like [105]. The model used and the method of induction of PCOS phenotypes therefore needs to be carefully scrutinized when generalizing findings from animal research to women with PCOS. Most of the animal and human research on the developmental origins of PCOS has focused on the role of prenatal androgen exposure. This has been extensively reviewed in numerous previous publications [41,46]. This research has resulted in a proposed “two hit” hypothesis for the development of PCOS phenotypes [43,45]. The “first hit” involves developmental programming of inherited susceptibility genes and the “second hit” arises due to lifestyle and environmental influences in childhood, adolescence and adulthood [41,106].

If PCOS is a quantitative trait involving normal gene variants, as suggested by the evolutionary considerations and findings from genetic research, then the “first hit” may result from normal developmental programming events as occurs with other gene variants [102]. According to this hypothesis, the polygenic susceptibility genes would be normally “activated” and “primed” to respond to future maternal and environmental conditions and exposures, as would be the case with many other normal genes [28]. In addition, the susceptibility alleles may be “activated” or “functionally enhanced” by a range of maternal and environmental factors, as is usually presumed to be the case in PCOS [5,14,102]. This developmental plasticity would provide a mechanism for a predictive adaptive response, based on inputs from the maternal environment that could be used to program metabolic and reproductive survival pathways, to better prepare the offspring for the future world in which they may be expected to live [107].

Parental lifestyle factors including diet, obesity, smoking and endocrine-disrupting chemicals, have all been shown to modulate disease risk later in life [104,108,109]. The original description of the fetal origin’s hypothesis proposed that poor maternal nutrition would increase fetal susceptibility to the effects of a Western-style diet later in life [49]. Subsequent studies have confirmed that maternal exposure to either nutrient excess or deficit, can have long-term consequences for the health of the progeny [104]. Evidence from human and animal studies suggests that maternal obesity programs the offspring for increased risk of developing obesity, hyperglycemia, diabetes, hypertension and metabolic syndrome [108].

The developmental origins of PCOS may have been due to different factors in ancestral and modern populations [17,60]. It has been hypothesized that environmental stress, infection, nutrient deprivation, fetal growth restriction and stress hormone responses may have resulted in maternally mediated modulation of gene expression in ancestral offspring [17,110]. Some of these factors have been investigated and confirmed in modern populations subject to starvation and extreme environmental conditions [111]. In contrast, altered fetal programming in modern societies may be secondary to maternal overnutrition, sedentary behavior, obesity, emotional stress, circadian rhythm disruption, poor gut health or environmental chemical exposure [35,101,112,113]. The preconception and pregnancy periods therefore provide a unique opportunity for lifestyle interventions that promote optimal future health for both the mother and the offspring (Figure 2).

3.4. Microbiome and Dysbiosis

The gastrointestinal microbiome is now appreciated to play a central role in human health and disease [114,115]. The microbiome is known to co-regulate many physiological functions involving the immune, neuroendocrine and metabolic systems via complex reciprocal feedback mechanisms that operate between the microbial ecosystem and the host [116,117]. Evidence from studies in Western populations, hunter-gatherer societies and phylogenetic studies in other species, have attempted to place the human microbiome into an evolutionary context [118]. Although microbes clearly impact host physiology and have changed along branches of the evolutionary tree, there is ongoing debate regarding whether the microbiome can evolve according to the usual evolutionary forces [119,120]. Nevertheless, it has been argued that focusing on functional pathways and metabolic roles of microbial communities, rather than on specific microbes, provides a better model for understanding evolutionary fitness [118]. The co-evolution of the microbiome and human physiology may therefore be important in understanding the differences between ancient adaptive physiological survival mechanisms and modern lifestyle-related pathological responses, in women with PCOS (Figure 1).

Twin studies and GWAS show that host genetics can influence the microbiome composition, and microbes can exert effects on the host genome, although the environment has an important role [121,122]. Humans are constantly adapting to the gut microbiome to try to determine which microorganisms are beneficial or harmful. Immune genes involved in this process are the most rapidly evolving protein-encoding genes in the mammalian genome [123,124]. Diversification of microbes allows humans to access dietary niches and nutritional components they otherwise would not be able to access, which may be beneficial and ultimately lead to the integration of specific microbes into the ecosystem [125]. Although no living population today carries an ancestral microbiome, comparison studies of non-Western and Western populations show significant differences in the relative abundances of common phyla and a much greater species diversity in non-Western populations [126,127]. A review of non-human primate and human gut microbiome datasets, revealed a changing microbiome in response to host habitat, season and diet, although there appear to be common species-specific symbiotic communities [118].

Rapid human cultural changes have resulted in significant dietary modifications in urban-industrialized communities and shifted the microbiome at an unprecedented rate. The result has been the development of a mismatch between human metabolic genes and bacteria that enhance fat storage [128]. In our evolutionary past, when nutrients were scarce, it has been theorized that host selection led to the maintenance of microbes that enhance nutrient uptake or host energy storage. However, in the modern environment, where a high-fat, high-sugar, low-fiber diet has become common and easily accessible, integration of these microbes leads to maladaptive physiological responses [40]. For metabolically thrifty individuals with PCOS, harboring microbes that enhance energy storage escalates the evolutionary conflict, furthering the development of insulin resistance and therefore progression to obesity and type 2 diabetes [12,129]. Further compounding this maladaptive response is the loss of microbes that are required to access other dietary niches. One example is the loss of symbiotic species of *Treponema* in individuals living in urban-industrialized communities [130]. A change from the ancestral hunter-gatherer diet, where foods consumed changed seasonally and a wide variety of food components were eaten, to a diet that is similar across seasons and significantly less varied, is another likely contributor to reduced diversity of the microbiomes of individuals living in urbanized-industrialized communities [131].

The majority of women with PCOS are overweight or obese and evidence indicates that the microbiome of obese individuals is capable of extracting more energy from the host diet compared with the microbiome of lean individuals [132]. This is thought to be driven by an expansion in pro-inflammatory species of bacteria, such as *E. coli*, and a depletion of anti-inflammatory bacteria such as *Faecalibacterium prausnitzii* [133,134]. Chronic low-grade

'metabolic' inflammation, or meta-inflammation, is a result of an imbalanced gut microbiome that promotes the development of insulin resistance and type 2 diabetes [135–137].

The dysbiosis of gut microbiota theory of PCOS, proposed by Tremellen in 2012, accounts for the development of all of the components of PCOS (multiple ovarian follicles, anovulation or menstrual irregularity and hyperandrogenism) [40]. The theory proposes that a poor-quality diet and resulting imbalanced microbiome, induces intestinal permeability and endotoxemia, exacerbating hyperinsulinemia. Increased insulin levels promote higher androgen production by the ovaries and disrupts normal follicle development. Metabolic, endocrine and environmental factors associated with PCOS are not mutually exclusive, and therefore their relative contributions to dysbiosis in PCOS remains uncertain [138]. Consuming a balanced diet that is low in fat and high in fiber, can also restore balance to the ecosystem (termed eubiosis) [50]. A recent study showed that dietary intake of fiber and vitamin D was significantly decreased in both lean and obese women with PCOS, compared to healthy controls, and correlated with lower diversity of the gut microbiome [139]. Dysbiosis is reversible with improvement in diet quality augmented by the addition of probiotics or synbiotics [51,56–58].

Dysbiosis is a consistent finding when looking at the microbiome of women with PCOS [140–143]. Although most studies are small, dysbiosis has consistently been found to correlate with different physiological parameters, such as obesity, sex hormones and metabolic defects [140,141,143]. Similar to microbiomes associated with obesity, the microbiomes of individuals with PCOS have generally been found to have lower alpha diversity (lower numbers of bacterial taxa) than controls, and most studies describe an altered composition of taxa relative to controls [140,143]. However, the bacterial taxa observed to be either increased, depleted or absent in PCOS differs from study to study. This is likely due to both the immense inter-individual variation in microbiotas, as well the fact that PCOS is a quantitative trait with women with various degrees and levels of obesity and sex hormones.

In keeping with the developmental origins hypothesis previously discussed, maternal androgens may alter the composition and function of the microbiome, therefore facilitating the pathogenesis of PCOS [140]. One study showed that beta diversity, which is used to measure differences between groups, was negatively correlated with hyperandrogenism, suggesting that androgens play a significant role in dysbiosis [140]. The 'first hit' in utero may therefore combine with vertical transmission of a dysbiotic microbiome from a mother with PCOS, resulting in dysbiosis in the offspring. Preconception and pregnancy provide a unique opportunities for lifestyle and dietary interventions aimed at restoring eubiosis, to enable the transference of a balanced ecosystem to the offspring, via vertical transmission [118].

The accumulating scientific evidence strongly supports the significant role played by the microbiome in the pathogenesis and maintenance of PCOS, consistent with research in other related metabolic conditions. The role of dysbiosis is supported by over 30 proof-of-concept studies that have recently been reviewed [144]. Dysbiosis is therefore a significant factor in the pathogenesis of PCOS and an important component of a unified evolutionary model. Dysbiosis represents a maladaptive response of the microbiome to modern lifestyle influences and is a modifiable factor in the treatment of women with PCOS.

3.5. Insulin Resistance

There are several dilemmas when assessing the role of IR in women with PCOS. There is no consensus on the definition of IR [145,146], measurement is difficult [147,148], whole-body IR is usually measured although it is recognized that IR can be selective being either tissue-specific or pathway-specific within cells [149–151], normal values are categorical and determined by arbitrary cut-offs (4.45 mg/kg/min) [145], testing is not recommended in clinical practice [38], reported prevalence rates in obese and lean women vary widely [147,152], and the significance of IR as a pathognomonic component of PCOS is an area of debate [153–155].

Despite these limitations, it is hypothesized that IR is a significant proximate cause of PCOS and is intrinsic to the underlying pathophysiology [44,156]. In addition, it is recognized that IR plays a major role in the pathophysiology of all of the metabolic diseases, cardiovascular disease, some neurodegenerative diseases, and selected cancers [22,157]. Insulin resistance is therefore considered to be the main driver for many diseases and makes a significant contribution to the chronic disease epidemic [158]. Nevertheless, being able to vary the sensitivity and physiological action of insulin is thought to have conferred a significant adaptive survival role in many animals throughout evolutionary history [146,159]. It has been proposed that IR may have evolved as a switch in reproductive and metabolic strategies, since the development of IR can result in anovulation and reduced fertility, in addition to differential energy repartitioning to specific tissues [159].

Insulin receptors are located on the cell membranes of most tissues in the body [160]. Ligand binding to the alpha-subunit induces autophosphorylation of specific tyrosine residues on the cytoplasmic side of the membrane [160,161]. The activated insulin receptor initiates signal transduction via the phosphatidylinositol-3 kinase (PI-3K) metabolic pathway and the mitogen-activated protein kinase pathway (MAPK) which is involved in cell growth and proliferation [161]. Insulin is an anabolic hormone that facilitates glucose removal from the blood, enhances fat storage and inhibits lipolysis in adipose tissue, stimulates glycogen synthesis in muscle and liver and inhibits hepatic glucose output [161]. IR can be defined as a state where higher circulating insulin levels are necessary to achieve an integrated glucose-lowering response [146]. IR results from alterations to cellular membrane insulin-receptor function or intracellular signaling, enzyme, metabolic or gene function [146,160,161].

Insulin resistance can be caused by a wide variety of mechanisms that have the ability to disrupt any part of this metabolic signaling system [53,161]. These include autoantibodies, receptor agonists and antagonists, hormones, inflammatory cytokines, oxidative stress, nutrient sensors and metabolic intermediates [160–163]. Physiological regulation of insulin function can be viewed as an adaptive mechanism to regulate the metabolic pathway of insulin signaling (PI-3K), in response to changing environmental conditions [starvation, fear, stress] [164,165] or during normal alterations of internal states (pregnancy, lactation, adolescence) [65,146,152].

The physiological activation of IR allows the organism to switch from an anabolic energy storage state to a catabolic or energy mobilizing state. This allows free fatty acids to be mobilized from adipose tissue, which are then converted to glucose in the liver and released into the circulation [161]. As a result of this metabolic change, blood sugar levels are maintained for vital metabolic processes and brain function [14]. This adaptive protective mechanism can be pathway-specific during periods of growth, such as pregnancy, lactation and adolescence, so that only the metabolic signaling (PI-3K) is inhibited and not the mitogenic pathway (MAPK), which may even be up-regulated [30,65,160].

When the physiology of insulin function is considered to be a quantitative or continuous variable from an evolutionary perspective, it is likely that all women with PCOS, whether obese or lean, have reduced insulin sensitivity [152,155,166]. A systematic review and meta-analysis of euglycemic-hyperinsulinemic clamp studies found that women with PCOS have a 27% reduction in insulin sensitivity compared to body mass index (BMI) and age-matched controls [155]. In evolutionary terms, women with a PCOS metabolic phenotype would have increased survival chances during times of environmental or physiological demand for altered energy metabolism, but be more vulnerable to the pathological effects of IR when exposed to modern lifestyle factors [14,17,159]. In particular, a poor-quality, high-glycemic, high-fat, low-fiber diet has been shown to cause IR [40,167]. As discussed in the dysbiosis section, diet-related changes in the gastrointestinal microbiome have also been shown to cause IR in women with PCOS [53,55]. Numerous studies have shown that dietary modification [168–170], or treatment with probiotics or synbiotics, has the potential to restore normal insulin function [57,171].

Consumption of a high-glycemic-load diet results in rapid increases in blood sugar levels that cause compensatory hyperinsulinemia [167,172]. Excessive dietary intake of glucose and fructose are converted to fatty acids by de novo lipogenesis in the liver, transported to adipocytes via lipoproteins, released as fatty acids to adipocytes and stored in fat globules as triglycerides [161]. As a result of nutrient overload, diacylglycerol, the penultimate molecule in the synthesis of triglyceride, accumulates in the cytoplasm and binds with the threonine amino acid in the 1160 position of the insulin receptor. This inhibits autophosphorylation and down-regulates the metabolic PI-3K pathway and causes IR [161]. This process has the potential to be reversible following changes in diet quantity and quality, as has been shown to occur with calorie restriction, fasting, time-restricted eating, gastric bypass surgery, low saturated fat and low glycemic diets [168,170,173]. Diets high in animal protein or saturated fat can also cause IR independent of BMI [174,175]. These mechanisms provide the rationale for the principal recommendation of the International Guidelines that women with PCOS should be advised about dietary modification as the first line of management in all symptom presentations [38].

3.6. Obesity and the Lean PCOS Paradox

Insight can be obtained into the role of obesity in women with PCOS by examining the evolutionary history, genetic studies and pathological disorders of adipose tissue [151,176,177]. The ability to store energy is a basic function of life beginning with unicellular organisms [176]. In multicellular organisms, from yeast to humans, the largest source of stored energy is as triglycerides in lipid droplets in order to provide energy during periods when energy demands exceed caloric intake [176]. Understanding the biological functions of adipose tissue has progressed from energy storage and thermal insulation to that of a complex endocrine organ with immune and inflammatory effects and important reproductive and metabolic implications [176,178].

Adipose tissue is organized into brown adipose tissue (BAT) and white adipose tissue (WAT), both with different functions [178]. Although the evolutionary origins of BAT and WAT are the subject of ongoing debate [176], BAT is located in the supraclavicular and thoracic prevertebral areas and is primarily involved in cold thermogenesis and regulation of basal metabolic rate [179]. WAT is distributed in multiple anatomical areas such as visceral adipose tissue (VAT) and subcutaneous adipose tissue (SAT) and functions as a fat storage depot and an endocrine organ [178,179]. An additional layer of SAT is thought to have evolved as insulation against cool night temperatures in the Pleistocene open Savannah [180]. The lower body distribution of SAT in women is hypothesized to have evolved to provide additional calorie storage for pregnancy and lactation and is unique to human females [14]. Lower body SAT has a metabolic program that makes it less readily available for every-day energy needs, but it can be mobilized during pregnancy and lactation [14]. In addition, excess accumulation of SAT is much less likely to cause IR and metabolic dysfunction and explains why IR is not observed in all obese individuals [151,181]. Visceral WAT is associated with IR in women with PCOS leading to both metabolic and reproductive problems [182].

Multiple lines of evidence from evolutionary history, genetic and twin studies, support a genetic basis for obesity and differences in obese and lean phenotypes in women with PCOS [183–186]. The majority of women with PCOS are overweight or obese, with reports ranging from 38–88% [152,186]. Studies comparing obese and lean women with PCOS have several methodological problems including small sample size, overlap of PCOS characteristics with normal pubertal changes, non-standardized diagnostic criteria, and limited generalizability to the entire population due to a focus on a specific ethnic group [166,182]. In addition, most of the studies examining body composition in PCOS have relied on anthropomorphic measurements (BMI, waist circumference, waist-to-hip ratio) which are considered inaccurate compared with the current gold-standard of magnetic resonance imaging [182]. Consequently, there is wide heterogeneity in reports examining the relation-

ship between body composition measures, including extent of VAT and metabolic changes such as IR [186].

In humans, there is large individual variation in the fat storage capability and expandability of different adipose tissue depots [151]. It has been hypothesized that once the genetically determined limit of expandability of SAT is reached, there is expansion of VAT and excess lipid accumulation in muscle, liver and other organs, resulting in IR, inflammation and metabolic dysregulation [151]. We hypothesize that lean women with PCOS have a genetically determined limited ability to store excess lipid in SAT, but develop increased lipid deposition in VAT and organs such as the liver, resulting in metabolic dysregulation and IR in a similar manner to what occurs in obese women with PCOS. The wide variation in the genetic limitation of SAT expansion is also supported by studies in individuals with lipodystrophy.

Lipodystrophies are a heterogeneous group of rare inherited and acquired disorders characterized by a selective loss of adipose tissue [177,187]. They are classified on the basis of the extent of fat loss as generalized, partial or localized [187]. Patients with congenital generalized lipodystrophy have a generalized deficiency of fat from birth, usually have severe IR and develop diabetes at puberty. As a consequence of genetically limited ability for SAT lipid storage, lipids can only be stored ectopically in non-adipocytes resulting in major health consequences including IR, fatty liver, diabetes and PCOS [188]. In contrast to generalized lipodystrophy, patients with familial partial lipodystrophy have normal fat distribution at birth but loose SAT in the limbs, buttocks and hips, at puberty. Fifty percent of women develop diabetes and 20–35% develop irregular periods and polycystic ovaries [177]. Despite the rare nature of these syndromes much has been learned about the underlying genetic variants involved [187].

Elucidation of clinical subtypes and the genetic background of patients with lipodystrophies may pave the way to new insights into the role of fat partitioning and obesity, and has implications for understanding the pathogenesis of insulin resistance, diabetes and PCOS [177]. Lean women with PCOS may have a genetic predisposition for limited SAT fat storage, coupled with underlying metabolic predispositions that result in deposition of excess lipid in VAT and liver and the observed metabolic features of IR, fatty liver and diabetes. If the extent of IR and ectopic fat deposition is excessive, the resulting hormonal changes may be sufficient to cause oligomenorrhea and subfertility as occurs with secondary familial partial lipodystrophy type 2 [188,189]. If this underlying mechanism is confirmed in future studies, the main difference between women with lean or obese PCOS may be the combined effects of metabolic programming and the genetically determined extent of SCT fat deposition. This would explain why lean women have all the same clinical, biochemical and endocrine features, although possibly less severe, than overweight and obese women with PCOS [186].

3.7. Endocrine-Disrupting Chemical Exposure

Anthropomorphic chemical exposure is ubiquitous in the environment and has possible effects on many aspects related to women's health and PCOS [36,190–192]. The identification of more than 1000 EDC in food, air, water, pesticides, plastics, personal care products, and other consumer goods, raises specific concerns for pregnant women and women with increased susceptibility to metabolic diseases such as PCOS [36,172,192–194]. Accumulating evidence suggests that EDC may be involved in the pathogenesis of PCOS given their known and potential hormonal and metabolic effects [36,190,195]. This includes many of the areas that have been considered in the unified evolutionary model, such as developmental epigenetic programming, microbiome composition and function, metabolic processes such as IR, and regulation of body weight.

Many observational studies have demonstrated the presence of EDC in maternal and fetal serum and urine, amniotic fluid, cord blood and breast milk [196–198]. Six classes of EDC have been shown to cross the placenta confirming that the fetus is exposed at all stages of development [109,196]. Although it is impossible to perform experimental studies

in humans, evidence from epidemiological, molecular toxicology and animal studies provide compelling evidence of adverse developmental effects and transgenerational toxicity [172,190,192,199]. The realization of the tragic effects of DES in the 1970's was first example of an in utero exposure causing serious transgenerational health effects [192].

Several estrogenic EDC have been associated with birth outcomes that are thought to be associated with the development of PCOS [190]. These include decreased birthweight (perfluoroalkyl substances [PFAS], perfluorooctanoic acid) and preterm birth (di-2-ethylhexyl phthalate) [190]. Prenatal exposure to androgenic EDC (triclosan, glyphosate, tributyltin, nicotine) is of increasing concern, given the suspected epigenetic role of in utero androgen exposure in the pathogenesis of PCOS [48,200,201].

As a result, implementation of the precautionary principle is a high priority in counselling women with PCOS [202]. International professional bodies (The Royal College of Obstetricians and Gynecologists, Endocrine Society, FIGO) have recommended that all pregnant women should be advised of the possible risks of EDC and that education programs be developed to inform health professionals [203–205]. An explanation of the pathogenesis of PCOS should include reference to environmental chemical exposure and open the way for more detailed discussion of specific personalized advice and lifestyle recommendations.

3.8. Lifestyle Contributors to the Pathogenesis of PCOS

Several lifestyle factors have been investigated for their role in the pathogenesis of PCOS. These include diet, exercise, stress, sleep disturbance, circadian disruption and exposure to environmental chemicals [28,41,206]. Recent advances in genomics, epigenetics, metabolomics, nutrigenomics, evolutionary biology, computer technology and artificial intelligence, are providing many insights into the mechanisms of how lifestyle factors impact the pathogenesis of PCOS [9,90,207,208]. Nutritional studies based on diet indices, diet composition and metabolomics have identified dietary components that contribute to a healthy eating pattern [51,207,209,210]. Healthy diet patterns, or wholefood diets, have been found to be effective in controlling and reversing many of the symptoms and metabolic alterations associated with PCOS [50].

As previously discussed, the modern Western diet and lifestyle is at odds with our evolutionary background. One dietary component that differs significantly in ancestral and modern populations is dietary fiber intake. Assessment of dietary fiber intake is also a good surrogate marker for a healthy wholefood diet. In general, our traditional hunter-gatherer ancestors consumed significantly more fiber than modern populations. Studies that have investigated the dietary patterns of remaining contemporary hunter-gatherer societies, have found their dietary fiber intake to be around 80–150 g per day [211]. This contrasts with the contemporary Western diet, where the average fiber intake is 18.2 g per day in children and 20.7 g per day in adults [212]. Adequate dietary fiber consumption is important as it has several benefits, such as improved insulin sensitivity, reduced blood glucose levels, decreased systemic inflammation, lower serum levels of androgens and LPS, all of which have been linked to the pathogenesis of PCOS [213–216].

Recent systematic reviews of observational studies and randomized controlled trials have found dietary fiber consumption to be inversely related to risk of obesity, type 2 diabetes, and cardiovascular disease [217,218]. A recent cohort study from Canada found that obese women with PCOS consumed significantly less dietary fiber than normal weight women without PCOS [219]. In addition, fiber intake of women with PCOS was negatively correlated with IR, fasting insulin, glucose tolerance and serum androgens [219]. Hence, the mismatch between the amount of fiber traditionally consumed and the fiber content of Western diets, may be an important dietary component contributing to the increased rates of PCOS seen in developed and developing nations.

3.9. Circadian Rhythm Disruption and PCOS

The circadian rhythm is a mechanism with which living organisms can synchronize their internal biological processes with the external light and dark pattern of the day [220].

Circadian rhythms have formed a central component of the evolutionary adaptation of all organisms to a variety of environmental conditions, from prokaryotes to complex multicellular organisms [221–223]. Most organisms experience daily changes in their environment, including light availability, temperature and food. Hundreds of thousands of years of evolution have synchronized the rhythmic daily programming of internal metabolic, endocrine and behavioral systems to the external environmental conditions [222]. Circadian clocks anticipate environmental changes and confer a predictive adaptive survival benefit to organisms.

The normal function of the circadian system is based on a hierarchical network of central and peripheral clocks [224]. The central, or master clock, is in the suprachiasmatic nucleus in the anterior hypothalamus. It is strategically placed to communicate with multiple physiological homeostatic control nuclei (body temperature, metabolic rate, appetite, sleep), pituitary hormonal systems (gonadal, thyroid, somatotrophic, adrenal), the autonomic nervous system (digestion, heart rate), and conscious cortical centers (behavior, motivation, reward, reproduction) [225]. Humans are programmed for specific day and night-time survival behaviors that are regulated by the availability of temperature, feeding and sunlight. Photons of light stimulate specialized photoreceptors in the retinal ganglion layer which transmit an electrical impulse to the cells of the master clock via the retinohypothalamic tract [226]. The central clock can then convey rhythmic information to peripheral clocks in other tissues and organs throughout the body [224]. Feeding and fasting cycles are the primary time cues for circadian clocks in peripheral tissues [227].

Circadian clocks exist in all cells, including the microbiome, and function as autonomous transcriptional-translational genetic feedback loops [228,229]. The changing length of daylight, determined by the rotation of the earth on its axis, requires that the autonomous clocks are reset, or entrained, on a daily basis [230]. The molecular mechanisms of circadian clocks are similar across all species and are regulated by genetic enhancer/repressor elements, epigenetic modulation by methylation and acetylation, post-translation modification of regulatory proteins, and a variety of hormonal and signaling molecules [220,229,231]. This complex interconnected regulatory framework, ensures that the same molecules that regulate metabolism and reproduction, also contribute to a bidirectional feedback system with the autonomous circadian circuits [224,231]. This results in synchronicity of internal physiology with environmental cues, to optimize both individual and species survival. Evolution has therefore provided a mechanism for humans to adapt and survive under the selective pressures of food scarcity, seasonal changes in sunlight and a range of temperature exposures.

The evolutionary adaptive survival benefit of synchronized circadian systems in ancient populations is in marked contrast to the multiple circadian disruptions that are associated with modern lifestyle. These include poor-quality diet [232], improper meal timing and altered feeding-fasting behavior [233,234], sub-optimal exercise timing [235], disrupted sleep-wake cycles [236], shift work [237], EDC [238], and stress [239,240]. Changes in all of these parameters are correlated with significant increases in obesity, diabetes, cardiovascular disease, and some cancers [222]. Not surprisingly, lifestyle-related disturbances of circadian rhythms have also been investigated for their role in the pathogenesis of PCOS [35,241,242]. The available evidence suggests that circadian disruption has detrimental effects on in utero development [243], altered metabolism and insulin resistance [241,244], body weight and obesity [245], and fertility [34]. All these influences are relevant to an evolutionary model of the pathogenesis of PCOS.

Recognition of the impact of lifestyle behaviors on circadian dysregulation and metabolic and reproductive function, opens the way for targeted intervention strategies to modulate and reverse these effects [246]. These include regular meal timing [222,247], time-restricted feeding [248,249], restoration of normal sleep cycles [250], optimal exercise timing [235], limitation of exposure to bright light at night [251], and improved diet quality [227]. Recognition of circadian dysfunction and the investigation of lifestyle interventions should be a priority in both clinical management and future research in PCOS.

3.10. Conceptual Framework and Summary of the Unified Evolutionary Model

The evolutionary model proposes that PCOS is a condition that arises from the inheritance of genomic variants derived from the maternal and paternal genome. In utero fetal metabolic, endocrine and environmental factors modulate developmental programming of susceptible genes and predispose the offspring to develop PCOS. Postnatal exposure to poor-quality diet, sedentary behavior, EDC, circadian disruption and other lifestyle factors activate epigenetically programmed pathways, resulting in the observed features.

Dietary factors cause gastrointestinal dysbiosis and systemic inflammation, insulin resistance and hyperandrogenism. Continued exposure to adverse lifestyle and environmental factors eventually leads to the development of associated metabolic conditions such as obesity, GDM, diabetes, NAFLD and metabolic syndrome (Figure 1).

Balanced evolutionary selection pressures result in transgenerational transmission of susceptible gene variants to PCOS offspring. Ongoing exposure to adverse nutritional and environmental factors activate developmentally programmed genes and ensure the perpetuation of the syndrome in subsequent generations. The DOHaD cycle can be interrupted at any point from pregnancy to birth, childhood, adolescence or adulthood by targeted intervention strategies (Figure 2).

In summary, we propose that PCOS is an environmental mismatch disorder that manifests after in utero developmental programming of a cluster of normal gene variants. Postnatal exposure to adverse lifestyle and environmental conditions results in the observed metabolic and endocrine features. PCOS therefore represents a maladaptive response of ancient genetic survival mechanisms to modern lifestyle practices.

Comprehensive International Guidelines have made 166 recommendations for the assessment and management of PCOS [38]. We believe the current unified evolutionary theory of the pathogenesis of PCOS provides a conceptual framework that may help practitioners and patients understand the development of PCOS symptoms and pathology in the context of our modern lifestyle and environment. It will hopefully contribute to improved communication, result in improved feelings of empowerment over the personal manifestations of PCOS, improve compliance, reduce morbidity, increase quality of life and inform future research (Figure 3).

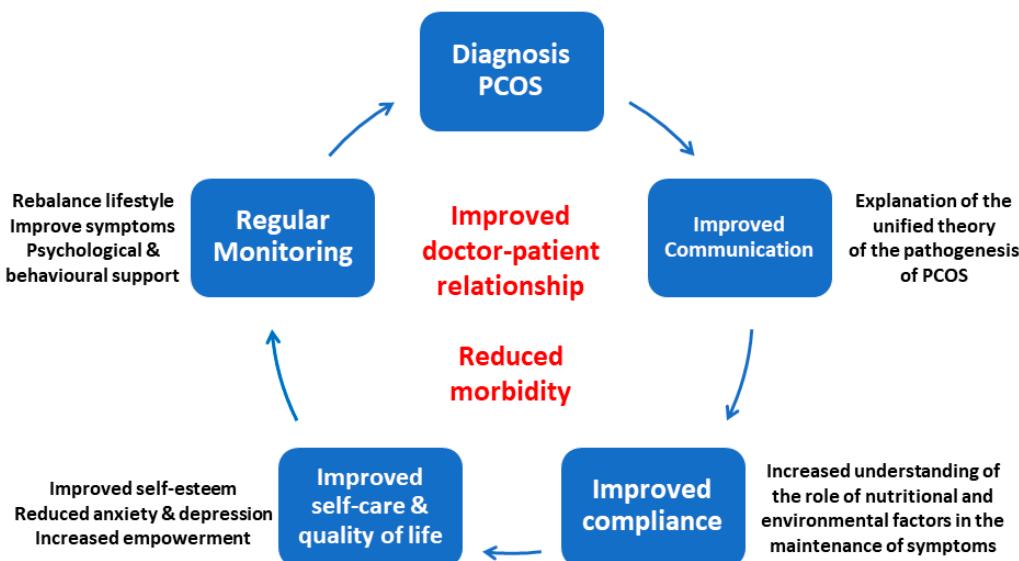

Figure 3. Impact of the unified theory on the management of polycystic ovary syndrome. Reprinted from Ref. [28].

4. Conclusions

Substantial evidence and discussion support an evolutionary basis for the pathogenesis of polycystic ovary syndrome, although many of the mechanistic details are yet to

be determined. Nevertheless, multiple lines of evidence from evolutionary theory, comparative biology, genetics, epigenetics, metabolism research, and cell biology, provide supportive evidence and hypothesis-generating data. The ability of animals to synchronize internal physiology, metabolism and reproductive function, with our changing external environment and habitat, are a necessary requirement for individual and species survival. The co-operative and sometimes competitive evolution of metabolism and reproduction provided adaptive survival mechanisms in ancestral environments that appear to be maladaptive in modern environments. An evolutionary model therefore provides a framework to enhance practitioner and patient understanding, improve compliance with lifestyle interventions, reduce morbidity, improve quality of life and will evolve and change over time.

Abstract

People of reproductive age are frequently affected with Polycystic Ovary Syndrome (PCOS), a common endocrine disorder with a range of clinical, hormonal, and metabolic features. The goal of this review paper is to give a thorough summary of the clinical presentation, diagnostic criteria, aetiology, epidemiology, and treatment options for PCOS. Between 5% and 20% of women in reproductive age worldwide are estimated to have PCOS. This syndrome is widely known for being complicated, involving both environmental factors and genetic predisposition. Common clinical symptoms include irregular menstruation, hyperandrogenism, and an ultrasound that reveals polycystic ovarian morphology. Although there are other sets of diagnostic criteria, including the National Institutes of Health standards and the Rotterdam criteria, a precise diagnosis is still necessary. Those with PCOS are more likely to develop metabolic problems such as obesity, dyslipidemia, and insulin resistance. An elevated risk of type 2 diabetes, cardiovascular disease, and infertility are among the long-term health consequences. The primary objectives of therapeutic interventions, which are tailored to the patient's presentation and goals and involve both lifestyle modifications and pharmacological therapies, are improvements in hormonal imbalances, metabolic abnormalities, and reproductive outcomes. This study compiles the most recent findings and clinical observations to improve healthcare professionals' comprehension of PCOS.

Keywords: Polycystic Ovary Syndrome (PCOS), hyperandrogenism, insulin resistance, lifestyle modifications, hormonal imbalance, infertility, metabolic syndrome.

INTRODUCTION

The complex endocrine condition known as polycystic ovarian syndrome (PCOS) has an impact on women's health all over the world. Since Stein and Leventhal first described it in 1935, a great deal of research has been done on its aetiology and clinical manifestations. PCOS symptoms include hyperandrogenism, irregular menstrual cycles, and polycystic ovaries on ultrasound imaging.

What do you mean by Polycystic ovary syndrome (PCOS)?

In patients with polycystic ovarian syndrome (PCOS), the ovaries produce an abnormally high amount of androgens, male sex hormones that are normally present in women in small amounts. A collection of microscopic cysts (fluid-filled sacs) that form in the ovaries is referred to as polycystic ovarian syndrome.

What factors lead to PCOS (polycystic ovarian syndrome)?

- It is unknown exactly what causes PCOS, however it often runs in families.
- The abnormal hormone levels in the body, including high insulin levels, are linked to it.
- An insulin-producing hormone controls blood sugar levels in the body.
- Many patients with PCOS produce larger amounts of insulin in an effort to overcome their body's resistance to it.
- The production and activation of hormones like testosterone increase as a result.

Pathophysiology:

The precise etiology of PCOS is still unknown, however a combination of genetic, environmental, and hormonal factors are considered to be involved in its development. Insulin resistance and hyperinsulinemia

are common findings in PCOS patients, and they can lead to compensatory hyperandrogenism and ovarian dysfunction. The relevance of inflammation and malfunctioning adipose tissue in the aetiology of PCOS has also been underscored by recent study.

Clinical Presentation: PCOS is characterized by a wide range of symptoms, which may differ from person to person.

1. Common clinical features include regular menstrual cycles or the absence of periods (oligo/anovulation).
2. Male-pattern baldness, acne, and hirsutism (excessive hair growth) are all associated with hyperandrogenism, which is defined by high levels of male hormones.
3. On ultrasonography, enlarged ovaries with multiple small follicles are diagnostic of polycystic ovaries.

Diagnosis

PCOS can be challenging to identify because of its variety of symptoms. Numerous criteria for diagnosis have been presented; the Rotterdam criteria is the most often used.

Two of the three qualities listed below have to be present, according to the Rotterdam criteria, for PCOS to be diagnosed:

1. Ultrasonography-detected polycystic ovaries,
2. Oligo/anovulation,
3. Clinical or biochemical signs of hyperandrogenism,

Excluding other disorders such as hyperprolactinemia and thyroid issues that mimic PCOS is crucial.

Management

PCOS is managed individually for each patient, taking into consideration their particular symptoms and concerns. To improve overall metabolic health and insulin sensitivity, lifestyle modifications like eating adjustments and frequent exercise are recommended. Pharmacological treatments for hyperandrogenism and irregular menstruation, including insulin sensitizers, anti-androgens, and oral contraceptives, can be effective.

Prospective Aspects:

Present research endeavors continue to explore novel therapeutic targets and decipher the complex pathophysiology of PCOS. With the use of phenotypic traits and genetic predisposition, personalised medicine improvements may result in more specific techniques of diagnosis and therapy. The long-term metabolic and

cardiovascular issues associated with PCOS are also being investigated and merit more research.

CONCLUSION

In conclusion, PCOS demands a comprehensive and multidisciplinary approach. Management strategies include lifestyle modifications, pharmacological interventions, and assisted reproductive technologies. Regular health monitoring is essential, considering the long-term implications for metabolic and cardiovascular health. Ongoing research on the genetic basis and emerging therapies offers hope for more personalized and effective treatments. This review underscores the need for continued collaboration between healthcare professionals, researchers, and individuals affected by PCOS to enhance our understanding and management of this prevalent endocrine disorder.

Polycystic ovary syndrome: a complex condition with psychological, reproductive and metabolic manifestations that impacts on health across the lifespan

H Teede^{1,2}, A Deeks¹ and L Moran*¹

Abstract

Polycystic ovary syndrome (PCOS) is of clinical and public health importance as it is very common, affecting up to one in five women of reproductive age. It has significant and diverse clinical implications including reproductive (infertility, hyperandrogenism, hirsutism), metabolic (insulin resistance, impaired glucose tolerance, type 2 diabetes mellitus, adverse cardiovascular risk profiles) and psychological features (increased anxiety, depression and worsened quality of life). Polycystic ovary syndrome is a heterogeneous condition and, as such, clinical and research agendas are broad and involve many disciplines. The phenotype varies widely depending on life stage, genotype, ethnicity and environmental factors including lifestyle and bodyweight. Importantly, PCOS has unique interactions with the ever increasing obesity prevalence worldwide as obesity-induced insulin resistance significantly exacerbates all the features of PCOS. Furthermore, it has clinical implications across the lifespan and is relevant to related family members with an increased risk for metabolic conditions reported in first-degree relatives. Therapy should focus on both the short and long-term reproductive, metabolic and psychological features. Given the aetiological role of insulin resistance and the impact of obesity on both hyperinsulinaemia and hyperandrogenism, multidisciplinary lifestyle improvement aimed at normalising insulin resistance, improving androgen status and aiding weight management is recognised as a crucial initial treatment strategy. Modest weight loss of 5% to 10% of initial body weight has been demonstrated to improve many of the features of PCOS. Management should focus on support, education, addressing psychological factors and strongly emphasising healthy lifestyle with targeted medical therapy as required. Monitoring and management of long-term metabolic complications is also an important part of routine clinical care. Comprehensive evidence-based guidelines are needed to aid early diagnosis, appropriate investigation, regular screening and treatment of this common condition. Whilst reproductive features of PCOS are well recognised and are covered here, this review focuses primarily on the less appreciated cardiometabolic and psychological features of PCOS.

Introduction

Polycystic ovary syndrome (PCOS) is a frustrating experience for women, often complex for managing clinicians and is a scientific challenge for researchers. As research in PCOS is rapidly advancing, it is vital that research evidence is translated to knowledge and action among women, healthcare professionals and policy makers. PCOS is the most common endocrine abnormality in

reproductive-age women. The prevalence of PCOS is traditionally estimated at 4% to 8% from studies performed in Greece, Spain and the USA [1-4]. The prevalence of PCOS has increased with the use of different diagnostic criteria and has recently been shown to be 18% ($17.8 \pm 2.8\%$) in the first community-based prevalence study based on current Rotterdam diagnostic criteria [5]. Importantly, 70% of women in this recent study were undiagnosed [5]. While the upper limit of prevalence for this study was imputed using estimates of polycystic ovaries (PCO) for women who had not had an ultrasound, non-imputed prevalences were calculated as $11.9 \pm 2.4\%$

[5]. PCOS has also been noted to affect 28% of unselected obese and 5% of lean women [5-8]. In 2006, based on US data and traditionally lower prevalence estimates the anticipated economic burden of PCOS in Australia was AU\$400 million (menstrual dysfunction 31%, infertility 12% and PCOS-associated diabetes 40% of total costs), representing a major health and economic burden [8]. With regards to fertility, the estimated cost per birth in overweight Australian women with PCOS is high [9]. Promisingly, lifestyle intervention comprising dietary, exercise and behavioural therapy improves fertility and reduces costs per birth significantly [9].

Aetiology: insulin resistance and hyperandrogenism

The exact pathophysiology of PCOS is complex and remains largely unclear. Although a detailed discussion is beyond the scope of this review, the underlying hormonal imbalance created by a combination of increased androgens and/or insulin underpin PCOS (Figure 1). Genetic and environmental contributors to hormonal disturbances combine with other factors, including obesity, ovarian dysfunction and hypothalamic pituitary abnormalities to contribute to the aetiology of PCOS [10,11]. However, greater understanding of pathophysiological contributors in PCOS have been hampered by a lack of ideal methods to assess either hyperandrogenism or insulin resistance. Hyperandrogenism is a well established contributor to PCOS aetiology, detected in around 60% to 80% of cases. Insulin resistance is a pathophysiological contributor in around 50% to 80% of women with PCOS [12], especially in those with more severe PCOS diagnosed on National Institutes of Health (NIH) criteria and in women who are overweight. Conversely, lean women

[13] and women with milder PCOS diagnosed on newer European Society for Human Reproduction (ESHRE)/American Society of Reproductive Medicine (ASRM) criteria [14] appear to have less severe hyperinsulinaemia and insulin resistance. Insulin resistance contributes to metabolic features but also to reproductive features [15] through augmenting androgen production and increasing free androgens by reducing sex hormone binding globulin (SHBG). In this setting of unclear aetiology and mechanisms of insulin resistance, further research is clearly needed.

Impact of obesity on polycystic ovary syndrome

Obesity and excess weight are major chronic diseases in Western world countries. Obesity increases hyperandrogenism, hirsutism, infertility and pregnancy complications both independently and by exacerbating PCOS [16,17]. In general populations, obesity and insulin resistance further increase type 2 diabetes (DM2) and cardiovascular disease (CVD). Likewise, in PCOS obesity worsens insulin resistance and exacerbates reproductive and metabolic features [16,17]. Furthermore, women with PCOS have increased risk factors for DM2 and CVD, increased impaired glucose tolerance (IGT), DM2 and potentially increased CVD [18]. As obesity rates rise, the public health significance of PCOS will increase [18]. Treatment of obesity through lifestyle intervention is a key treatment strategy in PCOS and improves insulin resistance, reproductive and metabolic features [19].

Diagnosis of PCOS

Until recently no universally accepted clinical definition existed for PCOS. Over the past three decades, research has highlighted that PCOS is a heterogeneous condition. Symptoms and signs related to PCOS have been evaluated and the initial NIH diagnostic criteria based on oligomenorrhoea/amenorrhoea and clinical or biochemical hyperandrogenism have been broadened in the 2003 Rotterdam or ESHRE/ASRM criteria to include PCO at ultrasound in the key diagnostic criteria [20]. A total of 25% of young women have PCO on ultrasound and the inclusion of PCO in diagnostic criteria has increased the prevalence of PCOS. Recent data indicates that the prevalence of PCOS may be doubled on use of the ESHRE/ASRM criteria with a prevalence of 12% (not imputing presence of polycystic ovaries) to 18% (imputing presence of polycystic ovaries) reported in a community sample [5]. In 2006 the Androgen Excess PCOS Society suggested further modification of the diagnostic criteria to exclude those without symptoms (PCO on ultrasound and oligomenorrhoea/amenorrhoea but no hyperandrogenism) (Table 1) [21]. It should be noted that PCOS is a diagnosis of exclusion and conditions including thyroid

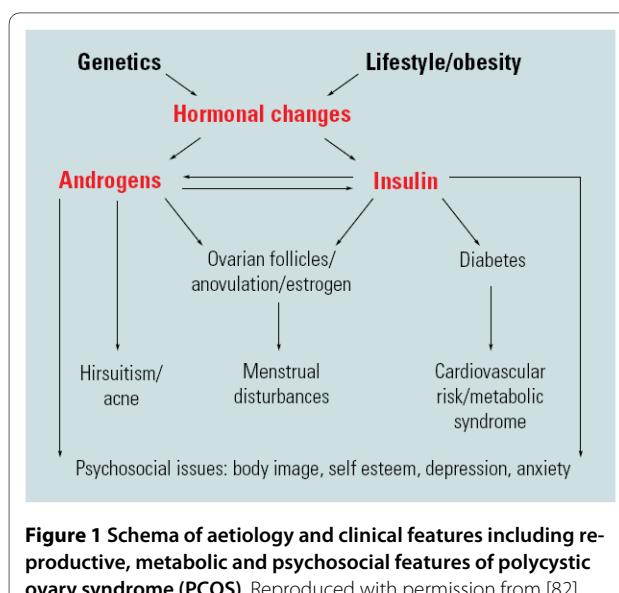

Figure 1 Schema of aetiology and clinical features including reproductive, metabolic and psychosocial features of polycystic ovary syndrome (PCOS). Reproduced with permission from [82].

Table 1: The different diagnostic criteria for polycystic ovary syndrome (PCOS)

Oligo-ovulation and clinical and/or biochemical signs of hyperandrogenism, and exclusion of other aetiologies*	Two out of three of: oligo-ovulation and/or anovulation, clinical and/or biochemical signs of hyperandrogenism, or polycystic ovaries, and exclusion of other aetiologies*	Hyperandrogenism (hirsutism and/or hyperandrogenaemia), ovarian dysfunction (oligoanovulation and/or polycystic ovaries), and exclusion of other androgen excess related disorders*

Table adapted from [14], with permission of Oxford University Press, Oxford, UK.

*Congenital adrenal hyperplasia, androgen-secreting tumours, Cushing's syndrome, 21-hydroxylase-deficient non-classic adrenal hyperplasia, androgenic/anabolic drug use or abuse, syndromes of severe insulin resistance, thyroid dysfunction, hyperprolactinaemia.

dysfunction and hyperprolactinaemia should be excluded biochemically, whilst more rare conditions should be excluded clinically (Cushing's syndrome, virilising tumours, and so on). However, cardiometabolic features and insulin resistance are not currently part of the PCOS diagnostic criteria. This is in part attributable to the lack of accurate methods to measure insulin resistance with measurement not currently recommended in clinical practice [22].

With the four key diagnostic features, (oligomenorrhoea/amenorrhoea, clinical or biochemical hyperandrogenism and PCO on ultrasound) there are many potential phenotypes (Table 1) [21]. This heterogeneity of the condition is further exacerbated by degree of obesity, insulin resistance, ethnicity and other factors [21]. Both the heterogeneity of PCOS and the lack of an understanding of its aetiology contribute to the evolving diagnostic criteria and ongoing controversy. Currently the ESHRE/ASRM or Rotterdam criteria are the agreed international diagnostic criteria for PCOS, although further research is needed.

Clinical features of PCOS

Women with PCOS may therefore present with a variety of serious clinical sequelae including psychological problems (reduced quality of life, poor self-esteem, depression, anxiety) [23,24], reproductive manifestations (hirsutism, infertility and pregnancy complications) [25], and metabolic implications (insulin resistance, metabolic syndrome, IGT, DM2 and potentially CVD) [14,26,27] (Figure 1 and Appendix 1). Given the heterogeneous nature of PCOS (Table 1) and the spectrum of clinical features, presentation can vary across the life cycle. PCOS is a chronic condition with psychological and reproductive manifestations usually beginning in adolescence then transitioning to include infertility and increasing metabolic complications over time. However, when combined with obesity, metabolic implications of PCOS such as IGT, DM2 and the metabolic syndrome can present in adolescence [28,29].

Reproductive features of PCOS

Ovarian dysfunction and infertility

Ovarian dysfunction usually manifests as oligomenorrhoea/amenorrhoea resulting from chronic oligo-ovulation/anovulation [30]. However, prolonged anovulation can lead to dysfunctional uterine bleeding which may mimic more regular menstrual cycles. The majority of PCOS patients have ovarian dysfunction, with 70% to 80% of women with PCOS presenting with oligomenorrhoea or amenorrhoea. Among those with oligomenorrhoea, 80% to 90% will be diagnosed with PCOS [30]. Among those with amenorrhoea, only 40% will be diagnosed with PCOS as hypothalamic dysfunction is a more common cause [31]. Oligomenorrhoea occurs usually in adolescence, with onset later in life often associated with weight gain. Menstrual irregularity is then often masked by the oral contraceptive pill (OCP), until cessation, when the underlying irregular cycles recur. Menorrhagia can occur with unopposed oestrogen and endometrial hyperplasia, further exacerbated by elevated oestrogen levels in obesity. Whilst inadequate research exists, it is generally recommended that greater than four cycles per year may protect the endometrium. Women with regular menstrual cycles can also now be diagnosed with PCOS based on newer diagnostic criteria (Table 1) [21].

PCOS is the most common cause of anovulatory infertility. It accounts for 90% to 95% of women attending infertility clinics with anovulation. However 60% of women with PCOS are fertile (defined as the ability to conceive within 12 months), although time to conceive is often increased [30]. In those with PCOS and infertility, 90% are overweight. Obesity independently exacerbates infertility, reduces efficacy of infertility treatment and induces a greater risk of miscarriage [30]. There is currently an active debate about the appropriate limit for body mass index for assisted reproduction therapies, given the reduced success rates and the demonstrated risks of pregnancy in overweight women [32]. Ideally, weight should be optimised prior to pregnancy. Age-

related infertility also exacerbates infertility and timely planning of families may warrant discussion.

Hyperandrogenism

The clinical and/or biochemical signs of androgen excess in PCOS result from increased synthesis and release of ovarian androgens. Elevated luteinising hormone and insulin synergistically increase androgen production. Insulin resistance leads to hyperinsulinaemia, reduces SHBG and raises free circulating testosterone and together, hyperandrogenism and hyperinsulinaemia impairs ovarian follicle development. Clinical hyperandrogenism primarily includes hirsutism, acne and male pattern alopecia [21]. Hirsutism is defined in females as male type terminal hair growth and distribution [33]. PCOS is a common cause of hirsutism occurring in approximately 60% of cases, however this varies with race and degree of obesity [21]. Hirsutism should be assessed with a standardised scoring system (Ferriman-Gallwey score). Acne affects one third of cases and is not particularly specific for PCOS [33]. Male pattern hair loss (androgenic alopecia) is less frequently seen in PCOS cases, as it generally requires a familial predisposition. Other features of hyperandrogenism include virilisation, which, especially if presenting with clitoromegaly and rapid onset, requires exclusion of other causes including adrenal or ovarian androgen-secreting tumours.

Biochemical hyperandrogenism is present in most patients with PCOS. Measurement of biochemical androgens in PCOS is limited by poor accuracy and reproducibility of assays, which are designed for significantly higher male androgen levels. Free androgen index measurements are generally recommended, derived in the lab from SHBG and total testosterone measurements [33]. Dehydroepiandrosterone sulfate (DHEAS) and androstenedione are not routinely recommended in PCOS [21].

Metabolic features of PCOS

Dyslipidaemia

Dyslipidaemia is common in PCOS compared to weight matched controls [34-37], with higher triglycerides and lower high density lipoprotein cholesterol [35]. The dyslipidaemia occurs independent of body mass index (BMI) [35,38], however there is a synergistic deleterious effect of obesity and insulin resistance in PCOS analogous to that seen in DM2. The causes of dyslipidaemia in PCOS are again multifactorial. Insulin resistance appears to have a pivotal role mediated in part by stimulation of lipolysis and altered expression of lipoprotein lipase and hepatic lipase [35].

Insulin resistance and abnormal glucose metabolism

Insulin resistance occurs in around 50% to 80% of women with PCOS [12], primarily in the more severe NIH diag-

nosed PCOS and in those who are overweight. Lean women [13] and milder Rotterdam diagnosed PCOS [14] appear to have less severe insulin resistance. A full discussion of the complex mechanisms involved in insulin resistance, hyperinsulinaemia, DM2 and CVD is beyond the scope of this review. Mechanisms involved in insulin resistance are likely to be complex with genetic and environmental contributors. Specific abnormalities of insulin metabolism identified in PCOS include reductions in secretion [39,40], reduced hepatic extraction [40], impaired suppression of hepatic gluconeogenesis [41] and abnormalities in insulin receptor signalling [42]. Interestingly, there is a paradoxical expression of insulin resistance in PCOS whereby insulin-stimulated androgen production persists while its role in glucose metabolism is impaired [42]. Therefore, insulin resistance in PCOS results in hyperinsulinaemia with its associated diverse and complex effects on regulating lipid metabolism, protein synthesis and modulation of androgen production. The cause of insulin resistance is likewise complex and multifactorial with genetic and environmental contributors [15]. Lean women with PCOS often but not always [13] have abnormalities of insulin secretion and action compared to weight-matched control subjects [41]. Where a woman with PCOS is overweight, she may also demonstrate extrinsic insulin resistance associated with adiposity, which is potentially mechanistically distinct from the insulin resistance present in lean women with PCOS. In women with insulin resistance and PCOS, only a subgroup develop coexistent pancreatic insufficiency with β cell failure and go on to DM2. In this setting, insulin output cannot overcome resistance and hyperglycaemia develops. Women with PCOS are at increased risk of developing IGT and DM2 with prevalence rates of 31.3% and 7.5%, respectively, compared to 14% for IGT and 0% for DM2 in age-matched and weight-matched non-PCOS control women [27].

Women with PCOS also develop abnormal glucose metabolism at a younger age and may demonstrate a more rapid conversion from IGT to DM2 [43]. The rate of conversion from IGT to DM2 in a general Australian population was estimated in the large cohort Australian Diabetes, Obesity and Lifestyle (AusDiab) study at 2.9% per year for young females [44]. Another Australian study has reported a substantially higher conversion rate (8.7% per year over 6.2 years) in women with PCOS [45], however this has not been uniformly reported [46]. Women with PCOS also have higher gestational diabetes (GDM) risk, with a recent meta-analysis reporting an odds ratio (OR) of 2.94 [25]. The risk of GDM occurs both independent of and is exacerbated by obesity [27,47]. Whilst there are few adequately powered studies assessing natural history of IGT, DM2 and CVD in PCOS and there is a need for further research, the International Diabetes Federa-

tion has identified PCOS as a significant non-modifiable risk factor associated with DM2 [48].

It is increasingly clear that IGT is also a clinically relevant state where early identification and intervention improve long-term outcomes [49]. IGT has been found to increase the risk of CVD, mortality and progression to DM2 in general populations [44]. Recent population-based data noted a mortality rate of 5.5% over 5 years for those with IGT versus 1.9% with normal glucose tolerance [44]. Furthermore, lifestyle intervention, metformin and glitazones can prevent IGT progression to DM2 [49], strengthening the argument for early detection of IGT, including in high-risk PCOS women.

There are currently no generic guidelines for IGT screening, only for DM2 based on fasting glucose or more recently on HbA1c as a first line. However, impaired fasting glucose is a poor predictor of IGT in women in general [50] and in PCOS [27,43]. Hence the ESHRE/ASRM-sponsored PCOS Consensus Workshop Group recommend an oral glucose tolerance test in all overweight women with PCOS [51]. Furthermore, emerging data shows increased risk of metabolic complications in first-degree family members of women with PCOS [52-56]. Screening for metabolic conditions may be also warranted in relatives of women with PCOS, although this requires further research.

Cardiovascular disease risk

Alongside insulin resistance, metabolic syndrome, IGT and DM2, women with PCOS also have increased novel cardiovascular risk factors (inflammation, oxidative stress and impaired fibrinolysis) [14]. Also, increased early clinical and subclinical markers of atherosclerosis seen in PCOS (endothelial dysfunction, impaired pulse wave velocity, increased carotid intima media wall thickness, presence of carotid plaque and increased coronary artery calcification) [34,57] are further exacerbated by obesity [27,58,59]. Given that large longitudinal cohort studies have reported up to 65% of CVD deaths occur in subjects with impaired glucose metabolism [60] and that IGT and DM2 are increased in PCOS, it would be expected that women with PCOS would have increased CVD risk. There is currently a lack of long-term studies in PCOS to appropriately address CVD risk. Some studies support an increased risk of CVD in PCOS [18], but these findings are not universal [61] and further research is needed. A recent study in postmenopausal women with premenopausal features of PCOS noted higher prevalence of angiographic coronary artery disease and that PCOS was associated with worsened cardiovascular event-free survival [18].

Psychological features of PCOS

Most research has focused on the biological and physiological aspects of the syndrome. The challenges to femi-

nine identity and body image due to obesity, acne and excess hair, as well infertility and long-term health-related concerns compromise quality of life and adversely impact on mood and psychological well-being [23,62]. Limited studies to date have reported that women who have PCOS are more prone to depression, anxiety, low self-esteem, negative body image, and psychosexual dysfunction [63,64]. The other critical aspect of psychosocial impact in PCOS is the negative impact of mood disturbance, poor self-esteem and reduced psychological well-being on motivation and on ability to implement and sustain successful lifestyle changes that are critical in this condition [19]. These issues all need to be explored and addressed as part of PCOS assessment and management.

Investigations and assessment in PCOS

There is no single diagnostic test for PCOS. Key investigations include prolactin and thyroid stimulating hormone to exclude other disorders and testosterone, SHBG and free androgen index to assess androgen status [33]. Other investigations include a pelvic ultrasound for ovarian morphology and endometrial thickness. An oral glucose tolerance test (rather than fasting glucose) and lipid profiles are appropriate in all women at diagnosis and 1 to 2 yearly after this, where women are overweight or have an increased risk of DM2 (for example, family history of DM2 in first-degree relatives, increased age or high-risk ethnic group). As noted, insulin levels should not be measured in clinical practice because of assay variability and inaccuracy. Metabolic syndrome and abnormal glucose metabolism best reflect insulin resistance in this population.

Treatment of PCOS

Targeted approach to therapy

Treatment options need to be tailored to the clinical presentation. Education on short-term and long-term sequelae of PCOS from a reliable independent source is important in allaying anxiety and minimising the impact of illness in chronic disease (Table 2). As a prelude to treatment psychological features need to be acknowledged, discussed and counselling considered [65], to enable lifestyle change which is unlikely to be successful without first addressing education and psychosocial issues (Figure 2 and Appendix 2).

Weight loss, exercise and lifestyle interventions

Lifestyle change is first line treatment in an evidence-based approach in the management of the majority of PCOS women who are overweight [19]. Furthermore, prevention of excess weight gain should be emphasised in all women with PCOS of both normal or increased body weight. As little as 5% to 10% weight loss has significant clinical benefits improving psychological outcomes [66], reproductive features (menstrual cyclicity, ovulation and

fertility) [9,67] and metabolic features (insulin resistance and risk factors for CVD and DM2). Evidence shows that lifestyle change with small achievable goals results in clinical benefits even when women remain in the overweight or obese range, [9,68,69]. Standard dietary management of obesity and related comorbidities [70] is a nutritionally adequate, low fat (approximately 30% of energy, saturated fat approximately 10%), moderate protein (approximately 15%) and high carbohydrate intake (approximately 55%), with increased fibre-rich wholegrain breads, cereals, fruits and vegetables and moderate regular exercise. A moderate energy reduction diet (500 to 1,000 kcal/day reduction) reduces body weight by 7% to 10% over a period of 6 to 12 months. Simple and practical tips that can be covered in minutes in medical consultation include targeting fruit juice, soft drinks, portion sizes and high-fat foods. Incorporating simple moderate physical

activity including structured exercise (at least 30 min/day) and incidental exercise increases weight loss and improves clinical outcomes in PCOS, compared to diet alone [71]. Exercise alone also improves clinical outcomes. As in the general population, goals for exercise must focus on overall health benefits not weight loss *per se*.

Fad diets are not encouraged as short-term weight loss, if achieved, is rarely sustainable [72]. The advantages of specific dietary approaches over that of caloric restriction alone are still unclear and more research is needed. Proposed specific dietary approaches in PCOS include high protein, low carbohydrate and low glycaemic index/glycaemic load diets. A number of small studies assessing specific dietary approaches in PCOS show similar results for diets moderately increased in dietary protein or carbohydrate [73-75] with one study reporting greater weight loss where a high protein supplement was added to a standard energy reduced diet [76]. Two small studies have assessed very low carbohydrate diets in PCOS, and one study reported on an audit of reduced glycaemic load diets in clinical practice. While reductions in weight, BMI, waist circumference, fasting insulin or testosterone were reported, these studies lacked a control group [77-79]. The current evidence suggests that a range of dietary strategies, as long as they are safe, nutritionally adequate and sustainable in the long term, will similarly improve weight, and reproductive and metabolic features in PCOS [19].

Pharmacological therapy in PCOS

There is currently no ideal medical PCOS therapy that fully reverses underlying hormonal disturbances and treats all clinical features. The OCP does improve hyperandrogenism and insulin sensitizers (primarily Metformin) reduce insulin resistance in PCOS [80]. Generally, medical therapy is targeted to symptoms and should not be used as an alternative to lifestyle therapy in PCOS (Figure 2). Simple medical therapy is summarised in Appendix 2. The OCP has long been used in PCOS to induce regular cycles, protect the endometrium and treat hyperandrogenism. Mechanisms of action include a significant first pass hepatic effect, increasing production of hepatic proteins including sex hormone binding globulin. This reduces free circulating androgen levels, even with low dose OCPs. This important mechanism of antiandrogenic action does not occur with progestin alone or non-oral oestrogen containing contraceptive preparations. The OCP also reduces ovarian androgen production. There has been concerning data that the OCP can increase insulin resistance and worsen glucose tolerance. Studies are inadequate and data conflicting with more research needed, however consideration should be given to cardiometabolic effects of medical therapy and low

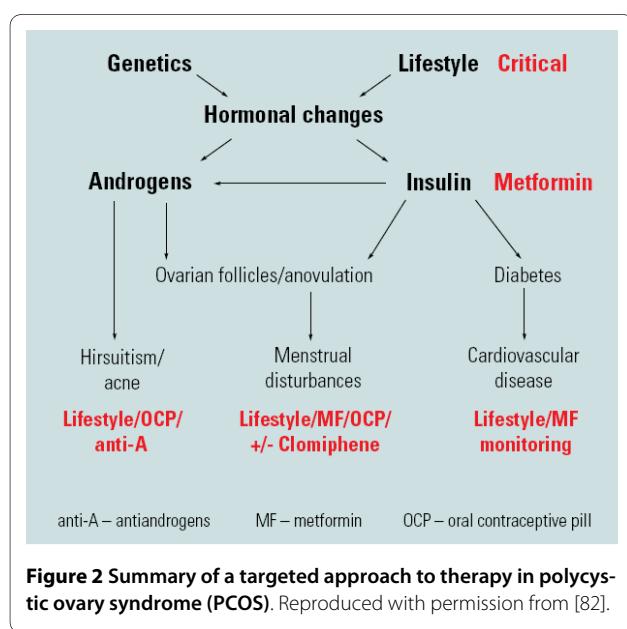

Figure 2 Summary of a targeted approach to therapy in polycystic ovary syndrome (PCOS). Reproduced with permission from [82].

dose OCP preparations may be a preferable alternative, with similar efficacy and reduced cardiometabolic effects [80].

Metformin has had an increasing role in PCOS management [22,81], improving clinical features (ovulation, cycle regulation, and potentially hirsutism) with positive cardiometabolic effects [22,81]. It does not appear to induce weight loss, although based on studies in DM2 it may assist in preventing future weight gain. Based on International Diabetes Federation recommendations [48,80], metformin has a role in prevention of diabetes where lifestyle therapy is inadequate. Given the increased insulin resistance and high risk of DM2, this includes PCOS especially if other risk factors including excess weight, family history of DM2, metabolic syndrome or prediabetes exist [22]. In infertility, the role of metformin remains controversial. It does reduce hyperstimulation in those on other fertility therapies, however more research here is important. When using metformin it is better tolerated if started at 500 mg of slow release daily and increased over weeks to months to reach 2 g daily. Lactic acidosis is a rare side effect in those with other significant illnesses including renal impairment [22]. It is important to note that neither metformin nor the OCP are approved by most regulatory authorities specifically for PCOS. The OCP is indicated for contraception and metformin for the treatment of diabetes. However, both treatments are recommended by international and national endocrine societies and are evidence based [20]. A detailed discussion of infertility therapy is beyond the scope of this review, however clomiphene is generally used as initial medical therapy.

Conclusions

PCOS is a common complex condition in women associated with psychological, reproductive and metabolic features. It is a chronic disease with manifestations across the lifespan and represents a major health and economic burden. Both hyperandrogenism and insulin resistance contribute to pathophysiology of PCOS. Insulin resistance occurs in the majority of women with PCOS, especially those who are overweight, and these women have a high risk of metabolic syndrome, prediabetes and DM2. Management should focus on support, education, addressing psychological factors and strongly emphasising healthy lifestyle with targeted medical therapy as required. Treatment for the large majority is lifestyle focused and an aggressive lifestyle-based multidisciplinary approach is optimal in most cases to manage the features of PCOS and prevent long-term complications. Small achievable goals of 5% loss of body weight result in significant clinical improvement even if women remain clinically in the unhealthy overweight or obese range. Addressing hyperandrogenism is clinically important and

monitoring for and managing longer-term metabolic complications, including dyslipidaemia, IGT, DM2, and cardiovascular risk factors, is crucial. Consideration should be given to screening high-risk family members for metabolic abnormalities also. Overall, further research is needed in this complex condition. In the interim, comprehensive evidence-based guidelines are needed to guide consumers and clinicians in optimal PCOS management.

Appendix 1

Reproductive, metabolic and psychosocial features of polycystic ovary syndrome (PCOS)

Clinical features of PCOS

(1) Reproductive features: hyperandrogenism, hirsutism, ovulatory and menstrual dysfunction, infertility, complications in pregnancy, miscarriage, pregnancy-induced diabetes (gestational diabetes), pregnancy-induced hypertensive disorders and neonatal complications and increased endometrial hyperplasia.

(2) Metabolic features: insulin resistance, metabolic syndrome, dyslipidaemia, high rates of premature impaired glucose tolerance, type 2 diabetes and increased cardiovascular risk factors.

(3) Psychological features: anxiety, depression, poor self-esteem, reduced quality of life, negative body image.

Appendix 2

Summary of treatment options in polycystic ovary syndrome (PCOS)

Oligomenorrhoea/amenorrhoea

- Lifestyle change (5% to 10% weight loss and structured exercise).
- Oral contraceptive pill (OCP; low oestrogen doses, for example 20 µg may be preferable).
- Cyclic progestins (for example, 10 mg medroxyprogesterone acetate for 14 days every 2 to 3 months).
- Metformin (improves ovulation and menstrual cyclicity).

Hirsutism treatment recommendations

- Cosmetic therapy.
- Laser treatment.
- Flornithine cream can be added and may induce a more rapid response.

Pharmacological therapy

- Medical therapy if patient concerned about hirsutism and cosmetic therapy ineffective, inaccessible or unaffordable.
- Primary therapy is the OCP (monitor glucose tolerance in those at risk of diabetes).
- Antiandrogen monotherapy should not be used without adequate contraception.
- Trial therapies for ≥ 6 months before changing dose or medication.

- Combination therapy: if ≥ 6 months of OCP is ineffective, add antiandrogen to OCP (daily spironolactone 50 mg twice a day or cyproterone acetate 25 mg/day for days 1 to 10 of the active OCP tablets).

Infertility

- Obesity independently exacerbates infertility and reduces effectiveness of interventions. Maternal and foetal pregnancy risks are greater and long-term metabolic outcomes in the child are related to maternal weight at conception. Consistent with international guidelines, women who are overweight prior to conception should be advised on folate, smoking cessation, weight loss and optimal exercise, prior to additional interventions.
- Given age-related infertility, advise women to optimise family planning.
- Infertility therapies may include clomiphene, gonadotrophins and *in vitro* fertilisation.

Metabolic syndrome, prediabetes, diabetes and cardiovascular disease risk

Obesity independently causes metabolic complications; lifestyle/exercise is critical:

- Lifestyle change with a 5% weight loss reduces diabetes risk by approximately 50% to 60% in high-risk groups [49].
- Metformin* reduces the risk of diabetes by approximately 50% in high-risk groups [49].

*Metformin and the OCP are not currently approved for use to manage PCOS by many regulatory bodies. The OCP is primarily indicated for contraception and metformin for diabetes. However, their use is recommended by international and national specialist societies and is evidence based [22].

Competing interests

The authors declare that they have no competing interests.

Authors' contributions

HT, AD and LM all made substantial contributions to conception and design of the paper, were involved in drafting the manuscript and revising it critically for important intellectual content and have given final approval of the version to be published.

ABSTRACT

Polycystic ovary syndrome (PCOS) is a common condition in women at reproductive age associated with reproductive and metabolic dysfunction. Proposed diagnosed criteria for PCOS include two out of three features: androgen excess, menstrual irregularity, and polycystic ovary appearance on ultrasound (PCO), after other causes of hyperandrogenism and dysovulation are excluded. Based on these diagnostic criteria, the most common phenotypes are the "classic PCOS" – hyperandrogenism and oligomenorrhea, with or without PCO; the "ovulatory phenotype" – hyperandrogenism and PCO in ovulatory women; and the "non-hyperandrogenic phenotype", in which there is oligomenorrhea and PCO, without overt hyperandrogenism. The presence of obesity may exacerbate the metabolic and reproductive disorders associated with the syndrome. In addition, PCOS women present higher risk for type 2 diabetes and higher prevalence of cardiovascular risk factors that seems to be associated with the classic phenotype. The main interventions to minimize cardiovascular and metabolic risks in PCOS are lifestyle changes, pharmacological therapy, and bariatric surgery. Treatment with metformin has been shown to improve insulin sensitivity, lowering blood glucose and androgen levels. These effects are more potent when combined with lifestyle interventions. In conclusion, besides reproductive abnormalities, PCOS has been associated to metabolic comorbidities, most of them linked to obesity. Confounders, such as the lack of standard diagnostic criteria, heterogeneity of the clinical presentation, and presence of obesity, make management of PCOS difficult. Therefore, the approach to metabolic abnormalities should be tailored to the risks and treatment goals of each individual woman. Arq Bras Endocrinol Metab. 2014;58(2):182-7

PCOS; obesity; insulin resistance; metformin

RESUMO

A síndrome dos ovários policísticos (PCOS) é um distúrbio frequente em mulheres em idade reprodutiva, associado com disfunção reprodutiva e metabólica. Os critérios diagnósticos atuais para PCOS incluem pelo menos dois dos três seguintes: hiperandrogenismo, irregularidade menstrual e aparência policística dos ovários à ultrassonografia (PCO), após exclusão de outras causas de hiperandrogenismo e anovulação. Com base nesses critérios diagnósticos, os fenótipos mais comuns são "PCOS clássico" – hiperandrogenismo e oligomenorreia, com ou sem PCO; o "fenótipo ovulatório" – hiperandrogenismo e PCO em mulheres ovulatórias; e o "fenótipo não hiperandrogênico" – no qual ocorrem oligomenorreia e PCO sem hiperandrogenismo evidente. A presença de obesidade pode exacerbar os distúrbios metabólicos e reprodutivos associados com a síndrome. Além disso, mulheres com PCOS apresentam maior risco para diabetes tipo 2 e maior prevalência de fatores de risco cardiovascular, que parecem estar associados com o fenótipo clássico. As principais intervenções para minimizar riscos metabólicos e cardiológicos em PCOS são mudanças de estilo de vida, tratamento farmacológico e cirurgia bariátrica. O tratamento com metformina melhora a sensibilidade à insulina, reduz a glicemia e os níveis de androgénios. Esses efeitos são mais evidentes quando a metformina é associada às mudanças de estilo de vida. Em conclusão, além das anormalidades reprodutivas, a PCOS tem sido associada com comorbidades metabólicas ligadas à obesidade. Fatores confundidores, como a falta de critérios diagnósticos padronizados, heterogeneidade da apresentação clínica e presença de obesidade, tornam difícil o manejo clínico de PCOS. Assim, a abordagem das anormalidades metabólicas deve ser individualizada para os riscos e objetivos terapêuticos de cada mulher. Arq Bras Endocrinol Metab. 2014;58(2):182-7

INTRODUCTION

Polycystic ovary syndrome (PCOS) is the most common endocrine disease affecting women of reproductive age. The prevalence of PCOS varies according to the diagnostic criteria used, with estimates ranging from 9% in women of reproductive age, according to NIH criteria, up to 18%, with the Rotterdam criteria (1-3).

PCOS is a multifactorial disease, and the individual susceptibility is probably determined by multiple genetic and environmental risk factors. It is primarily characterized by ovulatory dysfunction and hyperandrogenism (1,2), but the clinical presentation is heterogeneous and patients may present some of various signs and symptoms (Table 1). This heterogeneity seems to be modulated by multiple factors, such as prenatal androgen exposure, nutritional status in the uterus, genetic factors, as well as ethnicity, insulin resistance of puberty and/or exaggerated adrenarche and changes in body weight (4-6). Environmental factors, such as obesity, appear to exacerbate the underlying genetic predisposition. Concerning ethnicity, the presence of hirsutism is less frequent in Asian patients (around 10%), compared to Caucasian ones (70%) (1,6).

Hirsutism is defined as a score of 8 or more on the modified Ferriman-Gallwey index (7). Oligo/amenorrheic cycles are defined as 8 or less cycles per year and biochemical androgen determinations should be performed in the follicular phase in patients with preserved menstrual cycles.

Table 1. Clinical presentation of PCOS

Hirsutism, acne, alopecia
Irregular menstrual cycles, oligomenorrhea, amenorrhea
Ovulatory dysfunction and infertility
Increased risk for T2 diabetes, dyslipidemia, hypertension

DIAGNOSTIC CRITERIA

Proposed diagnosed criteria for PCOS include the NIH Consensus (8), defined, in 1990, as the presence of clinical and/or biochemical hyperandrogenism and oligomenorrhea/anovulation (Table 2). Later, in 2003, the Rotterdam Consensus (9) introduced the polycystic ovary appearance (PCO) on ultrasound as a new criterion to be added to the two previous criteria of the NIH, and the diagnosis requires two out of these three criteria. In turn, the Androgen Excess and PCOS Society (10) considered that androgen excess is a central event in the pathogenesis and development of PCOS,

and established that this criterion should be present and accompanied by one of the others: oligomenorrhea and/or PCO (Table 2). In all cases, exclusion of other androgen excess disorders, such as non-classical congenital adrenal hyperplasia (NC-CAH), Cushing's syndrome, androgen-secreting tumors, hyperprolactinemia, thyroid diseases, drug-induced androgen excess should be excluded, as well as other causes of oligomenorrhea or anovulation.

Table 2. Diagnostic criteria for PCOS

NIH Consensus 1990 (all required)	Rotterdam Consensus 2003 (two out of three required)	AEPCOS definition 2006 (androgen excess and one other criterion)
Clinical and/or biochemical hyperandrogenism	Clinical and/or biochemical hyperandrogenism	Clinical and/or biochemical hyperandrogenism
Oligo/amenorrhea, anovulation	Oligo/amenorrhea, anovulation	Oligo/amenorrhea, anovulation
	Polycystic ovaries appearance on ultrasound	Polycystic ovaries appearance on ultrasound

Exclusion of other androgen excess disorders: NC-CAH, Cushing's syndrome, androgen secreting tumors, hyperprolactinemia, thyroid diseases, drug-induced androgen excess. Other causes for anovulation should also been excluded.

In consequence, new phenotypes have arisen in addition to the classic phenotype, in which patients present hyperandrogenism and oligomenorrhea with or without PCO on ultrasound. These new phenotypes are the "ovulatory phenotype", which means hyperandrogenism and PCO in an ovulatory woman, and the "non-hyperandrogenic phenotype", in which there is oligomenorrhea and PCO, without overt hyperandrogenism.

PCO has been defined as the presence of 12 or more follicles of 2-9 mm or ovarian volume greater than 10 cm³ (9). However, with the new equipment, it is possible to visualize and count small follicles of less than 2 mm nowadays (11). Therefore, the consequence of the improved ovarian imaging is the revaluation of the current follicle number threshold, and the probable increase in the number of follicles to more than 19-26 follicles per ovary and per age classes to better define PCOS (11,12). Anti-Müllerian Hormone (AMH) levels are correlated with follicle counts and its measurement has been useful for screening and prognosis of reproductive issues. The determination of an AMH cutoff value is still lacking, but may become an additional tool to define PCO and PCOS phenotypes in the near future (11-13).

In turn, morphological ovarian changes are not exclusive of PCOS, and the presence of PCO in non-hirsute women with normal cycles is not negligible, varying from 2.5 to 33% in different studies (10,14). In addition, while the inclusion of a non-hyperandrogenic phenotype of the diagnosis of PCOS is still controversial, some authors consider the presence of PCO as being itself a sign of hyperandrogenism.

Recently, an Expert Panel from a NIH Evidence-Based Methodology Workshop on PCOS reinforced the use of the wider Rotterdam Criteria to diagnose the Syndrome. Therefore, the prevalence of PCOS is now greater than before when using the NIH criteria (15). Classic PCOS is the most common phenotype, with a prevalence of around 70%, with the ovulatory and the non-androgenic phenotypes sharing the other 30% of prevalence (1,3,13).

Clinical characterization also changes throughout the lifespan, especially during the post-menarche years and in the menopause transition.

DEFINITION AND PREVALENCE OF PCOS IN ADOLESCENT GIRLS

PCOS is a persistent challenge to the clinician, as the phenotype of the syndrome can vary widely. This is still more evident during the post-pubertal period, as signs and symptoms of PCOS overlap with normal puberty. There is a relatively high rate of menstrual irregularity and anovulatory cycles in this period, as well as some difficulties in interpreting clinical and biochemical evidence of hyperandrogenism: acne is a very common complaint during adolescence, alopecia is a rare phenomenon in girls, and hirsutism is sometimes borderline and aggravates slowly.

Uncertainty also regards the significance of polycystic ovarian morphology on ultrasound: microcysts are often seen even before menarche. In a previous study with normal girls from 1 to 13 years old, we have shown the presence of paucicystic ovaries on ultrasound (up to five follicles measuring less than 10 ml) in 7% of girls before puberty and in 18% of girls with telarche. The prevalence of multicystic ovaries (more than six follicles measuring less than 10 mL) was found in 9% of girls 12 and 13 years with initial puberty (16). In contrast, ovary volume greater than 10 mL seems to be a better marker of PCOS in adolescent girls presenting hyperandrogenism and oligo/amenorrhea for at least 2 years post-menarche (17,18).

Because of these uncertainties, and the fact that the majority of ultrasound examinations in adolescent girls is abdominal and not transvaginal, the diagnosis of PCOS in adolescents needs all three Rotterdam criteria, and not only two (13). Therefore, for the diagnosis of PCOS in adolescent girls, one should consider: 1) oligo/amenorrhea at least 2 years post-menarche or primary amenorrhea at age 16 years; 2) PCO morphology including increased ovarian volume ($> 10 \text{ cm}^3$); 3) biochemical hyperandrogenemia, and not only clinical hyperandrogenism. However, even if the diagnosis cannot be confirmed and needs to be postponed, individual manifestations (hirsutism, irregular menses) should be treated.

PCOS IN MENOPAUSAL TRANSITION AND POST-MENOPAUSE: ARE THERE SPECIFIC FEATURES?

In menopausal transition, there may be an amelioration of clinical features. In fact, there is a trend towards more regular cycles and improvement on hirsutism with aging (19). This is in part due to the well-known decrease in androgen secretion from the third to the fifth decade of life that occurs in normal women (20), and has been also reported in PCOS (13,19,21). In addition, ovarian volume decreases along with pre-menopause and menopause transition, as previously reported (22). Thus, alterations in ovarian volume and morphology may be less evident in PCOS during menopausal transition, and PCO criteria are not useful after menopause.

In fact, no specific clinical presentation during menopause has been established, and the diagnosis of PCOS is, in general, confirmed before this period, based on the history of oligomenorrhea and hyperandrogenism. Additionally, clinical or biochemical hyperandrogenism appearing in previously normal peri- or post-menopausal women should be carefully investigated in order to screen them for androgen-secreting tumors.

OBESITY, INSULIN RESISTANCE AND METABOLIC COMORBIDITIES

Obesity is a prevalent characteristic of PCOS (9,23), ranging from 12.5% (24) to 100% (25), with a pooled estimated prevalence of 49% (26), as shown by a recent meta-analysis (27). The presence of obesity may exacerbate the metabolic and reproductive disorders

associated with the syndrome (28), including insulin resistance, dyslipidemia, and metabolic syndrome (23,29-31). A meta-analysis (32) has shown that women with PCOS have higher levels of triglycerides (TG), LDL-cholesterol and total cholesterol (TC), and lower HDL-cholesterol levels compared with control women, regardless of body mass index (BMI). In addition, PCOS women present higher risk for type 2 diabetes (13,14). PCOS is also associated with a clustering of cardiovascular risk factors (10,13,29,33,34). However, there is no definitive evidence for increased cardiovascular events, nor data showing that PCOS alone leads to increased cardiovascular risk independent of associated risk factors. In fact, more rigorous cohort studies of long-term cardiovascular outcomes and clinical trials of risk factor modification are required for women with PCOS.

In addition, evidence suggests clinical phenotypes are related with different metabolic risks (Table 3). In this sense, insulin resistance seems to be a specific feature of the classic phenotype and, to a lesser extent, of the ovulatory phenotype (29,35,36). Non-hyperandrogenic phenotype behave as a separate group that is metabolically similar to non-PCOS women (15,32).

Table 3. Clinical features of different phenotypes

Classic PCOS	Ovulatory PCOS	PCOS without hyperandrogenism
Hyperandrogenism and anovulation with or without PCO	Hyperandrogenism and PCO	Anovulation and PCO
More severe menstrual disturbances and hyperandrogenism	Lesser degrees of hyperandrogenism	Minor menstrual irregularity
Higher prevalence of total and abdominal obesity and metabolic syndrome	Lower prevalence of metabolic syndrome and milder forms of dyslipidemia	Metabolic profile often similar to normal women
Higher prevalence of T2DM and cardiovascular risk factors		

MANAGEMENT OF METABOLIC DISTURBANCES

Insulin resistance (and compensatory hyperinsulinemia) is an important factor in maintaining hyperandrogenemia by acting directly on theca cells inducing excess androgen production. Insulin also acts as a co-gonadotropin, increasing the effect of LH on ovarian androgen secretion. In consequence, both insulin and androgens act on the liver inhibiting SHBG secretion,

leading to increased free and bioactive androgen circulating levels and making clinical hyperandrogenism worse. In addition, insulin resistance plays a central role on the pathophysiology of metabolic syndrome and on the cardiovascular risk in PCOS women.

However, insulin resistance is a common, but not universal feature of PCOS, and treatment should be directed to the consequences rather than to insulin resistance *per se* (37). These consequences are metabolic syndrome; clinical features shown to improve with insulin-sensitizing drugs, such as acanthosis nigricans; total and abdominal adiposity, as well as impaired fasting glucose (IFG, fasting glucose equal or higher than 100 mg/dL); impaired glucose tolerance (IGT, 2 h post-glucose equal or higher than 140 mg/dL); and type 2 diabetes (T2DM) (37,38).

The main interventions to minimize cardiovascular and metabolic risks in PCOS are lifestyle changes, pharmacological therapy, and bariatric surgery (Table 4). Lifestyle modification is the first form of therapy combining behavioral (reduction of psychosocial stressors), dietary, and exercise management. Frequently, however, it will be necessary to add an insulin-sensitizing drug (ISD) to the treatment. Metformin and thiazolidinediones (pioglitazone) are the main available ISD. However, due to the eventual weight gain and cancer risks of thiazolidinediones, the prescription of these drugs has been limited to diabetic patients and will not be discussed here.

Table 4. Treatment of metabolic comorbidities in PCOS

Non pharmacological interventions
Physical activity
Diet and lifestyle changes
Insulin sensitizing drugs
Metformin
Specific treatment for diabetes, hypertension, dyslipidemia and obesity
Bariatric surgery

Metformin, a biguanide, has been widely used for PCOS patients, and evidence indicates it is beneficial for women with PCOS with metabolic syndrome and/or obesity, as well as for affected women who have impaired glucose tolerance, since the efficacy of metformin for diabetes prevention has been demonstrated in individuals with pre-diabetes (38). Its main action is in the liver, with suppression of gluconeogenesis and hepatic glucose output, but it also enhances peripheral insulin action, and reduces glucose absorption from the

digestive tract, with no significant direct effect on pancreatic insulin production (39). Metformin also directly inhibits thecal androgen production (40).

In women with PCOS, treatment with metformin has been shown to ameliorate the cardiometabolic profile by improving insulin sensitivity, lowering blood glucose and androgen levels and possibly by its effects on body weight (41-44). These effects of metformin are more potent when it is combined with lifestyle intervention (41). Diets with low caloric intake are part of the treatment and those with low glycemic index appear to be better adjusted for PCOS patients (26,43).

It is important to underscore, however, that the first-line treatment for hirsutism, menstrual irregularities and infertility are anti-androgens, contraceptive steroids, and clomiphene citrate, respectively. While metformin is more effective than oral contraceptives in reducing fasting insulin and not increasing triglycerides, it is less effective in improving menstrual pattern, hirsutism or decreasing testosterone (45). Importantly, there is no evidence of benefits in the absence of insulin resistance.

Metformin is also a reasonable treatment option for those women to whom oral contraceptives may not be recommended, such as PCOS patients presenting moderate to severe high blood pressure, high triglycerides levels, class II or III obesity and/or metabolic syndrome. In this case, and especially if antiandrogen drugs are added to the treatment, other options for contraception should be recommended, including progestogen-only pills (mini-pill) or IUDs.

The usual dose of metformin for PCOS is 1,500 to 2,500 mg per day. A main limitation can be side effects, which are predominantly gastroenterological, consisting of abdominal discomfort, nausea, and diarrhea. These symptoms are usually dose-dependent and can be minimized by gradually increasing the dose of metformin over a period of 1-2 months. Initial doses should be 250-500 mg/day, taken just before the main meal. In the case gastrointestinal side effects recidivate, the current dose may be reduced for a period of 7-10 days, followed by a resumption of the dosage increase. Hepatic and renal function should be monitored before and during treatment.

Specific additional treatment for high blood pressure, dyslipidemia or obesity may be needed for individual PCOS women. Additionally, bariatric surgery may be another option for severe obesity or obesity with metabolic comorbidities (13,46).

In conclusion, besides reproductive abnormalities, PCOS has been associated to metabolic comorbidities, most of them, but not all, linked to obesity. Confounders, such as the lack of standard diagnostic criteria, the heterogeneity of the clinical presentation, and the presence of obesity, make the management of PCOS difficult. Therefore, the approach to metabolic abnormalities should be tailored to the risks and treatment goals of each individual woman.

Abstract

Although the diagnostic criteria for polycystic ovary syndrome (PCOS) have become less stringent over the years, determination of the minimum diagnostic features in adolescents is still an area of controversy. Of particular concern is that many of the features considered to be diagnostic for PCOS may evolve over time and change during the first few years after menarche. Nonetheless, attempts to define young women who may be at risk for development of PCOS is pertinent since associated morbidity such as obesity, insulin resistance, and dyslipidemia may benefit from early intervention. The relative utility of diagnostic tools such as persistence of anovulatory cycles, hyperandrogenemia, hyperandrogenism (hirsutism, acne, or alopecia), or ovarian findings on ultrasound is not established in adolescents. Some suggest that even using the strictest criteria, the diagnosis of PCOS may not be valid in adolescents younger than 18 years. In addition, evidence does not necessarily support that lack of treatment of PCOS in younger adolescents will result in untoward outcomes since features consistent with PCOS often resolve with time. The presented data will help determine if it is possible to establish firm criteria which may be used to reliably diagnose PCOS in adolescents.

Keywords

- polycystic ovary syndrome
- polycystic ovarian morphology
- type 2 diabetes mellitus

Polycystic ovary syndrome (PCOS) is a common endocrinopathy that by strictest definition affects 5 to 10% of women of reproductive age.¹ It is characterized by menstrual irregularity, hyperandrogenism, and polycystic ovarian morphology (PCOM) and is also associated with insulin resistance, obesity, and components of the metabolic syndrome (MetS).^{2,3} PCOS often presents during adolescence, but the diagnosis in this age group is complicated by the overlap between the features of PCOS and physiologic findings observed during the normal progression of puberty.⁴ Further, the diagnosis is difficult to make with certainty given the absence of universally accepted diagnostic criteria for adolescents.

Three distinct sets of diagnostic criteria have been suggested for the diagnosis of PCOS in adults. The National Institutes of Health Consensus Statement¹ proposed that PCOS be defined as menstrual irregularity (chronic anovulation or oligomenorrhea) and evidence of clinical or biochemical hyperandrogenism with the exclusion of other

etiologies. The 2003 European Society of Human Reproduction and Embryology/American Society for Reproductive Medicine Rotterdam criteria (ESHRE/ASRM)⁵ broadened the diagnosis of PCOS, requiring two of three features: anovulation or oligo-ovulation, clinical and/or biochemical hyperandrogenism, and polycystic ovaries by ultrasound (US). Finally, the Androgen Excess and PCOS Society⁶ defined PCOS as hyperandrogenism with ovarian dysfunction or polycystic ovaries. Most recently, the NIH Evidence-Based Methodology Workshop on PCOS³ recommended use of the 2003 Rotterdam criteria with identification of specific phenotypes within the diagnosis.

As stated, at present there is not a total agreement regarding definitive criteria for the diagnosis of PCOS in adolescents. We reviewed 73 papers published since 2006 where adolescents with PCOS were described (**►Table 1**).^{7–79} Of interest, 22 studies used NIH, 42 used Rotterdam, and 8 used Androgen Excess Society (AES) or other criteria to

Table 1 Review of diagnosis of PCOS in adolescents (2006–2013)^{7–79}

Abbreviations: AES, Androgen Excess Society; NIH, National Institute of Health, PCOS, polycystic ovary syndrome.

^aFive of the above mentioned articles used multiple criteria.

diagnose PCOS, some using more than 1. Seven of the studies reviewed did not specify any diagnostic criteria used. Of these studies, 31 were from North America, 21 were from Asia, 14 were from Europe, 1 was from Africa, and 3 were from Australia and New Zealand. Only 22 of the studies mentioned number of years postmenarche of the subjects.

Further, the variability of diagnoses in and of PCOS poses various challenges. Use of different criteria can result in a different prevalence of PCOS, even within the same cohort.^{43,44} Clearly, while early diagnosis in adolescents may allow for earlier treatment and prevention of PCOS-associated morbidity, premature diagnosis carries risks of psychological distress and unnecessary treatment.

Numerous studies have called into question the appropriateness of applying adult criteria to adolescents because the features of PCOS are often physiologic or transitory during normal puberty.^{80,81} Thus, several adolescent-specific criteria have been proposed. Sultan and Paris⁸² suggests requiring four out of five of the following: oligomenorrhea or amenorrhea at least 2 years postmenarche, clinical hyperandrogenism, biologic hyperandrogenism, insulin resistance, and polycystic ovary morphology, while Carmina et al⁸⁰ and the 2012 ESHRE/ASRM Consensus Workshop Group⁸³ propose defining PCOS in adolescents by the presence of all three of the 2003 ESHRE/ASRM criteria: hyperandrogenism, chronic anovulation, and polycystic ovaries.

This review will discuss the components utilized by the many suggested criteria to allow one to establish the diagnosis of PCOS in adolescents as well as the ongoing challenge and controversy related to this goal.

Hyperandrogenism

Hyperandrogenism is a hallmark of PCOS; the NIH and AES criteria both require clinical and/or biochemical hyperandrogenism for the diagnosis of PCOS in adults, while the Rotterdam criteria recognize a phenotype of PCOS without androgen excess.^{1,5,6} This feature of PCOS is especially important given its reported association with metabolic dysfunction.^{21,29,35} However, the physiologic rise in androgens that occurs during puberty makes hyperandrogenism difficult to define in adolescents. Furthermore, there is not yet a consensus regarding the preferred assay or reference values for assessing hyperandrogenemia in this age group.⁸⁴

Clinical hyperandrogenism is defined by most adult PCOS diagnostic criteria as the presence of hirsutism, acne, or androgenic alopecia.^{1,5} Hirsutism, as measured by the modified Ferriman-Gallwey (mFG) score, is recognized as the most reliable marker of clinical hyperandrogenism in women with PCOS.⁸³ In Caucasian and African American women, an mFG score of ≥ 8 is often used to define hirsutism in the diagnosis of PCOS,⁷⁰ and this cutoff has been used by numerous studies of PCOS in adolescents.⁴⁴ However, because of less cumulative time of exposure to androgens, this cutoff may require modification for use in adolescents.⁸⁵ In addition, expression of hirsutism in and of itself appears to have ethnic variability.^{86,87}

Roe et al⁷⁰ recently reported that 65% of adolescents with PCOS presented with hirsutism, which is consistent with other studies that report a high prevalence.⁴⁰ The common finding of acne in healthy adolescents, which is as high as 69%,⁴⁴ precludes its utility as a specific marker of hyperandrogenism in PCOS. Hickey et al⁴⁴ found no relationship between acne score and free testosterone (T) level or PCOM. Finally, androgenic alopecia has not been studied widely in adolescents and does not appear to be important for the assessment of hyperandrogenism in this population.⁸⁸ Of the three markers of clinical hyperandrogenism, progressive hirsutism is considered the most useful in adolescents.^{80,88}

Biochemical hyperandrogenism, a more objective measure of excess androgens, can be assessed using a variety of assays to test for serum levels of total testosterone (TT), free T, androstenedione, and dehydroepiandrosterone sulfate. The adult PCOS criteria provide little consensus and guidance as to which assay to use, albeit use of highly specific assays is increasingly being recommended.⁸⁹

The 2007 Endocrine Society position statement about the utility, limitations, and pitfalls of measuring T⁸⁴ does not specifically discuss androgens in adolescents, but suggests the use of TT assays, as opposed to free T, when measuring androgens in children. The position statement also suggests the use of T assays that use extraction and chromatography techniques, instead of direct immunoassays, to maximize sensitivity and accuracy and also stresses the need for standardized assay-specific reference values. Because of diurnal and menstrual cycle variation of T, for consistency it is recommended to be measured between 08:00 and 10:00 hours during the follicular phase.⁸⁴

More recently, liquid chromatography-tandem mass spectrometry (LC-MS/MS) has been studied as a technique for measuring total T in adults^{90,91} and adolescents.^{92,93} Two groups^{92,93} recently developed reference ranges for total T in adolescents using LC-MS/MS and determined this method to be sufficiently sensitive and precise to be used in adolescents. Both groups measured T between 8:00 and 10:00 AM, and one made separate cutoffs based on menstrual cycle phase. However, a comparison of radioimmunoassay and LC-MS/MS measurement of TT in women did not find a significant difference between the results of the two methods although "there is significant variability between LC/MS assays and poor precision with all assays at low T levels."⁸⁹

Thus, while hirsutism appears to be an important clinical marker of hyperandrogenism in adolescents, and a common presenting sign of PCOS, some have argued that biochemical hyperandrogenism is a more reliable and consistent marker of hyperandrogenism in the diagnosis of PCOS in adolescents.^{4,5} Both should be evaluated in the workup of an adolescent with suspected PCOS.

Menstrual Irregularity

Menstrual irregularity is an important feature of PCOS in adults and common in the presentation of PCOS in adolescents.⁷⁰ Chronic oligo-ovulation or anovulation are included in all adult diagnostic criteria for PCOS. However, menstrual irregularity and anovulation are common among healthy adolescents, making their use in the diagnosis of PCOS in this group difficult.

In a study of 200 healthy girls, Apter and Vikho⁹⁴ found that at least 55% of menstrual cycles were anovulatory during the first 2 years postmenarche. The percentage of ovulatory cycles increased with age, reaching 80% at 4 to 5.5 years of gynecological age. While menstrual irregularity is common, its persistence after 2 years after menarche is associated with PCOS. Nair et al⁵¹ studied a cohort of 136 adolescent girls with confirmed menstrual irregularity; at 2 year follow-up, 51.5% continued to have menstrual irregularity and 36% were diagnosed with PCOS using the Rotterdam criteria. In their cohort, Roe et al⁷⁰ found that 98% of adolescents diagnosed with PCOS by the AE-PCOS criteria presented with menstrual irregularity—68.3% with oligomenorrhea, 27.7% with secondary amenorrhea, and 4% with primary amenorrhea.

There is evidence that greater menstrual irregularity is associated with a more severe PCOS phenotype and higher androgen levels.⁵ Rachmiel et al³⁰ reported that adolescents with primary amenorrhea and PCOS have increased features of MetS and higher androstenedione compared with those with oligomenorrhea. A study of a Finnish cohort found that adolescent girls with menstrual irregularity had increased T, decreased sex hormone binding globulin, and an increased free androgen index.⁵⁴ van Hooff et al found that about half of 14 to 16 year olds with oligomenorrhea remained oligomenorrheic at 18 years; body mass index (BMI) and menstrual history, but not androgen and luteinizing hormone concentrations, were predictive of persistent amenorrhea.⁹⁵

Although it is often difficult to distinguish physiologic adolescent anovulation from PCOS-related menstrual irregularity,⁹⁶ some have offered suggestions for how menstrual irregularity should be defined in adolescents and when it should be evaluated. Merino et al⁸⁸ suggested that adolescent ovulatory dysfunction should be considered with the absence of menstrual periods for longer than 90 days, or persistent cycles longer than 45 days. Rosenfield suggested evaluation for menstrual irregularity when adolescents exhibit abnormal menstruation for at least 1 year or if it is associated with other signs and symptoms.⁹⁶

The high prevalence of anovulatory cycles and menstrual irregularity in adolescence has led some to recommend that oligoamenorrhea should persist for at least 2 years and that only then can PCOS be diagnosed in adolescents who are at least 2 years postmenarche.^{5,40,80} Advocates of this proposal state that because of the high frequency of menstrual irregularity in healthy adolescent girls, the diagnosis of PCOS in adolescents should not be made on the basis of menstrual irregularity alone.^{80,97}

It is interesting to speculate that although dysfunctional intermittent uterine bleeding in adolescents can be confused with normal cycling with long interval cycles, in fact, it may be that these adolescents are actually those who already have evidence of chronic anovulation. In addition, some authors suggest that measurement of progesterone is the most specific way to assess ovulation⁹⁸; however this is usually impractical in a clinical setting.

Ovarian Morphology

PCOM is included in both the AES-PCOS and Rotterdam diagnostic criteria for PCOS, which define PCOM as 12 or more follicles of 2 to 9 mm or ovarian volume > 10 cm³ in at least one ovary.⁵ Recently Dewailly et al actually suggested that the former threshold of greater than 12 follicles per ovary may even be too low and a count of 19 follicles would be needed for more accurate diagnosis.⁹⁹ In adults, transvaginal US is the standard imaging method used to evaluate ovarian morphology, however because it is inappropriate for use in virginal adolescents, transabdominal US (TA-US) is instead often used in younger patients. Polycystic ovaries are a common finding in healthy adolescents, making the use of PCOM as a diagnostic criterion for PCOS in adolescents difficult.⁸¹

Mortensen et al⁹ reported that 54% of healthy eumenorrheic girls between 1.3 and 3.8 years postmenarche had polycystic ovaries on TA-US, with a significant correlation between ovarian size and gynecological age. This correlation between increasing age and decreasing ovarian volume has also been found in adults.¹⁰⁰ Several other studies of healthy adolescents found the incidence of PCO to be 33 to 35% by TA-US.^{43,44,101} While up to half of healthy adolescents meet PCO criteria, a third of adolescents with PCOS do not.⁹⁶

Furthermore, the limitations of TA-US present a challenge in using PCOM in the diagnostic criteria for adolescents. This method is less discriminating than transvaginal US and especially difficult to use in obese patients, who make up

about half of the PCOS population.⁹⁷ Transrectal US and magnetic resonance imaging (MRI) have been used in a few studies, but these methods may be less practical in a clinical setting.^{97,102}

Several authors have argued for the need for adolescent-specific thresholds for mean ovarian volume (MOV) for use in the diagnosis of PCOS. New thresholds have been suggested by groups using different imaging modalities. Villa et al⁵³ found that a MOV threshold of 5.6 mL was 89% sensitive and 80% specific for diagnosing PCOS using TA-US, while Chen et al¹⁰³ reported that a cutoff of 6.74 mL maximized specificity and sensitivity in Chinese adolescents using transvaginal US. Another study found an average MOV of 15.1 in adolescents with PCOS compared with 5.9 in healthy controls using MRI. In a comparison of TA-US and MRI in 11 obese adolescents with PCOS, Yoo et al found that MOV was not significantly different between the two methods, but that the number of patients who met Rotterdam criteria for PCO was different between the US and MRI groups.¹⁰⁴

The limitations of using US for the detection of PCO have led to interest in anti-Müllerian hormone (AMH) as a surrogate marker. AMH is a glycoprotein secreted by granulosa cells of growing follicles and has been found to correlate with the number of small antral follicles.⁸⁸ However, reports about the utility of AMH as a marker for PCO in adolescents have been mixed. Hart et al³⁶ found that while serum AMH is significantly higher in adolescent girls with PCO, AMH level had insufficient specificity and sensitivity for detecting PCO. Villarroel et al,¹⁰¹ who studied adolescents with regular menstrual cycles, and Li et al,³⁹ who studied Chinese adolescents with PCOS, developed similar cutoffs for AMH to predict PCO with sensitivities of 64 and 61% and specificities of 89.8 and 70%, respectively. Eilertsen et al¹⁰⁵ reported that serum AMH has good accuracy for diagnosing PCOS in adults when it replaces PCOM as a criterion for PCOS diagnosis. Although more work remains to assess the use of AMH as a surrogate marker for PCO, it may prove useful as a component to aid in the diagnosis of PCOS.

Obesity, Insulin Resistance, and Metabolic Syndrome

PCOS is associated with metabolic abnormalities including insulin resistance, obesity, type 2 diabetes mellitus (T2DM), nonalcoholic fatty liver disease, dyslipidemia, and the MetS.^{2,4,106} There is evidence that these metabolic impairments begin as early as adolescence in women with PCOS. Although metabolic features are not included in the diagnostic criteria for PCOS, they are important to consider in adolescents given their implications on long-term health. At present, the molecular mechanisms responsible for the interactions between hyperandrogenism, obesity, and insulin resistance in PCOS are not fully understood.

Obesity is common in both adults and adolescents with PCOS. It is unclear whether PCOS predisposes women to obesity or whether obesity exacerbates PCOS.¹⁰⁷ Several studies show the prevalence of obesity in PCOS to be above 60%;¹⁰⁸ Glueck et al found that 73% of adolescents with PCOS had a BMI above the 95th percentile.¹⁰⁹

While a large portion of adolescents with PCOS are obese, obesity likely does not fully explain the other metabolic features associated with PCOS. Impaired glucose tolerance (IGT), which is associated with insulin resistance and is a strong predictor for T2DM, cardiovascular disease, and premature mortality,¹¹⁰ is found at an increased rate in adolescents with PCOS. Several studies of adolescents with PCOS have reported the incidence of IGT to be 10 to 30%.^{34,37,79,111} Flannery et al⁷⁹ found that IGT occurred across the spectrum of BMI and Huang et al³⁷ found that when matched for obesity, PCOS is associated with increased risk for insulin resistance, hyperinsulinemia, and prediabetes. However, Hart et al⁴³ found that PCOS was not associated with insulin resistance after controlling for BMI, and Glueck et al found that when matched for age, PCOS subjects did not have significantly different insulin or lipid levels than healthy controls.¹⁰⁹ While IGT is the most common form of abnormal glucose metabolism found in adolescents with PCOS, impaired fasting glucose and T2DM have also been reported in this group.^{1,56,79}

MetS, a group of risk factors that increase the risk for cardiovascular disease and diabetes, is also associated with PCOS. Up to 40% of adults with PCOS have MetS.³⁴ In adolescents, multiple sets of criteria are used to define MetS and the prevalence of MetS varies among different cohorts. Most studies, however, report an increased incidence of MetS in PCOS compared with control subjects.^{21,41,52,70} Coviello et al²¹ found that 35% of girls with PCOS had MetS compared with 5% of controls and that this difference could not be accounted for by obesity alone. The reported prevalence in other studies ranges from 10 to 60%.^{41,52,70} Gleuck et al¹⁰⁹ found that a diagnosis of PCOS at age 14 was a significant independent determinant for MetS at age 24. However, in a cohort that included only obese and overweight participants, Rossi et al³⁴ reported that the prevalence of MetS did not differ significantly between PCOS and controls when matched for obesity, regardless of the definition of MetS used. Similarly, Huang et al³⁷ found that PCOS was not associated with an increased risk for MetS when matched for obesity in a Chinese adolescent cohort.

It has been proposed that the hyperandrogenism associated with PCOS contributes to the metabolic abnormalities discussed above. Fruzzetti et al³⁵ reported that hyperandrogenemia was an important risk factor for lipid alterations in adolescents with PCOS. Another study²¹ found higher levels of free T in adolescents with MetS and reported that levels of the hormone were positively correlated with BMI percentile, waist circumference, and fasting insulin. Elevated systolic and diastolic blood pressures have also been shown to be related to androgen levels in girls with PCOS.^{21,29} In a large prospective study of schoolgirls, Glueck et al¹⁰⁹ reported that low sex hormone-binding globulin was the only significant predictor of MetS and that women with MetS at 24 years of age were more likely to have had a top decile free T at age 14. However, Forrester-Dumont et al⁵⁰ found that metabolic profile was not affected by the degree of hyperandrogenism in girls with PCOS, instead, low HDL best explained the high prevalence of MetS. While most studies agree that obesity and MetS occur

more frequently in adolescents with PCOS compared with the general population, the role of hyperandrogenism in this association remains controversial.

This review will not focus on therapy, however many clinical investigators still suggest that weight loss and lifestyle changes should be the first line of therapy. Metformin and oral contraceptive pills are also considered as secondary treatments that can improve the symptoms of PCOS. However, medical treatment of a condition not fully diagnosed can result in premature use of pharmacologic agents. The issue of treatment of PCOS in the adolescent further underlines the need for consensus and further research about the diagnosis of PCOS in this group. The many points of overlap between physiologic puberty and the features of PCOS may continue to suggest that a more conservative approach to the diagnosis of PCOS in adolescents compared with adults is prudent.

Acknowledgment

The authors acknowledge Dr. Selma Witchel for her thoughtful review and comments.

Background: Adolescents with Polycystic Ovary Syndrome (PCOS) use different coping strategies to confront the challenges of this disorder. Various studies extracted coping strategies amongst adult women with PCOS, but regarding the mental difference between adults and adolescents, specific study was conducted to gain a deep understanding of how adolescents cope to the many health issues they experience.

Methods: Fifteen adolescents aged 13–19 years with PCOS participated in comprehensive individual interviews with goal-oriented, semi-structured questions. Sampling was purposive and continued until data saturation was reached. Data were analyzed using the thematic analysis technique. The validity of the data was verified through measures including credibility, transferability, dependability, confirmability and authenticity.

Results: The analysis of the data helped extract the main theme of the research as “dealing with PCOS”. The main theme consisted of three themes and 12 sub-theme: (1) Escaping the problem (sub-themes: Adopting a forgetting mindset, and concealment and minimization of the disorder); (2) Depressive mood (sub-themes: Poor self-perception and low self-esteem, isolation, sleep disturbances, passive aggressive behavior, emotional turmoil, feelings of humiliation, and adolescents’ perceptions); and (3) Coping with the disease (sub-themes: Recovery of health, positive thinking, hope for recovery).

Conclusion: In this study, the adolescents with PCOS showed a coping response to their disorder in the form of problem-solving, developing a depressive mood or adjusting to the disorder. Recognizing the mental health needs of these adolescents and improving their quality of life require the identification of ways through which they deal with PCOS.

Keywords: polycystic ovary syndrome, adolescents, qualitative research

Introduction

Polycystic Ovary Syndrome (PCOS) is a multifactorial disorder caused by interactions between genetic, environmental and intrauterine factors.¹ Various studies have reported the prevalence of this syndrome in adolescence as 9% to 15%.^{2–4} Based on the available evidence, metabolic, inflammatory, oxidative, emotional and psychological stress is an important part of PCOS.⁵ While the incidence of any disease or disorder can lead to anxiety and worry,⁶ studies have shown that women with PCOS experience emotional distress, depression and anxiety more frequently than others, and when confronted with the disorder, some become more anxious and stressful.^{7–10} PCOS therefore affects the daily life of many people.¹¹ It disturbs the joys of adolescence, because the stigma associated with hyperandrogenism is more intensely felt in this age group and is likely to damage the psychosocial development of adolescent girls.¹²

Patients with this disorder have to go through different stages of coping wherein they will likely have to respond to internal stress (physiological and psychological stressors) and external stress (environmental and social factors related to the syndrome) using coping responses.¹³ The acceptance of any disorder is a complicated process that depends on factors such as the manifestation of the disorder, the availability and quality of treatment, individual demands (eg, mental demands, emotional demands, stress, coping strategies, etc.), support of the family members and other relatives and socioeconomic status.¹⁴ Adolescence is a time of physical, cognitive and emotional changes as well as a period of great change in various aspects of life.¹⁵ Adolescents usually deal with their problems through a variety of methods, including problem-solving methods that focus on changing the status quo, problem-solving, approaching others (seeking spiritual and social support from friends), using strategies to ignore their problems and running away from them, and self-blaming and non-coping behaviors.¹⁶ Managing chronic conditions such as chronic pain, diabetes and cancer in adolescents leads to a variety of coping responses and some are associated with successful adaptation.¹⁷

The aim of qualitative research is to understand the experiences and circumstances of individuals and explain concepts from their perspective, and experiences often vary from one person to the other.¹⁸ The review of literature suggests the diversity of the coping strategies used by adult women with PCOS,^{19,20} while studies on adolescents with this syndrome are rather limited. Given the crucial role of coping strategies in adolescents with this chronic disease, the present study was conducted to gain a comprehensive understanding of the strategies used by adolescents with PCOS to cope with the challenges of this disorder.

Methods

Fifteen adolescents with PCOS able to share their rich experiences of coping with the disorder participated in this qualitative study. All the interviews were in Persian. The entire research team members and participants were fluent in Persian. The research team was composed of a qualitative methodologist as the principal researcher, a gynecologist and a PhD student of reproductive health. Purposive sampling continued until data saturation was achieved. The inclusion criteria for the study consisted of being an adolescent with PCOS as diagnosed by a gynecologist (based on the National Institute of Child Health

and Human Development (NICHD) or the National Institutes of Health (NIH) criteria), having hyperandrogenism, oligo-ovulation/anovulation, age between 13 and 19 years, and willingness of the patient and their parents for participation in the study and sharing experiences. In this study parent or legal guardian provided written informed consent for any participant under the age of 18 years.

Before beginning data collection, the research project was approved by the ethics committee of Shahid Beheshti University of Medical Sciences in Tehran, Iran. The ethical principles observed for the research included obtaining informed consent, preserving the confidentiality of the data and giving the participants the right to leave the study whenever they desired.

Individual in-depth interviews were held with semi-structured questions ("What are your experiences with this disorder at this stage of life?" and "How has this disorder affected your mental state?"). The minimum and maximum duration of the interviews was 30 and 55 mins. The interviews were held in a relaxed and private environment in the health centers of Shahid Beheshti University of Medical Sciences in Tehran, Iran. All the interviews were recorded with prior permission from the participants. Thematic analysis was used in this study. Thematic analysis is a flexible and foundational method for qualitative analysis.²¹ In the beginning, to immerse in the data, the research team transcribed the recorded audio interviews and the members read transcripts thoroughly. In order to generate the initial codes, the research team members extracted the semantic units. Then, the codes were collated into potential themes. The themes were reviewed for generating a thematic map. Finally, the themes were defined and given names and the final report was prepared.

Trustworthiness

Credibility, transferability, dependability, confirmability and authenticity measures were used to verify the data. The methods used in this study to verify the accuracy of the data included the selection of contributors with a variety of experiences, persistent observation, member checking, use of a coding framework, prolonged engagement with data, team consensus on themes, thick descriptions of context, purposive maximum variation sampling (selection of adolescents with different characteristic such as age, family economic status, education, etc.) and discussing some of the findings with a number of the participants.

Results

Thematic analysis categorized coping strategy into one main-theme as “Dealing with PCOS” and 3 themes and 12 sub-themes. Themes and sub-themes are as follow:

Escaping the problem (sub-themes: Adopting a forgetting mindset, and concealment and minimization of the disorder).

Depressive mood (sub-themes: Poor self-perception and low self-esteem, isolation, sleep disturbances, passive aggressive behavior, emotional turmoil, feelings of humiliation, adolescents’ perceptions)

Coping with the disease (sub-themes: Recovery of health, positive thinking, hope for recovery), as shown in Figure 1.

The characteristics of selected participants are mentioned in Table 1.

Escaping the problem

The “escaping the problem” theme was formed in this study by combining two sub-themes, namely “forgetting” and “concealment and minimization of the disorder”. The adolescents tried to escape their challenges by not disclosing their disorder to others so as to reduce the burden of psychological issues, and they used the method of forgetting to rid themselves of intrusive thoughts. The experiences of some of the participants in the study showed that

they used the method of “forgetting” to escape their problems and tried to understand which thoughts resulted in their stress and then chose different ways to distract themselves from these thoughts. In the words of the participants:

“Sometimes, when I think of the disorder, I push the thoughts away. I’ve become inattentive” (Participant 1, 19 years old).

Because I was immersed in my university entrance exam, my mind was preoccupied. This issue (PCOS) has not been important to me at all. I’m always busy studying. I do not have the time to think about it. (Participant 8, 18 years old).

I’ve become indifferent now. It’s no more important to me how it has gotten on my nerves. I don’t think about it anymore because I can’t do anything about it. I went to the doctor, I took medicines, but it didn’t get better. (Participant 6, 19 years old).

The experiences of some of the participants also showed that they somehow tried to escape the problem by “concealing and minimizing the syndrome”. In the words of the participants:

“I’m not upset because they say it is very common and could happen to anyone, and it’s not a rare disorder. Anyone I see, I tell them I have PCOS and I’m taking medicines. It’s normal” (Participant 1, 19 years old).

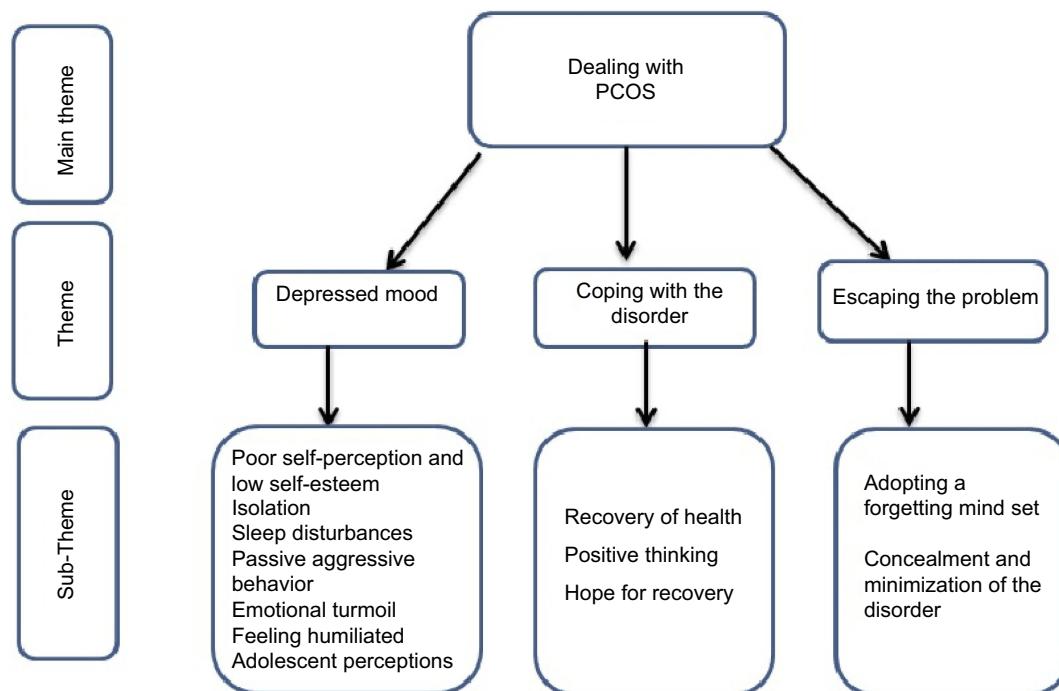

Figure 1 Theme and sub-themes.

Table I Characteristics of study samples (n=15)

Variable		Number
Age group	13–15	2
	15–17	3
	17–19	10
Marital status	Single	13
	Married	2
Years living with PCOS	<1 year	8
	>1 year	7
Main symptom	Obese or overweight	8
	Acne	11
	Hair loss	11
	Hirsutism	13
	Irregular menstruation	12

"I try not to take my pills in front of people because they ask why I'm taking pills. I don't tell anyone about my disorder" (Participant 9, 18 years old).

Depressive mood

The "depressive mood" theme was developed with seven sub-themes, including "poor self-perception and self-esteem", "isolation", "sleep disturbances", "passive aggressive behavior", "emotional turmoil", "feeling humiliated" and "adolescents' perceptions". Some of the adolescents experienced "laziness" and "sadness" after their diagnosis with PCOS and also concerns about failing to recover, constant worries about the disorder and psychological distress, which eventually ended in their "losing the joys of adolescence" and they began to lose focus. These experiences led to unpleasant feelings, and struggles with the disorder for many years caused "emotional disturbances" for some of the adolescents. According to participants' experiences, some of them tried to cope with their problems through "aggressiveness" and "making excuses." Often, they became isolated because of "limiting their relationships with their friends and close relatives" and "preferring to be alone than to be with others". The experiences of the participants also showed that, because of "internal feelings of distress when in gatherings where people were inquisitive" and "being in turmoil due to feeling different from peers", some of them felt humiliated and had a low self-esteem and sometimes also experienced symptoms of physical change caused by their psychological changes. The experiences of most participants showed that the visibility of their symptoms to their peers and others made them feel vulnerable, and as a result, they

preferred not to be in touch with anyone in order to avoid showing their vulnerability. In the words of the participants:

"When I'm in front of the mirror, I feel bad, cause I have a lot of hair and acne" (Participant 15, 19 years old).

"I do not have much confidence when with others, cause I think they are better than me. It's the same for my family, my friends ..." (Participant 3, 16 years old).

Loneliness and "isolation" were one of the common strategies of the adolescents in this study to cope with their disorder. In the words of the participants:

I don't have much patience for myself; I don't have patience for others; I prefer to be left alone at home. What I mean is that I prefer everyone to go out visiting and enjoying themselves but leaving me home alone. (Participant 13, 19 years old).

"I try not to be in touch with my friends ... I've only told my best friend about my polycystic ovary syndrome" (Participant 15, 19 years old).

Stressful conditions were associated with "sleep disturbances" in some of the participants. In the words of the participants:

"I'm always sleepy. I feel so sleepy. I'm constantly falling asleep. It's awful. It has been two or three years that I've become like this. I mean, since the morning, when I wake up, I feel sleepy" (Participant 6, 19 years old).

"I think so much about it that I can't sleep. I go out [of my bedroom] to drink water. I can't sleep at all until 5 or 7 am" (Participant 12, 13 years old).

Some of the adolescents who participated in the study expressed their agitation and negative feelings about the onset of their syndrome and were unknowingly showing passive aggressive behavior. In the words of the participants:

"I'm always fighting with everyone. I've become stubborn. When I get worried about something, I go to my room and shut the door. I start to cry and then lock the door" (Participant 3, 16 years old).

"I'm so distressed that I keep fighting with my family. I say, 'It's all your fault, you've caused this problem for me!' (Participant 12, 13 years old).

Concerns about the syndrome and its presentations and reasons caused tension in most of the participants and they were faced with "emotional disturbances". In the words of these participants:

"I'm worried about seeking further treatment because they told me that no special treatment exists yet" (Participant 2, 15 years old).

"I really don't have the patience, unlike in the past. For example, I had so many interests to pursue that I really enjoyed going out, but not anymore" (Participant 10, 19 years old).

"I don't think so much about it. It makes me very upset. My entire life has become consumed with this problem. I've lost my appetite. I'm so upset" (Participant 12, 13 years old).

"My inner feelings are such that, like, when you want to do something for yourself, say, make an effort for the sake of your life, continuing it causes problems because of this disorder" (Participant 2, 15 years old).

"Right now, I feel that, the way my friends hang out and are happy in each other's company, I'm not like that" (Participant 6, 19 years old).

"Most of the time, my mind was preoccupied and I couldn't concentrate on a particular problem" (Participant 2, 15 years old).

"My particular concern is that if this continues, what's going to happen ... Will this illness be with me all my life and will I have to always cope with it and take medications?" (Participant 4, 19 years old).

"I think so much about it. When I look at myself in the mirror, I say, 'What kind of life is this?'" (Participant 2, 15 years old).

"My nerves are so weakened ..." (Participant 12, 13 years old).

I didn't use to go and visit others ... not that I said I didn't like to go and see people. For example, when I sat down, someone would ask me if I was on a diet and I would get angry and want to answer back, but I had to keep the boundaries of respect, so I wouldn't say anything. And then, I wouldn't go to visit people at all because of this. (Participant 13, 19 years old).

Some of the adolescents who participated in the study perceived themselves as below optimal because of the symptoms of their syndrome and imagined that they were not worthy and felt "humiliated". In the words of the participants:

Compared to my friends, I see myself very different. For example, they wear fashionable items that I have always liked to own, but I could never be like that, because of the excessive hair that I have to hide, my obesity and hair loss. (Participant 2, 15 years old).

The manifestation of mental stress as a result of the syndrome and mental turmoil in some of the participants led to "adolescents' perceptions". In the words of the participants:

"I'm usually tired. My activities have diminished, unlike the vitality I had before" (Participant 14, 17 years old).

"I don't like to move too much. I like to just always sit somewhere" (Participant 10, 19 years old).

Coping with the disorder

"Coping with the disorder" consisted of three sub-themes, namely "the recovery of health", "positive thinking" and "hope for recovery". Most of the adolescents who participated in this study tried to reduce the mental stress of having PCOS through academic accomplishments and took measures to promote their physical health. Although the adolescents felt responsible for their own health, they neglected it nonetheless, because they prioritized their studies and future career prospects.

Some of the adolescents attempted to create a positive image of their disorder and created a positive vibe for seeking treatment by adopting a "hope for recovery" approach. Some of them coped with the syndrome through a "positive internal dialogue". Some of the participants in this study were taking "health recovery" measures to cope with their syndrome. In the words of the participants:

"Right now, studying is my priority, and when I've completed my studies, I want to go to the doctor again" (Participant 1, 19 years old).

"I am far too busy with the university entrance examination and my studies to have any time for this disease at all" (Participant 8, 18 year-old).

"I used to regard my disorder as trivial. I didn't think it was necessary for me to take my pills. Later, I began taking it very seriously" (Participant 9, 18 years old).

Some of the participants were able to rid themselves of disturbing thoughts through "positive thinking" and coped with their disorder. In the words of these participants:

"I came to accept myself, 'Okay, you have this condition, you have this pimple!' I accepted it as it was and then wouldn't think about it" (Participant 4, 19 years old).

"It's a mild illness –not a very dangerous disorder" (Participant 4, 19 years old).

Some of the participants took steps to cope with the disorder through a "hope for recovery". In the words of this group of the participants:

"My medications are one too many, but I take them with the hope of getting better. Just like this. I take my

medications to get better soon" (Participant 6, 19 years old).

"When I take my medicines, since they regulate my period, I feel good" (Participant 8, 18 years old).

Discussion

The findings of this study include concepts such as escaping the problem, depressed mood and coping with the disorder. In conjunction with each other, these concepts led to the formulation of dealing with PCOS.

As the sociocultural context of any society can affect individuals' strategies for coping with critical situations, the sociocultural and religious contexts of the Iranian society can also affect the type of strategies adolescents adopt to cope with PCOS. Like in many Middle Eastern countries, cultural and educational issues also have a major role in adolescents' mental health in Iran.²²

Evidence suggests that dealing with a chronic disease, such as adolescent diabetes, requires a coping strategy that can help improve the health outcomes and quality of life of the patient.²³

Other chronic diseases such as adolescent cancer or serious infections that may cause future infertility have also become a serious concern for both adolescent patients and their parents as per their responses.^{24,25} The diagnosis of any fertility disorder in adolescents can disrupt the normal psychosocial development of the individual.²⁶ In general, the manifestation of symptoms such as obesity, acne, hirsutism and the disruption of the menstrual cycle lead to stress in these patients and they cope with this stress in different ways.

In the experiences of the participants, some of the adolescents with PCOS were trying to escape their problems by forgetting and often with the concealment and minimization of their disorder. The results of a study on women with PCOS showed that those who suffered more psychological problems used maladaptive coping strategies, such as avoidance strategies, and used less problem-focused coping strategies.²⁷ Avoidance coping is known as an effective short-term strategy, but in the long term, it prevents psychological adjustment and increases depression.^{28,29}

The results of other studies on social coping strategies have shown that adolescents use different coping techniques, such as avoidance coping, problem-solving and seeking social support.³⁰

It seems that most participants in the present study were turning to these strategies to escape being labeled

as "sick" and to be able to cope with the disorder in some way by denying its existence to themselves and others. It is a proven fact, however, that avoidance coping could cause a downward spiral in the long-term.

The experiences of the participants of this study showed that adaptation to illness could emerge as a depressive mood in some adolescents. The diagnosis of PCOS has psychological ramifications.³¹ Depression and moodiness in adolescents and the appearance of a depressive mood have been argued to be associated with symptoms such as disturbed sleep, lethargy, restlessness, changes in appetite and weight, decreased motivation and concentration, decreased self-esteem and isolation.³² In one qualitative study, the experiences of 12 people with PCOS aged 17 to 51 years revealed great mental anxiety in coping with this disorder.¹⁹ The onset of PCOS is associated with the instability of emotions, confusion and moodiness and leads to feelings of irritability, fear and despair in social relationships and a general sense of unhappiness.^{33,34}

The establishment of social relationships is vital during adolescence.³⁵ Adolescents with this disorder choose isolation to counteract the reactions of those around them. The acceptance of adolescents with PCOS by the community and those close to them helps improve their behavior, while increased criticism, especially in this vulnerable age group, reduces self-esteem and increases anxiety and depression and ultimately leads to abandoned social relationships.³⁶ In contrast, a negative body image destroys the individual's social competence and causes the abandoning of intimate relationships.^{37,38} Changes in one's physical appearance, concerns over changes in one's mental body image and the development of anxiety about the ramifications of the disorder seem to play a role in the manifestation of a depressive mood as a kind of coping response to the disease.

The experiences of the participants in this study also showed that those who responded with positive thoughts and had hope for their future well-being and recovery chose an adaptive coping response to the disorder. The various factors affecting the acceptance of the disorder also contribute to the PCOS patient's coping with the disorder.³⁹ The results of a study on women with PCOS showed that coping strategies were more excitement-oriented.⁴⁰ Another qualitative study on women with PCOS also showed that coping strategies include deliberation (religious beliefs, paradoxical thoughts), practical steps (positive steps such as seeking information and treatment as well as negative steps such as detachment and

concealment) and seeking support (family support and peer support) in these patients.⁴¹ Evidence suggests that the types of coping strategies chosen by women with PCOS affect their quality of life.²⁰ Some studies have even suggested that hope is a very powerful force that can play a key role in coping with adolescent illnesses.⁴² Hope is occasionally a solution to tension that increases the individual's ability to adapt.⁴³ Some of the participants of this study were able to cope with their mental turmoil through their hope to recover. Meanwhile, some attempted to take steps towards coping with their disorder through positive thoughts. Positive thoughts comprise a branch of cognitive therapy that can be defined as the usage of hopefulness, happiness and positive mental abilities.⁴⁴

A study by Benson et al (2010) conducted on 449 women with PCOS showed that some participants had a passive coping strategy in dealing with this syndrome (retreating and accepting one's fate regarding the disorder), which is an unharmonious strategy that leads to the emergence of anxiety and depression and in turn decreases the quality of life. In contrast, some participants who adopted active coping strategies (problem-solving and information-seeking) had lower levels of depression.⁴⁵ The participating adolescents of this study had a positive attitude and took health-recovery measures to cope with the disorder.

Active coping involves problem-solving and social support-seeking while passive coping involves social isolation.¹⁷ The results of one study on children and adolescents with a chronic illness showed that coping with such a disease may lead to effective coping with daily stressors of life.⁴⁶

Some of the participants used problem-solving through positive thoughts and measures to deal with the stressful conditions of life. They used a rational strategy to accept their disorder and their tensions thus decreased. In general, chronic PCOS requires self-efficacy and lifestyle modifications.⁴⁷ As for the psychological burden of PCOS, choosing a proper coping strategy plays a decisive role in the quality of life of adolescents with the disorder, as irrational strategies could cause harm and threaten different dimensions of life. The use of clinical counseling, mental health services, beauty counseling services and support services for patients and their families can contribute significantly to the improvement of the quality of life of adolescents with chronic PCOS.⁴⁸

Implementing psychological counseling programs (by psychologists and other allied health professionals) and

teaching adolescents adaptive coping strategies are recommended to prevent future mental health problems. Attention to mental health and related care measures is imperative for medical teams.

The study limitations include the non-generalizability of the results to all adolescents with this syndrome, although this limitation applies to all qualitative studies in nature. Furthermore, forgetting certain experiences or the unwillingness to actually express these experiences and feelings on the part of the adolescents could be considered another limitation of the study.

Conclusion

When confronted with the stressful symptoms of PCOS, the participants adolescents of this study showed coping responses such as escaping the problem, depressive mood or coping with the syndrome. Identifying the ways through which these adolescents cope with their syndrome is vital for recognizing the mental health needs of PCOS patients and improving their quality of life.

Acknowledgments

This article is a part of a PhD thesis of Shahid Beheshti University of Medical Sciences, Tehran, Iran. The researchers are grateful to the adolescents who participated in the study and their parents and vice-chancellor of research from the Shahid Beheshti University of Medical Sciences.

Psychology Research and Behavior Management**Dovepress****Publish your work in this journal**

Psychology Research and Behavior Management is an international, peer-reviewed, open access journal focusing on the science of psychology and its application in behavior management to develop improved outcomes in the clinical, educational, sports and business arenas. Specific topics covered in the journal include: Neuroscience, memory and decision making; Behavior modification and management; Clinical

applications; Business and sports performance management; Social and developmental studies; Animal studies. The manuscript management system is completely online and includes a very quick and fair peer-review system, which is all easy to use. Visit <http://www.dovepress.com/testimonials.php> to read real quotes from published authors.

Background: Adolescents with Polycystic Ovary Syndrome (PCOS) use different coping strategies to confront the challenges of this disorder. Various studies extracted coping strategies amongst adult women with PCOS, but regarding the mental difference between adults and adolescents, specific study was conducted to gain a deep understanding of how adolescents cope to the many health issues they experience.

Methods: Fifteen adolescents aged 13–19 years with PCOS participated in comprehensive individual interviews with goal-oriented, semi-structured questions. Sampling was purposive and continued until data saturation was reached. Data were analyzed using the thematic analysis technique. The validity of the data was verified through measures including credibility, transferability, dependability, confirmability and authenticity.

Results: The analysis of the data helped extract the main theme of the research as “dealing with PCOS”. The main theme consisted of three themes and 12 sub-theme: (1) Escaping the problem (sub-themes: Adopting a forgetting mindset, and concealment and minimization of the disorder); (2) Depressive mood (sub-themes: Poor self-perception and low self-esteem, isolation, sleep disturbances, passive aggressive behavior, emotional turmoil, feelings of humiliation, and adolescents’ perceptions); and (3) Coping with the disease (sub-themes: Recovery of health, positive thinking, hope for recovery).

Conclusion: In this study, the adolescents with PCOS showed a coping response to their disorder in the form of problem-solving, developing a depressive mood or adjusting to the disorder. Recognizing the mental health needs of these adolescents and improving their quality of life require the identification of ways through which they deal with PCOS.

Keywords: polycystic ovary syndrome, adolescents, qualitative research

Introduction

Polycystic Ovary Syndrome (PCOS) is a multifactorial disorder caused by interactions between genetic, environmental and intrauterine factors.¹ Various studies have reported the prevalence of this syndrome in adolescence as 9% to 15%.^{2–4} Based on the available evidence, metabolic, inflammatory, oxidative, emotional and psychological stress is an important part of PCOS.⁵ While the incidence of any disease or disorder can lead to anxiety and worry,⁶ studies have shown that women with PCOS experience emotional distress, depression and anxiety more frequently than others, and when confronted with the disorder, some become more anxious and stressful.^{7–10} PCOS therefore affects the daily life of many people.¹¹ It disturbs the joys of adolescence, because the stigma associated with hyperandrogenism is more intensely felt in this age group and is likely to damage the psychosocial development of adolescent girls.¹²

Patients with this disorder have to go through different stages of coping wherein they will likely have to respond to internal stress (physiological and psychological stressors) and external stress (environmental and social factors related to the syndrome) using coping responses.¹³ The acceptance of any disorder is a complicated process that depends on factors such as the manifestation of the disorder, the availability and quality of treatment, individual demands (eg, mental demands, emotional demands, stress, coping strategies, etc.), support of the family members and other relatives and socioeconomic status.¹⁴ Adolescence is a time of physical, cognitive and emotional changes as well as a period of great change in various aspects of life.¹⁵ Adolescents usually deal with their problems through a variety of methods, including problem-solving methods that focus on changing the status quo, problem-solving, approaching others (seeking spiritual and social support from friends), using strategies to ignore their problems and running away from them, and self-blaming and non-coping behaviors.¹⁶ Managing chronic conditions such as chronic pain, diabetes and cancer in adolescents leads to a variety of coping responses and some are associated with successful adaptation.¹⁷

The aim of qualitative research is to understand the experiences and circumstances of individuals and explain concepts from their perspective, and experiences often vary from one person to the other.¹⁸ The review of literature suggests the diversity of the coping strategies used by adult women with PCOS,^{19,20} while studies on adolescents with this syndrome are rather limited. Given the crucial role of coping strategies in adolescents with this chronic disease, the present study was conducted to gain a comprehensive understanding of the strategies used by adolescents with PCOS to cope with the challenges of this disorder.

Methods

Fifteen adolescents with PCOS able to share their rich experiences of coping with the disorder participated in this qualitative study. All the interviews were in Persian. The entire research team members and participants were fluent in Persian. The research team was composed of a qualitative methodologist as the principal researcher, a gynecologist and a PhD student of reproductive health. Purposive sampling continued until data saturation was achieved. The inclusion criteria for the study consisted of being an adolescent with PCOS as diagnosed by a gynecologist (based on the National Institute of Child Health

and Human Development (NICHD) or the National Institutes of Health (NIH) criteria), having hyperandrogenism, oligo-ovulation/anovulation, age between 13 and 19 years, and willingness of the patient and their parents for participation in the study and sharing experiences. In this study parent or legal guardian provided written informed consent for any participant under the age of 18 years.

Before beginning data collection, the research project was approved by the ethics committee of Shahid Beheshti University of Medical Sciences in Tehran, Iran. The ethical principles observed for the research included obtaining informed consent, preserving the confidentiality of the data and giving the participants the right to leave the study whenever they desired.

Individual in-depth interviews were held with semi-structured questions ("What are your experiences with this disorder at this stage of life?" and "How has this disorder affected your mental state?"). The minimum and maximum duration of the interviews was 30 and 55 mins. The interviews were held in a relaxed and private environment in the health centers of Shahid Beheshti University of Medical Sciences in Tehran, Iran. All the interviews were recorded with prior permission from the participants. Thematic analysis was used in this study. Thematic analysis is a flexible and foundational method for qualitative analysis.²¹ In the beginning, to immerse in the data, the research team transcribed the recorded audio interviews and the members read transcripts thoroughly. In order to generate the initial codes, the research team members extracted the semantic units. Then, the codes were collated into potential themes. The themes were reviewed for generating a thematic map. Finally, the themes were defined and given names and the final report was prepared.

Trustworthiness

Credibility, transferability, dependability, confirmability and authenticity measures were used to verify the data. The methods used in this study to verify the accuracy of the data included the selection of contributors with a variety of experiences, persistent observation, member checking, use of a coding framework, prolonged engagement with data, team consensus on themes, thick descriptions of context, purposive maximum variation sampling (selection of adolescents with different characteristic such as age, family economic status, education, etc.) and discussing some of the findings with a number of the participants.

Results

Thematic analysis categorized coping strategy into one main-theme as “Dealing with PCOS” and 3 themes and 12 sub-themes. Themes and sub-themes are as follow:

Escaping the problem (sub-themes: Adopting a forgetting mindset, and concealment and minimization of the disorder).

Depressive mood (sub-themes: Poor self-perception and low self-esteem, isolation, sleep disturbances, passive aggressive behavior, emotional turmoil, feelings of humiliation, adolescents’ perceptions)

Coping with the disease (sub-themes: Recovery of health, positive thinking, hope for recovery), as shown in Figure 1.

The characteristics of selected participants are mentioned in Table 1.

Escaping the problem

The “escaping the problem” theme was formed in this study by combining two sub-themes, namely “forgetting” and “concealment and minimization of the disorder”. The adolescents tried to escape their challenges by not disclosing their disorder to others so as to reduce the burden of psychological issues, and they used the method of forgetting to rid themselves of intrusive thoughts. The experiences of some of the participants in the study showed that

they used the method of “forgetting” to escape their problems and tried to understand which thoughts resulted in their stress and then chose different ways to distract themselves from these thoughts. In the words of the participants:

“Sometimes, when I think of the disorder, I push the thoughts away. I’ve become inattentive” (Participant 1, 19 years old).

Because I was immersed in my university entrance exam, my mind was preoccupied. This issue (PCOS) has not been important to me at all. I’m always busy studying. I do not have the time to think about it. (Participant 8, 18 years old).

I’ve become indifferent now. It’s no more important to me how it has gotten on my nerves. I don’t think about it anymore because I can’t do anything about it. I went to the doctor, I took medicines, but it didn’t get better. (Participant 6, 19 years old).

The experiences of some of the participants also showed that they somehow tried to escape the problem by “concealing and minimizing the syndrome”. In the words of the participants:

“I’m not upset because they say it is very common and could happen to anyone, and it’s not a rare disorder. Anyone I see, I tell them I have PCOS and I’m taking medicines. It’s normal” (Participant 1, 19 years old).

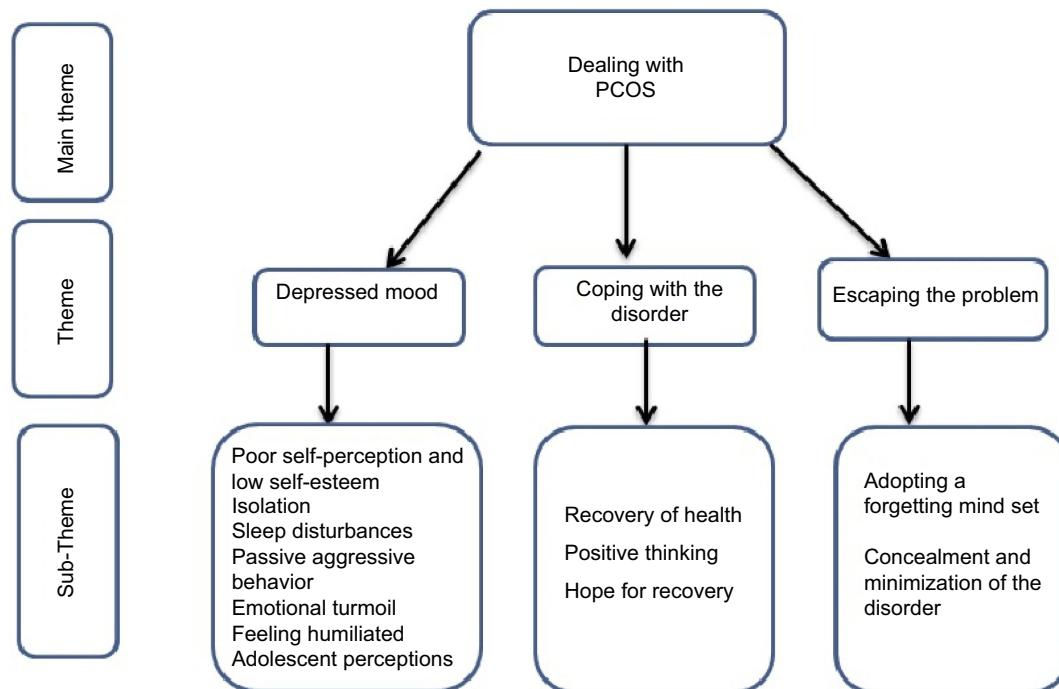

Figure 1 Theme and sub-themes.

Table I Characteristics of study samples (n=15)

Variable		Number
Age group	13–15	2
	15–17	3
	17–19	10
Marital status	Single	13
	Married	2
Years living with PCOS	<1 year	8
	>1 year	7
Main symptom	Obese or overweight	8
	Acne	11
	Hair loss	11
	Hirsutism	13
	Irregular menstruation	12

"I try not to take my pills in front of people because they ask why I'm taking pills. I don't tell anyone about my disorder" (Participant 9, 18 years old).

Depressive mood

The "depressive mood" theme was developed with seven sub-themes, including "poor self-perception and self-esteem", "isolation", "sleep disturbances", "passive aggressive behavior", "emotional turmoil", "feeling humiliated" and "adolescents' perceptions". Some of the adolescents experienced "laziness" and "sadness" after their diagnosis with PCOS and also concerns about failing to recover, constant worries about the disorder and psychological distress, which eventually ended in their "losing the joys of adolescence" and they began to lose focus. These experiences led to unpleasant feelings, and struggles with the disorder for many years caused "emotional disturbances" for some of the adolescents. According to participants' experiences, some of them tried to cope with their problems through "aggressiveness" and "making excuses." Often, they became isolated because of "limiting their relationships with their friends and close relatives" and "preferring to be alone than to be with others". The experiences of the participants also showed that, because of "internal feelings of distress when in gatherings where people were inquisitive" and "being in turmoil due to feeling different from peers", some of them felt humiliated and had a low self-esteem and sometimes also experienced symptoms of physical change caused by their psychological changes. The experiences of most participants showed that the visibility of their symptoms to their peers and others made them feel vulnerable, and as a result, they

preferred not to be in touch with anyone in order to avoid showing their vulnerability. In the words of the participants:

"When I'm in front of the mirror, I feel bad, cause I have a lot of hair and acne" (Participant 15, 19 years old).

"I do not have much confidence when with others, cause I think they are better than me. It's the same for my family, my friends ..." (Participant 3, 16 years old).

Loneliness and "isolation" were one of the common strategies of the adolescents in this study to cope with their disorder. In the words of the participants:

I don't have much patience for myself; I don't have patience for others; I prefer to be left alone at home. What I mean is that I prefer everyone to go out visiting and enjoying themselves but leaving me home alone. (Participant 13, 19 years old).

"I try not to be in touch with my friends ... I've only told my best friend about my polycystic ovary syndrome" (Participant 15, 19 years old).

Stressful conditions were associated with "sleep disturbances" in some of the participants. In the words of the participants:

"I'm always sleepy. I feel so sleepy. I'm constantly falling asleep. It's awful. It has been two or three years that I've become like this. I mean, since the morning, when I wake up, I feel sleepy" (Participant 6, 19 years old).

"I think so much about it that I can't sleep. I go out [of my bedroom] to drink water. I can't sleep at all until 5 or 7 am" (Participant 12, 13 years old).

Some of the adolescents who participated in the study expressed their agitation and negative feelings about the onset of their syndrome and were unknowingly showing passive aggressive behavior. In the words of the participants:

"I'm always fighting with everyone. I've become stubborn. When I get worried about something, I go to my room and shut the door. I start to cry and then lock the door" (Participant 3, 16 years old).

"I'm so distressed that I keep fighting with my family. I say, 'It's all your fault, you've caused this problem for me!' (Participant 12, 13 years old).

Concerns about the syndrome and its presentations and reasons caused tension in most of the participants and they were faced with "emotional disturbances". In the words of these participants:

"I'm worried about seeking further treatment because they told me that no special treatment exists yet" (Participant 2, 15 years old).

"I really don't have the patience, unlike in the past. For example, I had so many interests to pursue that I really enjoyed going out, but not anymore" (Participant 10, 19 years old).

"I don't think so much about it. It makes me very upset. My entire life has become consumed with this problem. I've lost my appetite. I'm so upset" (Participant 12, 13 years old).

"My inner feelings are such that, like, when you want to do something for yourself, say, make an effort for the sake of your life, continuing it causes problems because of this disorder" (Participant 2, 15 years old).

"Right now, I feel that, the way my friends hang out and are happy in each other's company, I'm not like that" (Participant 6, 19 years old).

"Most of the time, my mind was preoccupied and I couldn't concentrate on a particular problem" (Participant 2, 15 years old).

"My particular concern is that if this continues, what's going to happen ... Will this illness be with me all my life and will I have to always cope with it and take medications?" (Participant 4, 19 years old).

"I think so much about it. When I look at myself in the mirror, I say, 'What kind of life is this?'" (Participant 2, 15 years old).

"My nerves are so weakened ..." (Participant 12, 13 years old).

I didn't use to go and visit others ... not that I said I didn't like to go and see people. For example, when I sat down, someone would ask me if I was on a diet and I would get angry and want to answer back, but I had to keep the boundaries of respect, so I wouldn't say anything. And then, I wouldn't go to visit people at all because of this. (Participant 13, 19 years old).

Some of the adolescents who participated in the study perceived themselves as below optimal because of the symptoms of their syndrome and imagined that they were not worthy and felt "humiliated". In the words of the participants:

Compared to my friends, I see myself very different. For example, they wear fashionable items that I have always liked to own, but I could never be like that, because of the excessive hair that I have to hide, my obesity and hair loss. (Participant 2, 15 years old).

The manifestation of mental stress as a result of the syndrome and mental turmoil in some of the participants led to "adolescents' perceptions". In the words of the participants:

"I'm usually tired. My activities have diminished, unlike the vitality I had before" (Participant 14, 17 years old).

"I don't like to move too much. I like to just always sit somewhere" (Participant 10, 19 years old).

Coping with the disorder

"Coping with the disorder" consisted of three sub-themes, namely "the recovery of health", "positive thinking" and "hope for recovery". Most of the adolescents who participated in this study tried to reduce the mental stress of having PCOS through academic accomplishments and took measures to promote their physical health. Although the adolescents felt responsible for their own health, they neglected it nonetheless, because they prioritized their studies and future career prospects.

Some of the adolescents attempted to create a positive image of their disorder and created a positive vibe for seeking treatment by adopting a "hope for recovery" approach. Some of them coped with the syndrome through a "positive internal dialogue". Some of the participants in this study were taking "health recovery" measures to cope with their syndrome. In the words of the participants:

"Right now, studying is my priority, and when I've completed my studies, I want to go to the doctor again" (Participant 1, 19 years old).

"I am far too busy with the university entrance examination and my studies to have any time for this disease at all" (Participant 8, 18 year-old).

"I used to regard my disorder as trivial. I didn't think it was necessary for me to take my pills. Later, I began taking it very seriously" (Participant 9, 18 years old).

Some of the participants were able to rid themselves of disturbing thoughts through "positive thinking" and coped with their disorder. In the words of these participants:

"I came to accept myself, 'Okay, you have this condition, you have this pimple!' I accepted it as it was and then wouldn't think about it" (Participant 4, 19 years old).

"It's a mild illness –not a very dangerous disorder" (Participant 4, 19 years old).

Some of the participants took steps to cope with the disorder through a "hope for recovery". In the words of this group of the participants:

"My medications are one too many, but I take them with the hope of getting better. Just like this. I take my

medications to get better soon" (Participant 6, 19 years old).

"When I take my medicines, since they regulate my period, I feel good" (Participant 8, 18 years old).

Discussion

The findings of this study include concepts such as escaping the problem, depressed mood and coping with the disorder. In conjunction with each other, these concepts led to the formulation of dealing with PCOS.

As the sociocultural context of any society can affect individuals' strategies for coping with critical situations, the sociocultural and religious contexts of the Iranian society can also affect the type of strategies adolescents adopt to cope with PCOS. Like in many Middle Eastern countries, cultural and educational issues also have a major role in adolescents' mental health in Iran.²²

Evidence suggests that dealing with a chronic disease, such as adolescent diabetes, requires a coping strategy that can help improve the health outcomes and quality of life of the patient.²³

Other chronic diseases such as adolescent cancer or serious infections that may cause future infertility have also become a serious concern for both adolescent patients and their parents as per their responses.^{24,25} The diagnosis of any fertility disorder in adolescents can disrupt the normal psychosocial development of the individual.²⁶ In general, the manifestation of symptoms such as obesity, acne, hirsutism and the disruption of the menstrual cycle lead to stress in these patients and they cope with this stress in different ways.

In the experiences of the participants, some of the adolescents with PCOS were trying to escape their problems by forgetting and often with the concealment and minimization of their disorder. The results of a study on women with PCOS showed that those who suffered more psychological problems used maladaptive coping strategies, such as avoidance strategies, and used less problem-focused coping strategies.²⁷ Avoidance coping is known as an effective short-term strategy, but in the long term, it prevents psychological adjustment and increases depression.^{28,29}

The results of other studies on social coping strategies have shown that adolescents use different coping techniques, such as avoidance coping, problem-solving and seeking social support.³⁰

It seems that most participants in the present study were turning to these strategies to escape being labeled

as "sick" and to be able to cope with the disorder in some way by denying its existence to themselves and others. It is a proven fact, however, that avoidance coping could cause a downward spiral in the long-term.

The experiences of the participants of this study showed that adaptation to illness could emerge as a depressive mood in some adolescents. The diagnosis of PCOS has psychological ramifications.³¹ Depression and moodiness in adolescents and the appearance of a depressive mood have been argued to be associated with symptoms such as disturbed sleep, lethargy, restlessness, changes in appetite and weight, decreased motivation and concentration, decreased self-esteem and isolation.³² In one qualitative study, the experiences of 12 people with PCOS aged 17 to 51 years revealed great mental anxiety in coping with this disorder.¹⁹ The onset of PCOS is associated with the instability of emotions, confusion and moodiness and leads to feelings of irritability, fear and despair in social relationships and a general sense of unhappiness.^{33,34}

The establishment of social relationships is vital during adolescence.³⁵ Adolescents with this disorder choose isolation to counteract the reactions of those around them. The acceptance of adolescents with PCOS by the community and those close to them helps improve their behavior, while increased criticism, especially in this vulnerable age group, reduces self-esteem and increases anxiety and depression and ultimately leads to abandoned social relationships.³⁶ In contrast, a negative body image destroys the individual's social competence and causes the abandoning of intimate relationships.^{37,38} Changes in one's physical appearance, concerns over changes in one's mental body image and the development of anxiety about the ramifications of the disorder seem to play a role in the manifestation of a depressive mood as a kind of coping response to the disease.

The experiences of the participants in this study also showed that those who responded with positive thoughts and had hope for their future well-being and recovery chose an adaptive coping response to the disorder. The various factors affecting the acceptance of the disorder also contribute to the PCOS patient's coping with the disorder.³⁹ The results of a study on women with PCOS showed that coping strategies were more excitement-oriented.⁴⁰ Another qualitative study on women with PCOS also showed that coping strategies include deliberation (religious beliefs, paradoxical thoughts), practical steps (positive steps such as seeking information and treatment as well as negative steps such as detachment and

concealment) and seeking support (family support and peer support) in these patients.⁴¹ Evidence suggests that the types of coping strategies chosen by women with PCOS affect their quality of life.²⁰ Some studies have even suggested that hope is a very powerful force that can play a key role in coping with adolescent illnesses.⁴² Hope is occasionally a solution to tension that increases the individual's ability to adapt.⁴³ Some of the participants of this study were able to cope with their mental turmoil through their hope to recover. Meanwhile, some attempted to take steps towards coping with their disorder through positive thoughts. Positive thoughts comprise a branch of cognitive therapy that can be defined as the usage of hopefulness, happiness and positive mental abilities.⁴⁴

A study by Benson et al (2010) conducted on 449 women with PCOS showed that some participants had a passive coping strategy in dealing with this syndrome (retreating and accepting one's fate regarding the disorder), which is an unharmonious strategy that leads to the emergence of anxiety and depression and in turn decreases the quality of life. In contrast, some participants who adopted active coping strategies (problem-solving and information-seeking) had lower levels of depression.⁴⁵ The participating adolescents of this study had a positive attitude and took health-recovery measures to cope with the disorder.

Active coping involves problem-solving and social support-seeking while passive coping involves social isolation.¹⁷ The results of one study on children and adolescents with a chronic illness showed that coping with such a disease may lead to effective coping with daily stressors of life.⁴⁶

Some of the participants used problem-solving through positive thoughts and measures to deal with the stressful conditions of life. They used a rational strategy to accept their disorder and their tensions thus decreased. In general, chronic PCOS requires self-efficacy and lifestyle modifications.⁴⁷ As for the psychological burden of PCOS, choosing a proper coping strategy plays a decisive role in the quality of life of adolescents with the disorder, as irrational strategies could cause harm and threaten different dimensions of life. The use of clinical counseling, mental health services, beauty counseling services and support services for patients and their families can contribute significantly to the improvement of the quality of life of adolescents with chronic PCOS.⁴⁸

Implementing psychological counseling programs (by psychologists and other allied health professionals) and

teaching adolescents adaptive coping strategies are recommended to prevent future mental health problems. Attention to mental health and related care measures is imperative for medical teams.

The study limitations include the non-generalizability of the results to all adolescents with this syndrome, although this limitation applies to all qualitative studies in nature. Furthermore, forgetting certain experiences or the unwillingness to actually express these experiences and feelings on the part of the adolescents could be considered another limitation of the study.

Conclusion

When confronted with the stressful symptoms of PCOS, the participants adolescents of this study showed coping responses such as escaping the problem, depressive mood or coping with the syndrome. Identifying the ways through which these adolescents cope with their syndrome is vital for recognizing the mental health needs of PCOS patients and improving their quality of life.

Acknowledgments

This article is a part of a PhD thesis of Shahid Beheshti University of Medical Sciences, Tehran, Iran. The researchers are grateful to the adolescents who participated in the study and their parents and vice-chancellor of research from the Shahid Beheshti University of Medical Sciences.

Psychology Research and Behavior Management**Dovepress****Publish your work in this journal**

Psychology Research and Behavior Management is an international, peer-reviewed, open access journal focusing on the science of psychology and its application in behavior management to develop improved outcomes in the clinical, educational, sports and business arenas. Specific topics covered in the journal include: Neuroscience, memory and decision making; Behavior modification and management; Clinical

applications; Business and sports performance management; Social and developmental studies; Animal studies. The manuscript management system is completely online and includes a very quick and fair peer-review system, which is all easy to use. Visit <http://www.dovepress.com/testimonials.php> to read real quotes from published authors.

ABSTRACT

Polycystic ovary syndrome (PCOS) is an endocrine disorder linked to type II diabetes and the leading cause of female infertility worldwide. Despite being considered a "lifestyle" disease, PCOS has received scant attention in the social science literature. In India, media accounts citing prominent doctors have expressed concern that the syndrome affects a growing number of urban middle-class Indian women. The general public, doctors, and afflicted women all attribute the condition to stress, lifestyle changes, "Westernization," modernization, and disrupted circadian rhythms. These factors are associated with changes in diets, gender roles, and aspirations since 1991, when the introduction of neoliberal reforms opened up the country to processes of globalization. Women with PCOS have come to be seen as living embodiments of the biosocial stresses associated with modern urban middle-class living, and discourse about PCOS serves as commentary indexing anxieties about social and political-economic shifts in the country. In this paper, based on ethnographic fieldwork in Mumbai, India, with 141 participants from 2012 to 2014, we point to local understanding of PCOS as corresponding to an ecosocial perspective that highlights the structural vulnerabilities of urban middle-class women. Whereas most research on structural vulnerabilities and health has centered on economically and otherwise disadvantaged groups, we use PCOS as a case study to draw attention to the rise of lifestyle disorders linked to the impact of globalization and the pressures of "modern" identities and aspirations among middle-class populations.

1. Introduction

Polycystic ovary syndrome (PCOS), an endocrine disorder with no known cure, is the leading cause of female infertility worldwide (Boomsma et al., 2008; Goldenberg and Glueck, 2008). The syndrome gets its name from multiple ovarian follicles—which look like cysts—often seen upon a gynecological sonography of women with the condition. In a normal menstrual cycle, an egg is released from a dominant follicle. In PCOS, several follicles develop, but none of them becomes dominant (Soulez et al., 1996). There is often a lack of ovulation, and the menstrual cycle may be delayed or absent, resulting in subfertility. The exact etiology of PCOS is unknown, but genetic history and lifestyle factors are known to play a part, and PCOS is considered a lifestyle disease in which genetic predispositions may in fact be activated by lifestyle factors (Balen et al., 2009; Ehrmann, 2005; Franks, 1995).

PCOS is associated with symptoms such as cystic acne, male-pattern hair loss, hirsutism, insulin resistance (precursor to diabetes; cells become less responsive to insulin), and darkened skin patches (acanthosis nigricans). Obesity is both a symptom and a contributory factor and is associated with the worsening of other symptoms. Weight loss is therefore often the first recommended line of management. Management also involves medication, such as hormonal contraceptives to regulate menstruation, ovulation inducers and fertility treatments, and insulin sensitizers. The syndrome is also associated with increased risks of diabetes and cardiovascular disease (Franks, 1995; Legro et al., 1999). Not all women with PCOS manifest all symptoms, and not all women with PCOS are overweight; the syndrome also manifests in a "lean" phenotype (Franks, 1995). An emerging contention is that PCOS results from insulin resistance (Franks, 1995), and some argue that PCOS has a male equivalent associated with early baldness, obesity, insulin resistance, and hormonal changes (Kurzrock and Cohen, 2007; Starka et al., 2005). Thus, although the name suggests that the ovaries are the primary organs affected, PCOS is a multisystem endocrine condition.

2. PCOS in India

Media accounts have suggested that PCOS is on the rise in India and most prevalent among the urban middle and upper classes because of their lifestyles (e.g., [Garari, 2014](#); [Pal, 2013](#); [Times of India, 2012](#)). The prevalence of obesity, overweight, and insulin resistance, which are all associated with PCOS pathogenesis, appear to be higher among members of higher socioeconomic strata living in urban areas; medical researchers have attributed this to more sedentary lifestyles and access to more calorie-dense foods and laborsaving devices in urban and higher socioeconomic populations ([Chopra et al., 2013](#); [Kalra and Unnikrishnan, 2012](#); [Khandelwal and Reddy, 2013](#); [Wasir and Misra, 2004](#)). Although there have been no rigorous community-based epidemiological studies of PCOS published in India to date, a preliminary study among women aged 15–24 from the lower socioeconomic strata in Mumbai placed prevalence at near 22.5 percent (around one in four women) ([Joshi et al., 2014](#)). The authors of the study further observed that given trends in other metabolic disorders and nutritional and physical activity patterns, this prevalence might be even higher among the higher socioeconomic strata. This contrasts quite markedly with a prevalence of around 11 percent in Australia, 8 percent in the UK, and 4 percent in the US, using similar diagnostic criteria ([Wijeyaratne et al., 2013](#)). A prominent gynecologist conducting an epidemiological study of PCOS which compared prevalence across India was interviewed regarding whether the reported rise might be an artifact of improved diagnosis, increased clinician focus, or shifting health concerns in the population. Based on preliminary findings from a year of research, the gynecologist rejected these factors as the primary drivers and confirmed the trend of higher PCOS prevalence among urban middle-to upper middle-class women. Irregular menstrual cycles and subfertility have long been of considerable concern in India (e.g., [Leslie, 1996](#)), and a common reason for medical consultation from both allopathic and ayurvedic practitioners (vaidyas). These practitioners routinely ask patients about symptoms encompassed by PCOS, with allopaths inquiring about them for decades and vaidyas treating them as basic to their humoral science. The yet-to-be published research as well as the observations of several such practitioners interviewed (sample described below) indicated that PCOS was rapidly increasing among urban middle- and upper-class women and that with increasing prosperity, it was beginning to increase among women from the urban lower classes and those living in urbanizing semi-rural areas.

3. Economic liberalization and the emergence of “modern lifestyles”

Most features of the “modern” urban middle-class lifestyles associated with PCOS described by the media are relatively recent to India. Prior to 1991, the Indian economy was largely closed to the world. Economic policy emphasized business regulations, state-driven investment, and import restrictions. The result was a protected economy with limited consumer choice. In 1991, however, a balance-of-payments crisis forced the Indian government to hasten the opening up of the economy. This came to mark a watershed moment referred to as “economic liberalization” or “liberalization.” Since then, there has been a steady shift to a market-driven, globally integrated economy. India has been experiencing rapid economic growth, surfacing as one of the world’s ten largest economies. It has also seen the emergence of new middle classes, with many moving out from below the poverty line ([United Nations Development Programme, 2011](#)).

The resultant higher disposable incomes have contributed to a “nutrition transition” ([Popkin, 1993](#)), with increased consumption

of fats, oils, and sugars ([Griffiths and Bentley, 2001](#); [Nagesh, 2012](#)). Eating out, once rare and circumscribed by caste proscriptions (and for women by lack of access to certain public spaces), has become integral to India’s urban-centered public culture and a marker of middle-classness ([Conlon, 1995](#); [Fernandes, 2006](#)). Meanwhile, increased access to laborsaving devices and cars has reduced physical activity. As a result of the rise in these risk factors, the prevalence of diabetes and cardiovascular disease has escalated among India’s middle classes, especially in urban areas, and public health practitioners have identified these conditions as emerging epidemics ([Celermajer et al., 2012](#); [Khandelwal and Reddy, 2013](#); [Misra and Khurana, 2008](#); [Wasir and Misra, 2004](#)).

Another change following liberalization has been the new availability of previously inaccessible consumer products and services. The advent of satellite television also resulted in a host of new aspirational messages being aligned with this increased consumer choice, and such representations are based on a vision of the nation as tied to consumption, with an idealized portrayal of the urban middle classes ([Fernandes, 2000](#); [Mazzarella, 2003](#)). There has been an increasing acceptance of consumer culture ([Mazzarella, 2003](#); [Venkatesh, 1994](#)), consumption is now closely tied to notions of middle-classness ([Van Wessel, 2004](#)), and new spaces of consumption, such as coffee shops, shopping malls, and multiplexes, form the spaces where this new middle-classness is performed ([McGuire, 2011](#)).

Post-liberalization, the pace of life, especially for the middle classes, has also been affected by the restructuring of the labor market. Leela [Fernandes \(2000\)](#) describes how traditional middle-class public-sector employment in industries such as banking has been marginalized, and the middle classes are now associated with growth in the service sector and private sector white-collar employment. Middle-class ambition has moved away from old, stable government jobs toward jobs in multinationals with expanded chances for career and salary growth. The contemporary job market is characterized by higher job insecurity and emphasis on efficiency. The old, secure middle-class work environment of regular hours has shifted to a highly competitive, unstable environment requiring longer hours and continual improvements in productivity and skills. For women, in particular, the effects have been contradictory and pronounced:

On the one hand, the expansion of service sector and private sector employment has produced employment opportunities for middle class women in metropolitan centers. However, such opportunities often represent coping strategies as households attempt to negotiate increasing household costs and new lifestyle standards that correspond to public representations of the new middle class. This has produced familiar gendered pressures as middle class women must perform a dual shift of paid and unpaid household work. ([Fernandes, 2000:100–101](#))

Liberalization has, however, brought increased opportunities for urban middle-class women in terms of employment. Professional women, working in jobs requiring educational achievement, occupy an important social, economic, and symbolic position in contemporary India ([Radhakrishnan, 2009](#)). The public visibility of women and their freedom to pursue careers is considered another marker of new middle-class identity ([Ganguly—Scrase, 2003](#)). Being well educated and holding a professional position improves both, a woman’s career and marriage prospects ([Radhakrishnan, 2011](#); [Sharangpani, 2010](#)). This has, in turn, affected the age of marriage among the middle classes, as women pursue higher education and work before getting married.

Nevertheless, domestic tasks, child-rearing, and household management are still seen as the responsibility of women, and new

opportunities are circumscribed by the enactment of what has variously been called “respectable femininity” (Radhakrishnan, 2009), “respectable modernity” (Thapan, 2004), or “demure” modernity (Lukose, 2009), which tasks women with balancing their cosmopolitanism and modernity with their familial and community obligations (Donner, 2008). Their ability to successfully navigate these expectations can affect not just their own social standing and reputation but also that of their families (Dickey, 2002); what constitutes a “good balance” between tradition and modernity, however, varies across segments of the middle classes (Gilbertson, 2014). Women are required to exist between two cultural worlds and move seamlessly between them; they must take on the responsibility of being modern without foregoing the traditional. Therefore, increased opportunities for middle-class women place additional burdens upon them and expose them to new aspirations while circumscribing their ambitions.

A number of health problems have been linked, in both popular and medical discourse, to the middle classes and such changes following on the heels of economic liberalization, such as the stresses of consumer aspiration (Chua, 2014) and the “tensions” of balancing self-care with conforming to gender-specific roles (Weaver and Hadley, 2011). In this paper, we document how PCOS is interpreted in India as a condition that is both a reflection and a cost of modern middle-class living. Moreover, despite being one of the most reported endocrine disorders, PCOS has been largely ignored in the social scientific literature, although a rare sociological study in the UK (Kitzinger and Willmott, 2002) found that PCOS challenged women's perceptions of themselves as feminine. We aim to address this gap and adopt an ecosocial approach (Krieger, 1994, 2001), combining a focus on biological, social, ecological, and historical factors, to investigate PCOS as an embodied manifestation of the biosocial stresses of economic liberalization and to examine the structural vulnerabilities associated with PCOS as an emerging health issue in globalizing India.

4. Methods

The present study investigated perceptions of PCOS among community, patient, and practitioner populations in Mumbai—India's commercial and media capital. Fieldwork, conducted by the first author in Mumbai and guided by the second author during field visits, included observation, participant—observation, and interviews with 141 participants from 2012 to 2014. Informants hailed from what may be termed the aspirational middle class. Middle-classness in India is a difficult category to pin down, but scholars of contemporary South Asia treat it as a performative socioeconomic grouping rather than an economic bracket (e.g., Fernandes, 2006; Mazzarella, 2005; McGuire, 2011; Radhakrishnan, 2011). Following understandings gleaned from informants, we define aspirational middle-class status as comprising comfort with English, knowledge of global (mostly American) popular culture, engagement with new spaces and practices of consumption, and at least an undergraduate education and potential for white-collar (usually professional) employment.

Fifty-one participants functioned as a base of informants for in-depth interviews to understand the practices of Mumbai's urban aspirational class and changing patterns of living since economic liberalization. In-depth semi-structured interviews were conducted among a purposive sample of 30 lay informants who did not have PCOS (10 women over age 36, 10 women aged 21–35, 5 men over age 36, 5 men aged 21–35) to gain a sense of what they saw as emerging urban women's health issues and what they knew about PCOS specifically. Semi-structured interviews were also conducted with 30 medical/paramedical practitioners who help diagnose or manage PCOS (5 each of endocrinologists, gynecologists,

dermatologists, dieticians/nutritionists, homeopaths, and vaidyas). Through referrals by key informants who were medical practitioners, we selected practitioners exposed to patients from a range of socioeconomic strata, not just the middle or upper classes. Additionally, in-depth interviews, including illness narratives, were carried out among a core sample of 30 women diagnosed with PCOS (10 never married, 10 ever married without children, 10 ever married with children). Many of these women were visited on several occasions across time points or followed up by phone interviews and observed during their day-to-day interactions. We identified women diagnosed with PCOS aged 21 and above from the urban aspirational middle class using the first author's social circles and through referrals from within social networks. Recruiting this way enabled triangulation of data from interviews with data from observation and participant—observation. It also enabled observation of the degree to which PCOS is hidden or discussed in popular discourse and the body-related practices of core informants in naturalistic settings. Interviews were conducted in informants' homes, offices, coffee shops, or in case of medical practitioners, their clinics or consulting rooms. As informants were drawn from the aspirational middle class, which is comfortable with English, interviews were primarily conducted in that language. Nevertheless, interviews involved significant code switching between English, Hindi, and sometimes Marathi; only the English translations are presented here. The Institutional Review Board of the University of Arizona approved the research. In what follows, we first describe our findings with regard to perceptions of PCOS among lay informants, medical practitioners, and briefly, women with PCOS (a forthcoming publication will explore women's lived experiences of PCOS, including stigma and its effects on identities and relationships, in more detail). Then, we present and discuss data from our investigation as they relate to structural vulnerabilities of modern middle-class lifestyles before summarizing our arguments in the conclusion.

5. Lay perceptions of PCOS

PCOS does not correlate to indigenous categories of illness, but as women's hormonal, reproductive, and menstrual issues have always been significant in India, we approached PCOS as a subset of these. To account for a possible unfamiliarity with the term PCOS as a diagnostic category, we solicited informants' opinions on major emerging urban women's health issues before asking specifically whether they had heard of PCOS. In some cases, informants mentioned PCOS as a key health problem before the interviewer mentioned the condition. Overall, PCOS came across as a recognized condition (70%; see Table 1), especially among women and men aged below 35—informants heard of PCOS either through friends or relatives with the condition or through media reports. Some lay informants pointed to a rise in hormonal/menstrual disorders as a “new normal” for the middle classes resulting from a hectic modern lifestyle. In particular, informants blamed these disorders on the stress of women having to juggle the responsibilities of home and work. As one 57-year old female informant put it:

Working plus there is the home also. I feel that sometimes they cannot tackle both. There is stress of both these sides....Basically, life has become stressful. These days basically the lifestyle has become very stressed out. One thing I feel is that these days, women feel they can do everything. They can do—it is not that they are different from the males of the world, but they themselves have more expectations out of themselves. I feel in that stress really increases a lot.

Table 1

Themes in lay perceptions of women's hormonal/menstrual issues.

Theme	Women over 36	Women under 35	Men over 36	Men under 35	Total
Total	10	10	5	5	30
Heard of PCOS	8 (80%)	8 (80%)	1 (20%)	4 (80%)	21 (70%)
Hormonal/menstrual problems are increasing	6 (60%)	7 (70%)	3 (60%)	3 (60%)	19 (63%)
Increased stress	10 (100%)	5 (50%)	4 (80%)	3 (60%)	22 (73%)
Unhealthy diet	7 (70%)	4 (40%)	4 (80%)	1 (20%)	16 (53%)
Irregular meal timings	3 (30%)	1 (10%)	1 (20%)	—	5 (17%)
Lack of exercise	2 (20%)	4 (40%)	3 (60%)	1 (20%)	10 (33%)
Lack of sleep routine	2 (20%)	2 (20%)	—	—	4 (13%)
Pollution/food additives	5 (50%)	1 (10%)	2 (40%)	2 (40%)	10 (33%)
Over-reliance on biomedicines	3 (30%)	—	1 (20%)	—	4 (13%)

Forty-two year old Rahul also felt that women were “leading two lives—one with the husband and one with the rest of the family.” By this, he meant that women were required to fill both the role of the dutiful traditional mother and daughter-in-law and the modern wife: “After coming home [from work] and cooking, they [women] still have to get ready and go out to a party if the husband wants to, so he can show off his hot wife.”

The theme of the stresses of transition was also common. One male informant over 36 said that in India,

Society is in transition. You want to follow the norms in terms of lifestyles and all that, but culturally, there are still pressures on women....the percentage of working women in urban areas is much higher, but the women are still solely responsible for everything at home.

A 28-year old male lawyer stated:

There's financial, family stress, traveling stress...it has just increased over time. More women are working...Now we have smaller [nuclear] families, so you have to do everything for yourself—earlier, non-working members used to take care. There are more work pressures on women also.

In addition to mentioning the pressures on working women to shoulder responsibilities for the home and the workplace, informants mentioned intense competition for education and jobs and the pressures of consumerism. Prachi, an informant over 36, thought that urban individuals had more financial pressures and needs because of “keeping up with the Joneses” and being “constantly exposed to new things.” All this negative stress, she said, had somatic results, with “hormones playing havoc with your body.” Leela agreed: “There is a lot of peer pressure. Competition is a lot these days, for admissions [for higher education], jobs. There is also this competition that what their friends have, they want.”

Farhana, a woman under 36, echoed many informants' sentiments when she compared contemporary urban women's food choices with those of an earlier generation: “We end up eating junk food. Our grandmothers and mothers—bread they would not even consider as a food. It was always *roti*. Now, we only want bread for breakfast. There is no time to make *rotis*.” Yet others spoke of “no proper eating time” and that “food timings are not proper.” Thirty-three year old Preeti combined several observations in saying that PCOS “has a lot to do with stress and [a lack of] routine,” including “sleeping late at night, not having meals at regular times.” Overall, informants blamed stress; faulty diets (especially eating out); pollution, pesticides, and food additives; lack of exercise; and the lack of a routine (see Table 1). These observations are not without merit; there is evidence to link PCOS and insulin resistance to weight gain, lack of exercise, skipped/delayed meals, sleep deprivation/late nights, stress, and endocrine disruptors in the

environment (Bensona et al., 2009; Jacobowicz et al., 2013; Kandaraki et al., 2010; Moran et al., 2006; Spiegel et al., 2009).

6. Medical practitioners' perceptions

In our interviews with medical practitioners, they also spoke of a rise in PCOS cases, especially among the urban middle classes, associated increased prevalence with “modern lifestyles,” “changing lifestyles,” “urbanization,” and “Westernization,” and blamed unhealthy diets, sedentary habits, the busy pace of life, lack of regularity in meal and sleep timings, insufficient sleep, and even changing gender roles (see Table 2). Diet was the most commonly cited factor—practitioners blamed eating out, junk food, an unbalanced diet, and eating more because of material prosperity. Dietitian Asha Parekh quipped that people were going from “*homo sapiens* to *homo junkiens*,” with a move toward food that was “high fat, high carbs, fructose-based” as well as fast food. Along with diet issues, most informants also commented on a lack of physical activity. Gynecologist Dr. Keskar pointed out that these issues start young:

I think lifestyle changes are the main cause. The type of foods the people are eating, more of junk food, not a very balanced diet, lack of exercise, too much of sedentary work, like, I see a lot of young girls who are studying, so they are—between the school, tuitions [academic coaching classes]—they have no time for exercise whatsoever. And maybe nowadays we have more of a nuclear family and small families, so I think [there is an] overindulgence by parents in feeding [their children].

Vaidya Dr. Dixit added another element—that of distracted eating:

These days, people, even when eating, they sit in front of the TV and eat. Meaning what happens is that there is actually no attentiveness to the food. Food is there, no? That has to be chewed 32 times. That makes a difference. But then you are eating while watching TV or on one side you are working on your laptop and another side you are eating.

A lack of regularity in timings was also mentioned, especially by all the dietitians and ayurvedic practitioners that were interviewed. Dr. Sapre, a vaidya, observed, “Circadian cycle [the body clock] is disturbed; that is main, important in PCOS.” She added that by “late sleeping, not eating at regular times, working at times of rest,” individuals “waste dopamine,” causing endocrine issues. Similarly, endocrinologist Dr. Prasad talked of the fact that, “Nowadays teenagers have a lot of distractions. They are constantly getting engaged because of internet and social media like Facebook,” which contributed to disturbed circadian rhythms, affecting the regularity of hormonal and menstrual cycles. In a similar vein, four ayurvedic

Table 2

Themes in medical practitioners' views of PCOS.

Theme	Endocrinologists	Gynecologists	Dermatologists	Dietitians	Homeopaths	Vaidyas	Total
Rise in PCOS prevalence	3 (60%)	5 (100%)	4 (80%)	5 (100%)	5 (100%)	5 (100%)	27 (90%)
Unhealthy diet	5 (100%)	5 (100%)	5 (100%)	5 (100%)	5 (100%)	5 (100%)	30 (100%)
Lack of exercise	5 (100%)	5 (100%)	5 (100%)	4 (80%)	5 (100%)	5 (100%)	29 (97%)
Irregular sleep/meal times	2 (40%)	1 (20%)	2 (40%)	5 (100%)	3 (60%)	5 (100%)	18 (60%)
Increased stress	1 (20%)	3 (60%)	4 (80%)	5 (100%)	1 (20%)	5 (100%)	19 (63%)
Pollution/food additives	1 (20%)	—	3 (60%)	1 (20%)	—	1 (20%)	6 (20%)
Over-reliance on biomedicines	—	—	—	—	—	2 (40%)	2 (7%)
Tight clothes	—	—	—	—	—	2 (40%)	2 (7%)
Total	5 (100%)	5 (100%)	5 (100%)	5 (100%)	5 (100%)	5 (100%)	30 (100%)

practitioners commented that PCOS was much more common among women in call centers or information technology jobs because of their irregular timings and night shifts.

Medical practitioners also blamed stress for PCOS. Dermatologist Dr. Desai spoke about the various stresses experienced by women:

What happens is, when you're living in a city like Bombay [Mumbai], the day-to-day life is also quite stressful and specially for women. Cause they are managing home, and they are managing outside. And there is a lot of peer pressure, there is a lot of pressure regards to work, and in India, of course, work is totally done by the woman, nobody is going to share the work, the household work. And then they are earning also—I mean the financial aspect and the work outside is of course also there, so it's double work. That is a lot of stress. It's not only women. Even the girls I see, I think the stress in the teenage population is also quite high. That goes for both boys and girls, but girls then get PCOD [PCOS], whereas boys would probably only manifest only as acne and hair loss—male-pattern hair loss also I'm seeing very early.

Dr. Gopalan, a gynecologist, highlighted examination stress: "Lot of stress in the lifestyle. There is a lot of education stress, any stress of that kind."

Another aspect of stress to come up was that of the stress caused by women's aspirations, as they demanded more of themselves and then were under the pressure of their own expectations. Dermatologist Dr. Fernandes had an interesting take that involved a feedback loop between cultural practices, behaviors, and biological outcomes: "Women want to excel but they have very little time for everything—they have to do more than they can. Their aggression fuels testosterone, which then energizes these traits." Two homeopaths suggested that PCOS was the body's response to defective features of modernization that were resulting in the masculinization of female attitudes and behaviors; for example, Dr. Shah felt that PCOS resulted from women "following the male pattern [of behavior] that is too aggressive, too dominating." Another theme was of endocrine disruptors in the environment and pollution, pesticides, and food additives (particularly hormones in dairy). Two ayurvedic practitioners also mentioned tight clothes that constricted the uterine area and reliance on painkillers for menstrual pain, which interfered with the body's processes.

7. Patients' perceptions

Women with PCOS also viewed it as a condition that was part and parcel of modern urban middle-class living. They regularly mentioned the fact that they had heard, read, or been told by their doctors that around one in four urban Indian women had PCOS. As 32-year old Sucheta put it, "I did realize it's very common and

[nearly] everybody has it and it's okay to have it." Many informants took similar solace in PCOS being common, especially in their social milieu. The condition's association with modern living (rather than patient characteristics), its ubiquity, and the fact that it was considered medically manageable (through medical cosmetic and fertility treatments), meant that none of the informants considered or experienced PCOS to be a source of stigma, and they were very comfortable talking about the condition with others, including boyfriends, spouses, friends, and colleagues.

While informants associated poor eating habits and lack of exercise with their PCOS, most were unaware of the association between PCOS, a family history of diabetes, and increased risks of diabetes. Informants spoke at length of the difficulties in making the lifestyle changes required to manage their PCOS given their hectic schedules. The attitude of vivacious 23-year old Jaclyn was typical: "I feel stressed about it [a hectic lifestyle]. I need a work-life balance but that doesn't mean that I should compromise on my likes." She had not made any lifestyle changes—whether related to diet or physical activity—to manage the condition, relying instead on medication. It is beyond the scope of this paper to deal with the experiences and perceptions of women with PCOS in detail—these will be dealt with in a forthcoming publication—but fieldwork revealed that her strategy of accommodating rather than actively managing PCOS was not unusual. This usually entailed turning to medication or cosmetic technologies to manage symptoms or erratic attempts at basic dietary changes (such as reducing eating out) or increasing exercise (such as daily walks).

8. PCOS and structural vulnerabilities among the urban middle classes

Scholarship within medical and biocultural anthropology has long recognized that the body literally incorporates the social and material world it inhabits into its biology (e.g., Baer, 1996; Dressler et al., 2005; Farmer, 1999; Lock and Kaufert, 2001). The histories and socioeconomic contexts of individuals (and groups) are reflected in their bodies, and bodies cannot be understood in isolation from their contexts. By noting that urban middle-class women are the population most likely to be affected by PCOS, study participants were pointing to a health disparity and implicating urban environments and middle-class lifestyles in this disparity. The factors they associated with a rise in PCOS and women's health issues highlighted the role of rapid social and structural changes in India since liberalization, along with environmental concerns such as those regarding food additives and the overuse of pesticides. In many ways, their popular epidemiological (Brown, 1997) views are in concert with the ecocosial approach to epidemiology espoused by Nancy Krieger.

Nancy Krieger (1994, 2001) has criticized theories of the social production and political economy of health that highlight political-economic and sociocultural factors in illness distribution for

failing to focus on specific political and economic determinants in pathways to pathogenesis, rendering biology opaque. An ecosocial framework recognizes disease distribution as determined through multiple levels of influence, including biological, environmental, social, and historical factors. It combines analysis through biological pathways of the embodiment of social and environmental forces, attention to how social inequalities result in differentiated exposures, susceptibilities, and resistance to illness, and emphasis on the responsibility of the sociopolitical system on patterns of disease. We would argue that to truly understand PCOS in India, an ecosocial approach is necessary to situate the emergence of the condition as a significant health issue within the specific circumstances and biological pathways in which PCOS-affected bodies are enmeshed. To illustrate this point, we provide examples related to the impacts of examination pressures and modern expectations on urban middle-class women.

Research revealed that pernicious ecosocial feedback loops implicated in PCOS start early in the life course. In India, major school-finishing examinations are taken in the 10th and 12th grades. After these, students apply for admissions to educational institutes and fields of study—their exam results determine their ability to enter the educational streams of their choice. Additionally, admission to professional courses, such as medicine and engineering, depends upon performance in competitive entrance exams that occur directly after the 12th exams. Education is valued as both a marker of and pathway to success, particularly among the middle classes, and educational expectations of students are very high. Combined with the unforgiving examination system, this results in an intensely competitive educational environment. Furthermore, new expectations on girls to do well have made competition even fiercer, with boys and girls now competing for limited admissions.

As a result of this intense emphasis on academic performance, children lead increasingly sedentary lives as they enter grade six, if not sooner (see also Swaminathan et al., 2011). After-school academic coaching classes (“tuitions”) are common as early as the primary school level, and by secondary school, tuitions are the norm. Numerous tuitions, heavy homework loads, and extensive examination preparation leave little time for outdoor play or sports. A lack of available open spaces compounds the problem. The average age at menarche across parts of India has been reported to be in the 9–15 range (Bagga and Kulkarni, 2000; Dambhare et al., 2012; Khadilkar et al., 2006; Rokade and Mane, 2008). Thus, the formative years before and after menarche correspond to a time of drastically reduced movement. Informants also suggested that the time around menarche results in more gender-segregated play, with physical activity for girls dropping even more than it does for boys. Physical education classes cannot fill the gap, as few schools have the requisite space, and the time dedicated to physical education is at best two hours a week.

The time around menarche is also a period of decreased insulin sensitivity, which typically returns to pre-pubertal levels a couple of years after menarche (Goran and Gower, 2001). Weight gain (from insulin resistance and lack of physical activity) further decreases insulin sensitivity, leading to a negative spiral. PCOS, which is linked to reduced insulin sensitivity, even for lean women, is also implicated in this spiral. This makes menarche a particularly vulnerable time, but this is when examination-related stress is most intense. This is even more so for girls from the middle classes. Although studies show that students in India are often stressed or depressed in the years of crucial exams (Bhasin et al., 2010; Verma et al., 2002), middle-class students suffer more school-related stress than their upper- and lower-class counterparts (Deb et al., 2010). Furthermore, this stress is reinforced by a lack of physical activity and hectic schedules. Sleep cycles are disturbed, as students

study into the night and wake early, functioning on insufficient sleep—another factor contributing to insulin resistance and PCOS. Furthermore, students face high degrees of surveillance; parents supervise studying, and activities that can be sources of entertainment and leisure—such as socializing, television viewing, or play—are heavily curtailed. Typically, eating is the only sanctioned source of pleasure, and parents offer junk food and sugary treats to students to motivate or reward grueling examination preparation. Overall then, among the middle classes, adolescence—a key point in the developmental cycle—is precisely when the susceptible body is buffeted on all sides by multiple concurrent stressors.

For women of the aspirational middle class, stressors continue to accumulate across life stages, even after adolescence. The need to display empowered “modern” identities that correspond to the new emphasis on women’s education and employment results in competition for limited admissions into institutes of higher education into the early 20s, followed by struggles to build careers. Meanwhile, new work structures result in very little time (and energy) for exercise, skipped or late lunches (at 4 or 5pm), long hours, and late dinners (up to 11pm). Sedentary jobs that involve working late or taking work home at night and over weekends are the norm. At the same time, new communications technologies, such as email and mobile phones, allow individuals to be constantly accessible for work.

Furthermore, the lifestyle standards coming from representations of the new hegemonic middle class have led to greater desire for consumer goods and the financial pressures of such consumption. Living up to this consuming middle-class ideal has resulted in new ways of enacting “modern” identities at the site of the body. The emergence of social media has meant that the enactment of these identities is publicly chronicled for all to see. Eating out, staying up late, working hard, and playing harder were common among informants under the age of 35 (especially those without children), and these are all characteristic of new “modern” identities.

Informants spoke of their inability to make the lifestyle changes required to achieve peak wellness; eating on time, sleeping early, reducing stressful activities, and exercising religiously were deemed impractical to their circumstances. As one informant observed, “This is the age [the 20s and 30s] you can’t be slowed down, and thinking of health means you have to slow down.” It was not just a question of work or situational factors but also social pressures. To be concerned with eating or sleeping on time or not being seen consuming resulted in being teased, labeled, or left out. One informant with PCOS stated, “I’m always the first in the house party to leave, and I’m labeled by my friends for it.” Individuals were called terms such as “*behenji*” (Hindi word meaning sister with connotations of provinciality and lack of attractiveness), “*paavam*” (Tamil word with connotations of naivety and pity), “aunty” (meaning old and frumpy, which also points to a generational divide), or having “no life,” for not wanting to stay up late, party, drink, eat fast food, or eat out.

Even beyond the 20s, stressors continue to accumulate. Once married, women bear the burden of fulfilling multiple roles in their home and work lives, juggling workplace expectations with household responsibilities and familial obligations. Meanwhile, urban living exposes these women to an assortment of endocrine disruptors (present in pesticides, plastics, and other petrochemical residues) and constant sensory stimuli in the form of city noises, billboards, and bright lighting. Long urban commutes exacerbate the problem. Together, these elements synergize to create a perfect storm of health pressures implicated in PCOS. They also amplify the long-term risks of PCOS—such as the risk of diabetes—and the cumulative effect of exposure to these stressors can affect the illness trajectory of PCOS, worsening outcomes.

9. Conclusion

Urban middle-class living is placing unique burdens on Indian women that are associated with rising rates of PCOS in both popular and medical discourse. Rather than emphasizing genetic predispositions, popular and medical discourse on PCOS in India highlights changes in the lifestyles of the urban middle classes following economic liberalization, particularly disrupted meal and sleep routines and new stresses on women resulting from competition for education and jobs, consumerism, and juggling responsibilities of home and work. These perceptions also point to specific structural vulnerabilities linked to the pressures of aspiration and globalization on the urban middle classes, such as those associated with examination pressures and modern expectations of women. We have focused on these perceptions of PCOS and how these tie in to an ecosocial framework for understanding the condition as related to modern middle-class living.

While such an interpretation is supported by preliminary scientific data and observations from medical practitioners, more research is required into PCOS prevalence, the stressors of modern living that relate to it, and how these vary by class. It would also be interesting to examine the history of PCOS as a diagnostic category across India and to investigate patterns in perceptions of PCOS amongst different types of medical practitioners. Furthermore, an apparent rise in PCOS needs to be viewed in relation to other problems associated with the health transition in India. India is facing an epidemic of diabetes with a notable rise in prevalence that is related to increased urbanization, expansion of the middle classes, and the changing lifestyles accompanying these trends (Ramachandran, 2005).

We would argue that although urban middle-class women (especially women of the urban aspirational class) are in a position of relative privilege in India, they nevertheless face structural vulnerabilities resulting from the health pressures of globalization and economic liberalization. Indeed, these structural vulnerabilities and their associated health risks can even be thought to result from their position of privilege and the gains made from economic liberalization. To date, research on structural vulnerabilities, health disparities, and syndemics (e.g., Baer, 1996; Farmer, 1999; Holmes, 2011; Kim et al., 2000; Mendenhall, 2012; Mendenhall et al., 2012; Navarro, 2002; Quesada et al., 2011; Singer and Clair, 2003; Weaver and Mendenhall, 2014) has focused on populations that are socially or economically marginalized. In the age of the anthropocene, such a focus is dangerously limited. To truly address the human costs of the rise of PCOS and other metabolic disorders, medical anthropology needs to move beyond the underprivileged to investigate other structural vulnerabilities embroiled in the health pressures of globalization and the human manufacture of risks.

Acknowledgments

We are very grateful to our informants for their participation in the study. We also thank Mimi Nichter and the anonymous reviewers for their critical inputs and feedback. A research scholarship from the School of Anthropology, University of Arizona, helped offset the costs of the research presented in this paper.

ABSTRACT

40 **Objective:** The Androgen Excess Society (AES) charged a Task Force to review all available
41 data and recommend an evidence-based definition for Polycystic Ovary Syndrome (PCOS),
42 whether already in use or not, to guide clinical diagnosis and future research.

43 **Participants:** Expert investigators in the field.

44 **Evidence:** Based on a systematic review of the published peer-reviewed medical literature,
45 by querying MEDLINE databases, to identify studies evaluating the epidemiology or phenotypic
46 aspects of PCOS.

47 **Consensus Process:** The Task Force drafted the initial report, following a consensus
48 process via electronic communication, which was then reviewed and critiqued by the AES
49 Board of Directors. No section was finalized until all members were satisfied with the
50 contents, and minority opinions noted. Statements were not included that were not
51 supported by peer-reviewed evidence.

52 **Conclusions:** Based on the available data, it is the view of the AES Task Force on the
53 Phenotype of PCOS that there should be acceptance of the original 1990 National Institutes of
54 Health criteria with some modifications, taking into consideration the concerns expressed in the
55 proceedings of the 2003 Rotterdam conference. A principal conclusion that PCOS should be
56 firstly considered a disorder of androgen excess or hyperandrogenism, although a minority
57 considered the possibility that there may be forms of PCOS without overt evidence of
58 hyperandrogenism, but recognized that more data are required before validating this
59 supposition. Finally, the Task Force recognized, and fully expects, that the definition of this
60 syndrome will evolve over time to incorporate new research findings.

61 **Abstract:** 245 words

62

63 The disorder that eventually would be known as the polycystic ovary syndrome (PCOS) was
64 initially described by Stein and Leventhal in 1935 (1). There is little disagreement that PCOS
65 should be considered a syndrome, that is, a collection of signs and features, where no single
66 test is diagnostic. In essence, the whole (or global assessment) is greater than the sum of the
67 individual features. However, establishing a clear, contemporaneous, and evidence-based
68 definition for this syndrome has important clinical and investigational implications. Nonetheless,
69 the definition of PCOS has continued to generate significant controversy (2-4).

70 Clinically, diagnosing a woman as having PCOS implies an increased risk for infertility,
71 dysfunctional bleeding, endometrial carcinoma, obesity, type 2 diabetes mellitus (DM),
72 dyslipidemia, hypertension, and possibly cardiovascular disease (CVD) (5). Furthermore, it has
73 important familial implications, principally, but not exclusively, for her sisters and daughters (6-
74 8). Finally, a diagnosis of PCOS may mandate life-long treatments (e.g. the use of insulin
75 sensitizers) and may negatively affect her ability to access healthcare coverage, principally in
76 capitalistic markets. Consequently, the diagnosis of PCOS should not be assigned lightly, and
77 diagnostic criteria should be based on robust data.

78 A judicious definition of PCOS is also essential to guide current and future research. The
79 inclusion of patients whose definition, characterization, and selection criteria are unclear
80 continues to plague the PCOS scientific literature. This issue is becoming critical as the field
81 moves to the establishment of larger clinical trials, and to studies of the molecular biology and
82 genetic nature of the disorder. In addition, definitions not based on clear-cut evidence have the
83 potential effect of discouraging future and needed research into the nature of the disorder, its
84 breadth and its phenotype. Consequently, a contemporaneous definition based on what is
85 currently known will benefit future investigation in this area.

86 The Androgen Excess Society (AES) is an international organization dedicated to promoting
87 knowledge, and original clinical and basic research, in every aspect of androgen excess
88 disorders, such as the polycystic ovary syndrome, non-classic adrenal hyperplasia, idiopathic

89 hirsutism, and premature adrenarche. The Society was founded in 2000, and currently has over
90 200 members principally composed of investigators whose primary focus is the study of
91 androgen excess disorders and polycystic ovary syndrome. The Board of Directors of the
92 Society appointed the Task Force on the Phenotype of PCOS and charged it with reviewing all
93 current data concerning the phenotype of PCOS to answer the query: 'What different
94 component phenotypes (features) constitute PCOS, based on the available published and peer-
95 reviewed data, assuming that long-term morbidity is the anchor?' The following summarizes the
96 results of this Task Force's yearlong investigation.

97

98 **1) PROCESS**

99 The Board of Directors of the AES appointed a seven member Task Force of experts in
100 the field, intentionally including international investigators. Members of the Task Force and the
101 Board of Directors constituted the Writing Committee. No external funding was accepted for this
102 project. The evidence gathered was based on a systematic review of the published peer-
103 reviewed medical literature to identify studies evaluating the epidemiology or phenotypic
104 aspects of PCOS, by querying MEDLINE databases. The Medical Subject Headings (MeSH®)
105 heading used was 'polycystic ovary syndrome' [C04.182.612.765], with the following limitations:
106 Major topic AND adolescent (13-18 years) OR Adult (19-44 years) AND English AND
107 Publication Date from 1980 to 2005 AND Core Clinical Journals AND Female AND Humans). A
108 total of 527 articles were initially available for this review, although additional studies (cross-
109 references and those published in 2006) were also considered. Emphasis was placed on those
110 studies which included greater than 100 subjects, although in some areas no studies of this
111 size were available, and the paucity of data was noted. Studies in which epidemiologic (e.g.
112 prevalence) data could not be ascertained or calculated, or which reported on the same
113 parameter in mostly the same population as a larger study, were eliminated from consideration.
114 Unpublished data or personal communications were not included. Although only studies

115 where the criteria for PCOS were clearly stated were included, we did not define the
116 disorder *a priori*, and rather used each individual investigator's own definition. In essence,
117 we allowed PCOS to have a variety of definitions in order to more clearly define common
118 phenotypes or features irrespective of the definition used.

119 The Task Force drafted the initial report, following a consensus process via electronic
120 communication, which was then reviewed and critiqued by the AES Board of Directors. No
121 section was finalized until all members were satisfied with the contents, and minority opinions
122 noted. Statements were not included that were not supported by peer-reviewed evidence.
123

124 **2) CURRENT DEFINITIONS OF PCOS**

125 Currently, two definitions of PCOS are in widespread use. The first arose from the
126 proceedings of an expert conference sponsored in part by the National Institute of Child Health
127 and Human Disease (NICHD) of the U.S. National Institutes of Health (NIH) on April 16-18,
128 1990. During the meeting all participants were surveyed regarding their perception of what
129 features formed part of PCOS, and Drs. Zawadski and Dunaif summarized these findings in the
130 meeting proceedings (9). They concluded that the major criteria for PCOS "*should include (in*
131 *order of importance) : i) hyperandrogenism and/or hyperandrogenemia, ii) oligo-ovulation, [and*
132 *the] iii) exclusion of other known disorders*". This survey identified PCOS as an androgen
133 excess disorder of exclusion, with an ovarian etiology and/or consequences.

134 Another expert conference was convened in Rotterdam, The Netherlands, May 1-3, 2003
135 sponsored in part by the European Society for Human Reproduction and Embryology (ESHRE)
136 and the American Society for Reproductive Medicine (ASRM) (10, 11). The meeting
137 proceedings recommended that PCOS be defined when at least two of the following three
138 features were present: i) oligo and/or anovulation, ii) clinical and/or biochemical signs of
139 hyperandrogenism, and iii) polycystic ovaries. These criteria also recognize that other androgen
140 excess or related disorders should be excluded prior to assigning the diagnosis of PCOS.

141 Whether these definitions are consistent with currently available data, and whether they are
142 overly narrow or unjustifiable broad, were explored by the Task Force.

143

144 **3) THE ESSENTIALS OF DEFINING A SYNDROME**

145 The difficulties and intricacies of defining a syndrome is a challenge that many other
146 organizations have and continue to struggle with (12-21). A syndrome may be defined by: a)
147 historical usage in medical practice and/or literature, b) expert knowledge and consensus
148 processes, or c) evidence-based, via analysis of published data.

149 One evidence-based approach to establishing the limits of a syndrome is to determine
150 whether the various phenotypes defined by the criteria behave in a manner suggestive that they
151 are part of the same disorder. Firstly, all possible phenotypes generated by the definition of a
152 syndrome are catalogued and examined. Secondly, a feature not included in the definition (i.e.
153 the 'anchor') is chosen to serve as the common thread (e.g. inheritance pattern, morbidities, a
154 response to intervention). Essentially, for the phenotypes to be part of the same syndrome they
155 should have a common thread above and beyond the commonality of their definition (which in
156 itself may be arbitrary). For example, if the various phenotypes of PCOS have the same overall
157 morbidity (e.g. insulin resistance and hyperinsulinism) then we could consider these phenotypes
158 to reflect the same overall syndrome. The Task Force opted for this latter approach in
159 determining what phenotypes (and hence, what criteria) reflected PCOS based on current data.

160 Essentially, the Task Force considered that PCOS was defined by all those component
161 phenotypes which potentially signaled an increased risk for insulin resistance and the resulting
162 metabolic abnormalities. This is not to say that all individuals with a component phenotype had
163 to demonstrate metabolic abnormalities, but that the phenotype as a group should demonstrate
164 an increased prevalence of markers for metabolic dysfunction. A similar approach has been
165 taken when defining the limits of the metabolic syndrome (22).

166

167 **4) THE FEATURES OF PCOS**

168 The Task Force recognized four key features of PCOS: a) ovulatory and menstrual
169 dysfunction, b) hyperandrogenemia, c) clinical features of hyperandrogenism, and d) polycystic
170 ovaries. Clinically evident menstrual dysfunction, such as oligo-amenorrhea or abnormal uterine
171 bleeding, can be observed in a majority of patients with PCOS.

172

173 a) Ovulatory and menstrual dysfunction: In large series of patients diagnosed with
174 PCOS, approximately 75% have clinically evident menstrual dysfunction (23-37) (**Table 1**).
175 Current data also suggests that ~20% of women with PCOS will present with a history of
176 apparent eumenorrhea (i.e. subclinical oligo-anovulation) (23, 25-39) (**Table 1**). In clinical
177 practice, the presence of anovulation in clinically hyperandrogenic (i.e. hirsute) eumenorrheic
178 women may be determined by measuring a serum progesterone level sometime during days 20
179 through 24 of the cycle. If anovulation is present, it may be prudent to confirm this finding with a
180 repeat study.

181

182 b) Hyperandrogenemia: Elevated circulating androgen levels are observed in
183 approximately 60-80% of PCOS patients(**Table 2**) (35-37, 40-42). The vast majority of the
184 abnormal values are in the form of free testosterone (T), with the sole measurement of total T
185 adding a limited amount to the diagnosis (36).

186 The value of also measuring androstenedione is unclear, but it may increase the number of
187 subjects identified as hyperandrogenemic by ~10% (43). Approximately 25% of patients with
188 PCOS will demonstrate supranormal levels of the androgen metabolite DHEAS (44) which may
189 be the sole abnormality in circulating androgens in ~10% of these patients (36, 43).
190 Alternatively, measuring the level of DHEA, a weak androgen primarily of adrenal origin, has
191 limited diagnostic value.

192 The Task Force noted that the measurement of circulating androgen levels, including free T,
193 was to be used only as an adjuvant for the diagnosis of hyperandrogenic disorders, and never
194 as the sole criterion for diagnosis or in lieu of the clinical assessment. This recommendation
195 reflects the fact that between 20% and 40% of women with PCOS will have androgen levels
196 within the 'normal' range (36), and that assays for androgens, particularly total T, tend to be
197 highly variable and inaccurate (45-47)

198

199 c) Hirsutism, acne and androgenic alopecia: Clinical features of hyperandrogenism
200 frequently seen in PCOS include hirsutism, acne, and androgenic alopecia. Among women of
201 White, Black, Southern Asia (Pakistani, Bengali, Gujarati, or Dravidian Indian), Maori, or Pacific
202 Island descent, with PCOS defined by the NIH criteria, approximately 60% are found to be
203 hirsute (**Table 2**) (24-26, 29-32, 35-37, 40-42, 48-50). We note that the degree of facial and
204 body terminal hair growth in women represents a continuum, and that a value as low as three,
205 using the modified Ferriman-Gallwey (mFG) score, may be considered abnormal (51). However,
206 most investigators have used the 95th percentile of controls as the upper normal limit, which
207 corresponds to an mFG score of 6-8 in the White or Black populations studied (51, 52).

208 Acne affects 15-25% of PCOS patients (38, 39, 53) although it is unclear whether the
209 prevalence of acne is significantly increased in these patients over that observed in the general
210 population (54-58). Finally, androgenic alopecia is a recognized sign of PCOS (39, 40, 59-61),
211 although the prevalence of this abnormality in PCOS is unclear. In one study of 257 patients
212 undergoing treatment for hyperandrogenic symptoms, only 5% complained of hair loss (39).
213 Further studies are needed to better define the prevalence of acne and androgenic alopecia in
214 PCOS.

215

216 d) Polycystic ovaries: Current data suggests that polycystic ovaries detected by transvaginal
217 ultrasonography may be found in ~75% of women with a clinical diagnosis of PCOS (25, 26, 30-

218 32, 35, 37, 42, 49, 62-66) (**Table 3**). However, the Task Force also recognized that the false
219 positive rate is relatively high, as evidenced by the high rate of polycystic ovaries in the general
220 population (see above). The Task Force noted that the diagnosis of polycystic ovaries requires
221 strict criteria (65, 67), and should not be assigned based solely on a 'polycystic' or 'multicystic'
222 appearance of the ovary. The diagnosis of polycystic ovaries has been recently reviewed (68).
223 The most commonly used criteria today are those proposed by Dewailly and colleagues (65),
224 and reaffirmed in the Rotterdam 2003 consensus (10, 11), which indicate that polycystic ovaries
225 can be established when at least one ovary demonstrates an ovarian volume of greater than 10
226 cm³ (mL), or 12 or more follicles measuring 2-9 mm in diameter.

227 The Task Force noted that the diagnosis of polycystic ovaries should not be considered
228 more or less objective than that of hirsutism or hyperandrogenemia. Witness the changing
229 definition of 'polycystic ovaries' (67) and the 10% to 30% of women with PCOS who do not
230 demonstrate polycystic ovaries on ultrasound (68). In addition, there are also technical
231 limitations to this parameter, including the fact that at least 20% of women will refuse
232 transvaginal ultrasonography (69) and that most clinicians (even gynecologists) do not perform
233 their own ovarian ultrasonography, relying instead on the expertise of radiologists who may be
234 less familiar with the diagnosis.

235 Finally a number of other features of PCOS have been recognized, including gonadotropin
236 abnormalities, insulin resistance, and obesity. These features have not formed part of any of the
237 recognized definitions to date, and the Task Force found no evidence to suggest that this should
238 be otherwise.

239

240 6) PCOS: EXCLUSION OF OTHER ANDROGEN EXCESS AND RELATED DISORDERS

241 In addition to PCOS, there are a number of other disorders of androgen excess in
242 women, including the adrenal hyperplasias (CAHs), the syndromes of severe insulin resistance,
243 and androgen-secreting neoplasms (ASNs); that have the appearance of androgen excess (e.g.
244 idiopathic hirsutism); or that have not yet been well characterized (e.g. idiopathic
245 hyperandrogenism). There are also a number of other disorders that may result in ovulatory
246 dysfunction, including hyperprolactinemia and thyroid abnormalities. These disorders account
247 for approximately 5-10% of all patients with androgen excess (24, 26, 39-42, 60, 70-76) (**Table**
248 **4**), and should be excluded when establishing the diagnosis of PCOS.

249 Although not a true disorder of androgen excess, idiopathic hirsutism (IH) should be
250 excluded when assessing a hirsute patient for PCOS. Using the NIH 1990 criteria for PCOS, IH
251 can be strictly defined as hirsutism, in the presence of regular ovulation and in the absence of
252 hyperandrogenemia (77), such that approximately 5-7% of hirsute patients will have IH (27, 28,
253 77). It is possible that these patients may also need to demonstrate normal ovarian morphology
254 on ultrasound, which would reduce their prevalence even further.

255

256 7) A PHENOTYPIC APPROACH TO DEFINING PCOS: TASK FORCE RECOMMENDATIONS

257 The Task Force considered all data published and summarized above, emphasizing larger
258 epidemiologic and phenotypic studies, in arriving to its conclusions and recommendations
259 regarding the phenotype of PCOS. These include the following:

260

261 a) **That PCOS is a hyperandrogenic disorder:** The Task Force concluded that PCOS was
262 above all a disorder of androgen biosynthesis, utilization, and/or metabolism in women. As
263 such, with currently available evidence the diagnosis of PCOS cannot be established without
264 evidence of either clinical or biochemical hyperandrogenism. While the exact measures for
265 these may vary, the Task Force felt that the single most reliable indices of this feature included

266 hirsutism and free T levels. Nonetheless, the Task Force recognized that the methods for
267 measuring androgens in the circulation were frequently inaccurate and insensitive, and that
268 determination of hirsutism using visual scales was subjective, with significant inter-observer
269 variation (78), and whose cut-off level may be unclear (51). Finally, the Task Force also noted
270 that while many patients with PCOS may have evidence of acne or androgenic alopecia, these
271 features could not be used reliably as clinical signs of hyperandrogenism. The Task Force also
272 noted that support for this criteria is based on the risk for metabolic morbidity in the disorder, not
273 on whether hyperandrogenism per se is present or not.

274

275 **b) That the ovarian morphology should be considered when establishing the**
276 **diagnosis, as polycystic ovaries are found in the majority, although not all, women with**
277 **PCOS:** The Task Force recognized that ~75% of women with PCOS will demonstrate a
278 polycystic ovarian morphology on transvaginal ultrasonography, although they also recognized
279 that the false positive rate is high with up to one-quarter of unselected reproductive aged
280 women demonstrating this ovarian morphology. The Task Force also noted that the diagnosis of
281 polycystic ovaries required the use of clear and strict criteria. Consistent with recommendation
282 (6.a) above, the Task Force felt strongly that in those women with polycystic ovaries, but no
283 evidence of clinical or biochemical hyperandrogenism, the diagnosis of PCOS is less certain,
284 regardless of the presence of concomitant ovulatory dysfunction.

285

286 **c) That ovulatory dysfunction is a prominent, but not universal feature, of PCOS:** The
287 Task Force recognized that some patients with PCOS may demonstrate regular ovulation at the
288 time of their evaluation, the so-called “ovulatory PCOS” (79, 80). However, it was noted that
289 patients with “ovulatory PCOS” constituted a minority of the PCOS population, and had less
290 severe androgenic and metabolic features than anovulatory women with PCOS. It was also
291 recognized that there exists little data regarding the long-term maintenance of ovulation in

292 women with "ovulatory PCOS". Nonetheless, the Task Force recognized that there were
293 persuasive, albeit limited, data to suggest that hyperandrogenic ovulatory women with polycystic
294 ovaries had some degree of metabolic dysfunction, and were amenable to the inclusion of this
295 phenotype as a form of PCOS.

296

297 **d) That eumenorrhea in the presence of dermatologic features suggestive of**
298 **hyperandrogenism (e.g. hirsutism) could not reliably be used to establish the presence**
299 **of normal ovulation:** A history of regular predictable vaginal bleeding in a patient without
300 clinical signs of hyperandrogenism can be used as strong evidence of normal ovulation.
301 Alternatively, a history of 'regular' menstrual cycles in patients who demonstrate
302 hyperandrogenic features (e.g. hirsutism) could not be relied upon as evidence of normal
303 ovulation, since up to 40% of these women have oligo-anovulation when examined more
304 carefully. In these patients, confirmation of ovulatory function by more objective means is
305 required.

306

307 **e) That other well-defined disorders that could result in ovulatory dysfunction,**
308 **polycystic ovaries, or clinical or biochemical hyperandrogenism had to be excluded:**
309 Although the Task Force recognized that specific androgen excess or other endocrine disorders
310 needed to be excluded when establishing the diagnosis of PCOS, they also recognized the
311 validity of tailoring testing to reflect the prevalence of these disorders in the population being
312 studied.

313

314 **f) Recognition of associated abnormalities:** The Task Force noted that the presence of
315 obesity, insulin resistance and hyperinsulinism, and increased LH levels or an LH/FSH ratio,
316 while observed in a significant fraction of patients, should not be used as part of the definition of
317 PCOS.

318

319 **8) MINORITY REPORT:**

320 Notwithstanding the above recommendations, the Writing Committee acknowledged that
321 two of its members considered the possibility that there are forms of PCOS without overt
322 evidence of hyperandrogenism, and which may be associated with metabolic abnormalities and
323 morbidity. However, these investigators also recognized, as did the Committee as a whole, that
324 more data are required before validating this supposition. For example, a recent study noted
325 that women with oligo-anovulation and polycystic ovaries but without evidence of
326 hyperandrogenism (n=66) had basal insulin levels, the principal metabolic parameter assessed,
327 similar to controls and lower than patients with hyperandrogenemia and oligo-anovulation, with
328 (n=246) or without (n=27) polycystic ovaries, or those with hyperandrogenemia and polycystic
329 ovaries but without oligo-anovulation (n=67) (81).

330

331 **9) CONCLUSIONS**

332 Based on the above review of the available data, it is the view of the AES Task Force on the
333 Phenotype of PCOS that there should be acceptance of the original NIH/NICHD criteria of 1990
334 with some modifications, taking into consideration the opinion expressed in the proceedings of
335 the 2003 Rotterdam conference (**Figure 1**). Considering the four features of ovulatory
336 dysfunction, hirsutism, hyperandrogenemia, and polycystic ovaries, the Task Force identified
337 nine different phenotypes that could be considered as being PCOS with currently available
338 evidence (**Table 5**).

339 The Task Force noted that there was ample data to support an increased risk of metabolic
340 dysfunction in women with the following phenotypes: a) hirsutism and/or hyperandrogenemia,
341 and oligo-ovulation with and without polycystic ovaries (phenotypes A-F in **Table 5**) and b)
342 hyperandrogenemia and/or hirsutism, and normo-ovulation with polycystic ovaries (phenotype G
343 and H in **Table 5**) (7, 34, 36, 37, 82-94). Current evidence generally did not support an

344 increased metabolic dysfunction among women with polycystic ovaries only, with or without
345 oligo-ovulation (phenotype J in **Table 5**) (95, 96), although not all agreed (97). As expected, the
346 incidence of metabolic dysfunction in PCOS is also significantly increased by the concomitant
347 presence of obesity). However, the Task Force recognized that clinical features may not be
348 constant even in a single patient and can be modified by changes in body weight and lifestyle
349 choices, and age. In addition, the Task Force also recognized that there may be a number of
350 women who have features suggestive of PCOS, but who do not fulfill the criteria; clearly these
351 women and their symptoms should be treated accordingly, regardless of whether a diagnosis of
352 PCOS is established or not.

353 A principal conclusion of this report is that PCOS should be firstly considered a disorder of
354 androgen excess or hyperandrogenism. The absence of clinical or biochemical
355 hyperandrogenism in the untreated state, or in women under the age of 40 years, makes a
356 diagnosis of PCOS less certain, regardless of the presence of ovulatory or menstrual
357 dysfunction or the presence of polycystic ovaries. Overall, at the present time in the Task
358 Force's assessment, women with oligo-amenorrhea and polycystic-appearing ovaries on
359 ultrasonography but no evidence of hyperandrogenism do not have PCOS.

360 The Writing Committee also acknowledged that some of its members considered the
361 possibility that there are forms of PCOS without overt evidence of hyperandrogenism, but
362 recognized that more data are required before validating this supposition. Alternatively, the
363 diagnosis of PCOS in women who have evidence of hyperandrogenism and polycystic ovaries,
364 in the presence of ovulatory cycles, appears justified based on current data. Finally, while the
365 aim of this report was to yield criteria based on currently available data to guide research and
366 clinical diagnosis, and future investigations, the Task Force recognized that the definition of this
367 syndrome will evolve over time to incorporate new research findings.

ABSTRACT

Aim: To estimate the prevalence of impaired glucose tolerance (IGT) and diabetes mellitus type 2 (DMT2), as well as the predictors for glucose abnormalities in women with polycystic ovary syndrome (PCOS).

Material and methods: A cross-sectional study with 80 consecutive patients with newly diagnosed PCOS who underwent the standard 75g oral glucose tolerance test (OGTT) and the measurement of sex steroid hormone and lipid profile.

Results: According to the results from the OGTT, 63% had a normal test (NT), 23% had IGT, and 9% had DMT2. The NT group was younger with lower BMI than IGT and DMT2 groups (25.1 ± 7.3 , 31.5 ± 6.5 , 37.4 ± 4.0 years, and 29.1 ± 8.3 kg/m², 31.7 ± 4.6 kg/m², and 34.5 ± 5.6 kg/m², respectively). The testosterone levels were highest in the group with a normal test (2.7 ± 0.8 nmol/l) and lowest in the DMT2 group (1.9 ± 0.8 nmol/L), with statistical significance. The sex hormone binding globulin (SHBG) levels were low in all three groups, with statistically significant differences between NG and IGT, and the NT and DMT2 groups. The multivariate linear regression model identified age, BMI, SHBG and testosterone as major independent predictors for abnormal glucose metabolism.

Conclusion: It seems that the prevalence of IGT and DMT2 among PCOS women in our country is not as high as in Western countries. Age, BMI, and SHBG increase the risk for the development of IGT and DMT2. Thus, close monitoring of older, obese women with low SHBG is needed because of the higher risk for the development of IGT and DMT2 in such patients.

Keywords: polycystic ovary syndrome, OGTT, IGT, DMT2, testosterone

INTRODUCTION

PCOS is the most common endocrine disease affecting from 3% to 16% of women of reproductive age. PCOS is a metabolic-reproductive disorder with a very complex and not fully understood pathophysiology. Of note, accumulating evidence in literature indicates

that hyperinsulinemia is secondary to insulin resistance (IR) and plays an important role in the pathogenesis of the syndrome [1]. Tissues normally responsive to insulin for glucose uptake, such as the heart and skeletal muscle, protect themselves from nutrient-induced toxicity

by becoming insulin resistant [2]. Insulin resistance is the central mechanism linking together all parameters of the metabolic syndrome, such as: impaired glucose tolerance (IGT), type 2 diabetes mellitus (DMT2), hyperlipidemia and cardiovascular disease over-time [3–5]. Adolescent girls with PCOS have been shown to have early-onset insulin hypersecretion in association with insulin resistance [2], and approaches for reversal of severe hyperinsulinemia early in its course, prevented them from developing health problems later in life, such as diabetes, cardiovascular disease and infertility [6].

In spite of insulin resistance, some women with PCOS demonstrated beta cell dysfunction. Thus, both IR and beta cell dysfunction contribute to the development of DMT2 [7, 8]. Defects in insulin action and inadequate insulin response to glucose load have been found predominantly in obese [1, 7] and less in lean women with PCOS [9]. The risk for DMT2 in women with PCOS is estimated to be 5 to 10-fold higher than factors including age and weight, when compared with the normal control population.

In 1921 Archer and Thiers first reported a relationship between hyperandrogenism and insulin metabolism in their description of “diabetes des femmes a barbe” [10]. In 1980, Burghen and colleagues described a strong correlation between plasma insulin concentrations and testosterone and androstenedione in obese women with PCOS [11]. It became clear that PCOS also includes major metabolic morbidities. Hyperinsulinemia and peripheral insulin resistance are, however, the central feature of metabolic disorders, which is recognized to be typical of PCOS. Epidemiological studies and meta-analysis showed that the onset of IGT and DMT2 appears at an earlier age in patients with PCOS [12–14]. The risk for dysglycemia is the highest among PCOS patients with both anovulation and hyperandrogenism, amplified by obesity, or the classic NIH phenotype [15]. Recently, it has become clear that not only age but also obesity, family history of DMT2 and hyperandrogenemia may contribute to the increasing risk of diabetes in PCOS.

PCOS is a major risk factor for IGT and DMT2, with different prevalence among countries worldwide. Other factors may contribute to this heterogeneous prevalence, such as ethnicity, age, BMI, insulin resistance, dyslipidemia, and reproductive hormones. The aim of this study is to estimate the prevalence of IGT and

DMT2 among Macedonian women diagnosed with PCOS and to identify the parameters (age, BMI, testosterone, sex hormone binding globulin, lipids) as predictors for abnormal glucose tolerance.

MATERIALS AND METHODS

At the University Clinic of Endocrinology, Diabetes and Metabolic Disorders, Skopje, we conducted a cross-sectional study, including patients with PCOS. Applying the Rotterdam diagnostic criteria for PCOS [16], 80 women with PCOS were included and they were screened for glucose intolerance using the oral glucose tolerance test (OGTT) according to the ADA criteria [17].

PCOS was diagnosed when 2 out of the following 3 criteria were present: oligoanovulation and/or anovulation, clinical and/or biochemical signs of hyperandrogenism, and polycystic ovaries on ultrasound examination. Oligoanovulation was defined as the presence of oligomenorrhea (menstrual cycles of >35 days) or amenorrhea (lack of a menstrual period for 6 months or more). Clinical signs of hyperandrogenism were the presence of hirsutism, acne/seborrhea or alopecia. Biochemical hyperandrogenism was established based on elevated total or bioavailable testosterone levels, and DHEAs. Hirsutism was defined as an Ferriman-Gallwey score that was >8. Ovaries were classified as polycystic if 10 or more follicles measuring 2–8 mm in diameter were present in each ovary, and/or there was an increase in the ovarian volume >10ml. Transvaginal ovarian ultrasound scanning was performed between days 5 and 10 from the beginning of the last menstrual cycle using a 7.5-MHz vaginal probe transducer (General Electric LOGIQ 400MD, Milwaukee, WI, USA). Both ovaries were measured in the sagittal, transverse, and coronal planes.

All patients were in their reproductive period, free of chronic disease, including diabetes and hypertension. None of the women with PCOS had taken any oral contraceptive, other forms of hormonal contraception or fertility treatments.

All of the patients underwent 75-g OGTT, following the ADA criteria [17]. 75-g of hydrous glucose load was briefly administered after a 12 to 14 hour period of fasting and 2 hours post –

load samples for glucose were obtained from an antecubital vein. The samples were collected in tubes containing fluoride and kept at 4°C until centrifugation up to 2 hours later. Plasma measurements were performed with glucose oxidase methods.

The patients were divided into three groups according to the results from the OGTT: patients with a normal test (NT), impaired glucose tolerance (IGT) and patients with type 2 diabetes mellitus (DMT2). IGT and DMT2 were diagnosed according to the recommendations of the American Diabetes Association [17].

In all patients the following parameters were analyzed: patients' age, body mass index (BMI), days of the menstrual cycle, Ferriman-Gallwey score, waist/hip ratio, FSH, LH, estradiol (E2), total and free testosterone, DEHAs, 17-OHP, PRL, SHBG, fasting plasma glucose (FPG), 2 hour OGTT glucose values, and lipid parameters.

The BMI of women was calculated by dividing their weight by their squared height in meters (kg/m^2). The days of the menstrual cycle were self-reported by the patients. Hirsutism scoring scale of Ferriman and Gallwey was used. Waist/hip ratio was calculated. A morning blood sample was obtained after an overnight fast from all subjects for measuring hormones and lipoprotein parameters.

All hormones were measured in our laboratory using commercial kits. These included ELISA (DRG Diagnostics, DRG Instruments GmbH, Marburg, Germany) for FSH, LH, E2, 17-OHP, PRL, total and free testosterone. Chemiluminescence assays were used for DHEAs and SHBG. The blood samples for lipoproteins were analyzed using Cobas Integra 700, according to standard methods. Total cholesterol and triglycerides were determined by full enzymatic methods (TH-CHOD-POD-PAP and triglycerides-GPO; Cobas Integra 700, Hoffmann-La Roche, Basel, Switzerland). HDL-C was measured using the polyanion precipitation method, while LDL-C was calculated using the Friedewald formula.

The criteria for diagnosing type 2 DM and IGT were, as recommended by ADA [17], as follows: fasting plasma glucose, normal <5.6 mmol/l; IFG, 5.6-6.9 mmol/l; DMT2, 7.0 mmol/l. Two hour values: normal, 7.7 mmol/l; IGT, 7.8-11.0 mmol/l; DMT2, 11.1 mmol/l.

Normal laboratory values of other testing used were: total testosterone, normal, <2.1 nmol/l; SHBG, 52 - 150 nmol/l; cholesterol 3.4 -5.2 mmol/l; triglycerides, 0.45 – 1.7 mmol/l.

All patients gave informed consent to participate in the study after receiving explanations regarding the research protocols. The study was done according to the Helsinki Declaration.

*Data are presented as mean±SD. Student T-tests were used for analyzing the differences between the groups.

**F-G scor: Ferriman and Gallwey score system; BMI: body mass index; FSH: folliculostimulating hormone; LH: luteinizing hormone; E2: estradiol; F testosterone: free testosterone; DHEAs: dehydroepiandrosterone sulfate ; 17-OHP: 17-hydroxyprogesterone; PRL: prolactin; SHBG: sex hormone-binding globulin; OGTT-0': fasting glucose; OGTT-120': 2-hr glucose after 75 g oral glucose load; T. Cholesterol: total cholesterol; HDL-C: high density cholesterol; LDL-C: low density cholesterol.

The Statistical Package Statistics, version 7.0 was used. Baseline characteristics were expressed as a mean \pm S.D. Shapiro-Wilk test, showing that all variables have normal distribution. Differences between groups were detected by unpaired Student's t test for continuous variables. The correlation between the tested parameters was determined using Pearson's R for correlation. A GLM multivariate analysis was used for the evaluation of the independent effect of the analyzed variables on fasting, and 2 hour glucose values from OGTT. The value of $p < 0.05$ was taken as statistically significant.

RESULTS

The demographic, anthropometric, and biochemical (hormonal and lipid parameters) characteristics of the 80 women with PCOS are presented in Table 1.

The prevalence of alterations in glucose tolerance was as follows: IGT 16/80 (23%) and DMT2 6/80 (9%).

The women who had normal glucose tolerance were significantly younger than the women with PCOS and altered glucose tolerance. BMI was lower in women with normal glucose tolerance compared to women with altered glucose tolerance, but the differences were not statistically significant. With regard to the hormonal profile, the only difference found between the women with normal glucose tolerance and the IGT group was the statistically significantly lower level of SHBG. Interestingly, there were significantly lower levels of total testosterone and DHEAs in

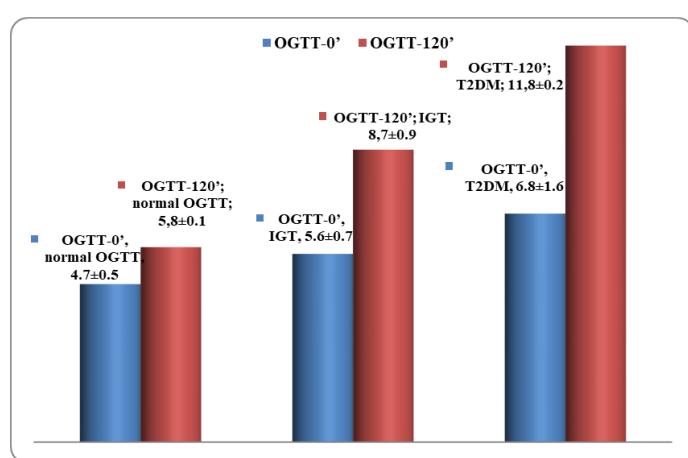

women with DMT2, than in women with normal glucose tolerance. Also, SHBG was significantly lower in the DMT2 group than in women with normal glucose tolerance (Table 1).

The glycemic values from OGTT of women with IGT and DMT2 were significantly higher compared to women with normal glucose tolerance (Table 1, Graph 1). The results from the lipid profile showed significantly higher triglyceride levels in women with DMT2 than in women with normal glucose tolerance (Table 1).

The results from the correlation revealed the following statistically significant correlation: a positive correlation between age and fasting glycaemia, and age with 2 hours post-load glucose from OGTT, a negative correlation between the SHBG and both glycemic values from OGTT, and a positive correlation between the 2 hours post-load glucose and triglycerides, and BMI.

Multivariate linear regression was used to determine the independent impact of the analyzed parameters on the OGTT-0' and OGTT-120' plasma glucose values. BMI, total testosterone, DHEAs, SHBG, and total cholesterol were shown to have an independent effect on the fasting glycaemia in PCOS women (Table 2). Age, BMI, total testosterone, DHEAs, SHBG, total lipids, total cholesterol, and HDL-C have an independent effect on 2 hour post-load glucose from OGTT in PCOS women (Table 3).

We compared our results with those from other countries, trying to explain the differences of IGT/DMT2 prevalence in our cohort to others, and we found mostly higher results, but also some lower prevalence which can partly be explained with the magnitude of BMI (Table 4) [12, 18–23].

DISCUSSION

Studies have shown that abnormal glucose tolerance is present in overweight and obese women with PCOS, compared to women without PCOS [18, 24]. One recent review [25] confirms the original findings of an increased prevalence of IGT and DMT2 among PCOS women in comparison to normal controls. This study revealed that 23% (16/80 patients) of women with PCOS had IGT while 9% (6/80 patients) had DMT2. The finding is in line with the prevalence of impaired glucose tolerance in Italian and European women with PCOS [23]. Different studies from the literature show that IGT was present in 35% of US women and 47% in Asian obese women [19] and in low to moderate weight women from Europe, at first clinical examination [25]. The International Diabetes federation [26] identified PCOS women as a non-modifiable risk factor for DMT2.

Differences in the results may be due to different ages, BMI, ethnicity, the impact of environmental factors, particularly dietary habits, and number of enrolled patients. The prevalence of IGT/DMT2 in our study is lower than the prevalence found in women from the USA and Asia, and higher compared to Australian, Italian and Mediterranean women.

PCOS women show a tendency to develop IGT/DMT2 at an early age and the prevalence is higher when compared to the general population [14, 27]. In our study, IGT was detected in the third decades and DMT2 in the fourth decades. Furthermore, we demonstrated a statistically significant positive correlation between age and FPG, and age with 2 hour post-load glycaemia from OGTT. It is notable that age was the contributing factor to have IGT in the third decade and DMT2 in the fourth decades, meaning that clinicians should keep this in mind. Age has an independent effect on 2 hour post-load glucose from OGTT.

Obesity is common among PCOS women [28]. There is a great variability of overweight (25- 30 kg/m²) and obese (>30 kg/m²) in the PCOS women among different population. The proportion of PCOS women who are overweight is 10% in Italy and 37% in Kuwait. The studies from the USA and Australia reported the highest prevalence of obesity, from 61% to 76% in PCOS women [23]. Obesity has a crucial role in the de-

velopment and maintaining of PCOS [29], and it significantly influences the severity of metabolic abnormalities. Obesity is also a major modifiable risk factor for DMT2 in women with PCOS [30]. In our study, we have found that women with IGT and diabetic PCOS women are significantly more obese in comparison to those with normal glucose tolerance (31.7 ± 4.6 kg/m², 34.5 ± 5.6 kg/m², 29.1 ± 8.3 kg/m², respectively). Obesity has a major impact on the development of PCOS, even more so in the creation of the phenotype of PCOS. Menstrual irregularity, hirsutism, and hyperandrogenemia are associated with morbid obesity in PCOS women. A recent review [14] showed that American and Asian obese women are presented predominantly with metabolic syndrome or the metabolic PCOS phenotype. European women are prone to hirsutism, acne, androgenic alopecia or the hyperandrogenic phenotype. Otherwise lean women with PCOS are rarely diagnosed with DMT2 and only a few percent of normal-weight women have prediabetes. Therefore, regular screening is recommended, particularly in overweight or obese patients and in those with a family history of DMT2, in order to identify impaired glucose metabolism early on [31]. The lower prevalence of IGT/DM2 in our patients with PCOS is partly due to the lower BMI in our study, a finding similar to other Mediterranean countries.

According to the recent guidelines of the American Association of Clinical Endocrinologists, the American College of Endocrinology, and the Androgen Excess and PCOS Society, OGTT should be performed at the moment of diagnosis of PCOS and every 1 to 2 years in patients with PCOS based on a family history of DMT2 and BMI >30kg/m², whereas this test should be performed every year in patients with PCOS and IGT [32].

PCOS is the condition that most often causes elevated testosterone concentrations, and PCOS consensus criteria define hyperandrogenemia on the basis of serum testosterone. Hyperandrogenemia is strongly associated with a diabetes risk in PCOS women. An important pathogenic element for DMT2 is insulin resistance. It is well known that hyperinsulinemia stimulates ovarian theca cells, thereby increasing androgen production and synergistically via LH hypersecretion. Therefore, another contributing factor to abnormal glucose tolerance is the interrelation between insulin resistance and hyperandrogenemia [33]. Hyperandrogenemia has been reported to increase insulin

resistance through the inflammation pathway, which could contribute to hyperglycemia. The correlation between high testosterone levels and insulin concentrations during OGTT may be interpreted as a marker of insulin resistance without direct contribution to the development of diabetes, possibly through the inflammation pathway. This finding was documented by Ehrmann et al. in 1999 for the first time [12] and was confirmed by Shorakae et al. [34]. In our study, multiple linear regression analysis showed that total testosterone has an independent impact on fasting glycaemia and on 2 hour post-load glucose from OGTT in PCOS women. This data from our PCOS cohort shows that other factors associated with abnormal glucose tolerance included testosterone, as well as elevated age and obesity. It seems that the incidence of dysglucaemia, according to an oral glucose tolerance test, increased with severity of the androgen phenotype. However, co-measurement of both androstenedione and testosterone can help to discover the PCOS cohort which is highest for metabolic risk [35].

Insulin resistance (IR) is the prevalent finding in PCOS women and it is predominant in women with the classic and severe PCOS phenotype presented with hyperandrogenism and chronic anovulation. One protein that functionally links those two apparently unparalleled phenotypes is SHBG. Insulin has a direct inhibitory effect on SHBG production from the liver, thus PCOS patients often have the lowest levels of SHBG [36] and the high amount of circulating free androgens [37]. The Study of Women's Health Across the Nation (SWAN) shows that low SHBG and high free androgen index are strongly related to metabolic and cardiovascular risk factors: higher insulin, glucose, hemostatic and inflammatory markers and more adverse lipid profile [38]. In this study, we found statistically significant lower levels of SHBG in IGT and DMT2 groups compared to the group with normal glucose tolerance. There are statistically significant differences between normal glucose tolerance and IGT, and between normal glucose tolerance and DMT2 groups of PCOS women. We found, however, that SHBG shows a statistically significant negative correlation with both fasting and 2 hour post-load glycaemia from OGTT. This is consistent with the fact that SHBG has been found to predict the development of type 2 diabetes. Our finding demonstrated the need to perform OGTT in women with PCOS and low levels of SHBG.

Alteration in the lipid profile is a common finding in women with PCOS. A great reduction of high-density lipoproteins (HDL-C) with both increase of triglycerides and total cholesterol levels, has been observed in obese PCOS women and less in lean PCOS women in comparison to normal weight women [39, 40]. Overall, most investigators agree that PCOS women have levels of triglycerides that are twice as high and a 25% lower concentration of HDL. In our study we found high levels of triglycerides and low levels of HDL-C. Furthermore, we demonstrated a significant negative correlation between FPG and HDL-C, while triglycerides correlated positively with 2 hour post-load glycaemia. Those metabolic patterns are seen in people with DMT2.

CONCLUSIONS

It seems that the prevalence of IGT and DMT2 among PCOS women in our country is not as high as in Western countries. The prevalence rate of IGT and DMT2 increases with age and BMI. The major predictors for abnormal glucose metabolism in PCOS are age, BMI, testosterone and SHBG. Thus, close monitoring of older, obese women with low SHBG is needed because there is a higher risk of developing IGT and DMT2 in these kinds of patients.

Резиме

ПРЕВАЛЕНЦИЈА И ПРЕДИКТОРИ НА НАРУШЕНА ГЛИКОЗНА ТОЛЕРАНЦИЈА И ДИЈАБЕТЕТ МЕЛИТУС ТИП 2 КАЈ ПАЦИЕНТКИ СО СИНДРОМ НА ПОЛИЦИСТИЧНИ ЈАЈНИЦИ

Бранкица Крстевска¹, Саша Јовановска Мишевска²,
Валентина Велкоска Накова³, Владимир Сеарфимоски⁴

¹ Центар за внатрешни болести Срце, Скопје, РС Македонија,

² Универзитетска клиника за ендокринологија, дијабетес и метаболички нарушувања, Скопје, РС Македонија

³ Клиничка болница, Штип, РС Македонија,

⁴ Владимир Сеарфимоски, Македонска академија на науките и уметностите, Скопје, РС Македонија

Цел: Процена на преваленцијата на нарушка гликозна толеранција (IGT) и дијабетес мелитус тип 2 (DMT2), како и предикторите за нарушувања во метаболизмот на гликоза кај жени со синдром на полицистични јајници (PCOS).

Материјал и методи: Пресечна студија со 80 последователни пациенти со ново дијагностициран PCOS беа подложени на стандарден тест со 75 g оптоварување со орална гликоза (OGTT) и мерење на половите стероидни хормони и липидниот профил.

Резултати: Според резултатите од OGTT, 63 % имаа нормален тест (NT), 23 % имаа IGT и 9 % имаа DMT2. Групата NT беше помлада со понизок БМИ од групата IGT и DMT2 ($25,1 \pm 7,3$, $31,5 \pm 6,5$, $37,4 \pm 4,0$ години и $29,1 \pm 8,3$ кг/м², $31,7 \pm 4,6$ кг/м² и $34,5 \pm 5,6$ кг/м² соодветно). Нивото на тестостерон беше највисоко во групата со нормален тест ($2,7 \pm 0,8$ nmol/l) и најниско во групата DMT2 ($1,9 \pm 0,8$ nmol/L), со статистичко значење. Нивото наекс-хормон врзувачки глобулин (SHBG) беше ниско во сите три групи, со статистички значајни разлики меѓу NG и IGT и групите NT и DMT2. Мултиваријатниот линеарен регресивен модел ги идентификуваше возраста, БМИ, SHBG и тестостеронот како главни независни предиктори за абнормален метаболизам на гликоза.

Заклучок: Се чини дека преваленцијата на IGT и DMT2 кај жените со PCOS во нашата земја не е толку голема како во западните земји. Возраста, БМИ и SHBG го зголемуваат ризикот за развој на IGT и DMT2. Потребно е внимателно следење на постарите дебели жени со низок SHBG, поради поголем ризик за развој на IGT и DMT2 кај таквите пациентки.

Клучни зборови: синдром на полицистични јајници, орален глукозен толерантен тест, нарушка гликозна толеранција, дијабетес мелитус тип 2, тестостерон

'AGE IS JUST A NUMBER:' HOW CELEBRITY-DRIVEN MAGAZINES MISREPRESENT FERTILITY AT ADVANCED REPRODUCTIVE AGES. S. Willson,^a K. N. Goldman.^b ^aNew York University School of Medicine, New York, NY; ^bNew York University Langone Medical Center, New York, NY.

OBJECTIVE: Reproductive-aged women frequently overestimate the likelihood of fertility at advanced reproductive ages resulting in the devastating consequence of unintended childlessness. We hypothesize that popular media over-represents celebrity pregnancies at advanced reproductive ages and thus contributes to public misconceptions surrounding age-related fertility decline. We sought to characterize the depiction of fertility and pregnancy among celebrities in widely-consumed mainstream print media.

DESIGN: Quantitative and qualitative analysis of three top-read print magazines targeting reproductive-aged women.

MATERIALS AND METHODS: Three top-read print magazines targeting reproductive-aged women were identified using publicly available demographic data: *US Weekly*, *Cosmopolitan*, and *People Magazine*. All archived magazines from January 2010 to January 2014 were systematically reviewed for any mention in text or photo of pregnancy, infertility, use of assisted reproductive technology (ART), gestational carrier (GC), or adoption. Depictions of mothers with children under the age of 2y at the time of publication and mentions of pregnancy-related health risks were recorded.

RESULTS: In total, 416 print magazines met inclusion criteria and were analyzed, with a total of 1,894 mentions related to fertility, pregnancy, or motherhood. Fertility was highlighted on nearly 1/3 of magazine covers. 240 individual celebrities received at least one fertility-related mention, with a mean and median age at mention of 35 y. The majority (56%) of women mentioned were AMA. In total, only 2 subjects (<0.008%) were reported as having used ART; this number increased to 6 (0.03%) when including celebrities publicly known to have used ART. Among all AMA women (n=135), 10 (7%) were mentioned as having adopted children, and 5 (4%) used GC. There was no mention of infertility prior to adoption/GC. 45 women were over the age of 40 years (33%); 10 used adoption or GC, and only 2 women (4%) over 40 were mentioned as utilizing ART with autologous oocytes. 7 subjects over the age of 44 years were depicted as pregnant or having delivered healthy infants with no mention of ART. The use of donor gametes received no mention. All magazines contained \geq 1 mention of contraception through sponsored advertisements, while only 10 magazines (2%) mentioned any form of ART. There were no mentions of AMA pregnancy-related health risks.

CONCLUSIONS: Widely-consumed popular media downplays the impact of age on fertility and glamorizes pregnancy at advanced ages. Magazines concurrently advertise contraception contrasted with fertility at advanced reproductive ages, with rare or no mention of ART, donor gametes, or AMA-related health risks. Magazine content reflects a continued stigma surrounding the use of ART and further the public's misconceptions about fertility at advanced reproductive ages. This depiction perpetuates the general notion that fertility is 'flexible' and is highly damaging to young women.

OPIOID PRESCRIBING PATTERNS AFTER EGG RETRIEVAL. P. Bortolotto,^a M. Prabhu,^b E. Garry,^c K. F. Huybrechts,^d R. M. Anchan,^a B. T. Bateman.^a ^aBrigham and Women's Hospital, Boston, MA; ^bMassachusetts General Hospital, Boston, MA; ^cUniversity of North Carolina at Chapel Hill, Chapel Hill, NC; ^dDivision of Pharmacoepidemiology and Pharmacoeconomics, Brigham and Women's Hospital, Boston, MA.

OBJECTIVE: We sought to describe opioid prescribing patterns following egg retrieval (ER).

DESIGN: A retrospective cohort of commercially insured patients from the Truven Marketscan database from 2003-2014.

MATERIALS AND METHODS: We identified a cohort of women who underwent egg retrieval (CPT code 58970) and had filled no more than 1 opioid prescription in the 12 weeks prior to ER (in order to exclude chronic opioid users). We also excluded women with a diagnosis of opioid or substance use disorders. We assessed for factors that might influence the decision to prescribe opioids including mood or anxiety disorder, smoking, use of SSRIs/TCA, pelvic pain or endometriosis. Patient age, region, and year of ER were also captured. The outcomes of interest were i) proportion who filled an opioid prescription within 3 days of ER and ii) quantity dispensed, expressed as oral morphine equivalents (median, interquartile range [IQR]). Differences in the frequency

of opioid fill by patient characteristics were tested using a chi-squared test.

RESULTS: A total of 57,727 women had an ER meeting criteria for analysis. Their mean age was 34.9 (standard deviation 4.8), 2.8% had a diagnosis of anxiety, 3.0% had a diagnosis of mood disorder, 5.7% used SSRI/TCA's, and 5.5% had a diagnosis of endometriosis. Among women having an ER, 11.9% (6,885/57,727) had a post-procedure opioid fill. The most frequently prescribed opioids were hydrocodone (48.8%), codeine (22.5%), and oxycodone (17.4%). The median (IQR) oral morphine equivalents prescribed after ER was 90 (50-125) mg, or 18 tablets of hydrocodone 5 mg. Women with mood disorders, smoking history, or SSRI/TCA use were more likely to fill an opioid prescription, compared to their counterparts without these diagnoses. The frequency of opioids filled over time varied from a low of 10.3% in 2003 to a high of 13.6% in 2006, and was 12.1% for the last year in the study period (2014). Opioids filled after ER varied significantly by region, from a high of 21.2% in the South to a low of 5.3% in the Northeast.

CONCLUSIONS: Whereas only a small proportion of women fill a prescription for opioids after ER, those who do receive a large quantity of opioids. This suggests a disconnect between expected procedural pain and provider prescribing patterns for this subgroup of patients. Patients with a concurrent diagnosis of mood disorder or users of antidepressants were more likely to fill opioid prescriptions, and significant differences existed by region. As most patients tolerate the procedure without using opioids, this should prompt physicians who routinely prescribe these medications to reevaluate this practice.

QUALITY OF LIFE AND DEPRESSION IN POLYCYSTIC OVARY SYNDROME. E. A. Greenwood,^a

L. Pasch,^a R. S. Legro,^{b,c} M. Cedars,^d H. Huddleston.^a ^aUCSF, San Francisco, CA; ^bPenn State University College of Medicine; ^cReproductive Medicine Network, New Haven, CT; ^dUCSF, San Francisco, CA.

OBJECTIVE: Polycystic ovary syndrome (PCOS) has known pronounced quality of life effects in the domains of emotional, body hair, infertility, weight, and menstrual problems. The purpose of this study is to examine PCOS-related quality of life in depressed and non-depressed PCOS patients.

DESIGN: Secondary analysis of a randomized clinical trial

MATERIALS AND METHODS: 725 women ages 18-40 with PCOS-Rotterdam, desiring pregnancy, were enrolled in the Pregnancy in Polycystic Ovary Syndrome II (PPCOSII) clinical trial comparing letrozole and clomid. Anthropometric data and hirsutism assessment by modified Ferriman-Gallwey (mFG) scores were obtained. Depression was assessed by the self-administered Patient Health Questionnaire (PHQ), using a validated cutoff algorithm. The PCOS Health-Related Quality of Life (PCOSQ) survey, a validated 26-item questionnaire, was self-administered. PCOSQ scores were calculated for each of five domains: Emotional, Body Hair, Infertility, Weight, and Menstrual Problems. Domain scores range from 1-7, with 1 indicating poorest function and 7 optimal function. Two-sided t-tests compared PCOS QOL symptom scores between depressed and non-depressed patients. Linear regression models assessed the impact of a depression diagnosis on PCOSQ domain scores, controlling for age, BMI and mFG score.

RESULTS: 63/725 (8.7%) of women met the criteria for clinically significant depression. Depressed patients reported significantly lower scores (i.e. poorer function) on all five domains, compared to patients without depression: Emotions (3.1 vs 4.6), Weight (2.0 vs 3.5), Infertility (1.9 vs 3.0), Body Hair (3.5 vs 4.2), Menstrual Problems (3.2 vs 4.1); $p < 0.001$. Depressed PCOS patients reported greater sense of lacking of control over their PCOS than patients without depression. In a multivariate analysis controlling for age, BMI and mFG scores, women with depression reported lower quality of life in all domains.

Effect of depression on PCOS QOL domain scores. *Analysis controlled for age, BMI, hirsutism score.

Domain	Coefficient	95% CI	p-value
Emotions	-1.36	(-1.66, -1.07)	<0.001
Body Hair	-0.49	(-0.83, -0.15)	<0.001
Weight	-1.28	(-1.68, -0.89)	<0.001
Infertility	-1.00	(-1.35, -0.65)	<0.001
Menstrual Problems	-0.83	(-1.11, -0.56)	<0.001

CONCLUSIONS: Depression is associated with poor subjective quality of life from PCOS symptoms. This finding remained after controlling for objective measures of symptoms including weight and hirsutism. Although the direction of the effect cannot be determined, these findings may suggest that depression colors the subjective experience of PCOS symptoms. Treatment of depression may improve subjective assessment of symptoms and quality of life in patients with PCOS.

LEIOMYOMA 2

REGULATION OF PD-1 AND LEPTIN RECEPTOR EXPRESSION BY ESTROGEN THROUGH AKT3 IN HUMAN UTERINE FIBROIDS. A. El Andaloussi,^a A. Al-Hendy,^b ^aOb/Gyn, Augusta University, Augusta, GA; ^bOB/GYN, Dept of Obstetrics & Gynecology, Augusta, GA.

CrossMark

OBJECTIVE: To study the regulation of PD-1 expression by estrogen and its cross talk with Leptin receptor through AKT3 in human uterine fibroids.

DESIGN: In vitro laboratory study with the use of human uterine fibroid (UF) cells.

MATERIALS AND METHODS: To verify our hypothesis, we stimulated HuLM and primary UF patients cells (n=7) with E2 conjugated with BSA (E2-BSA, is too large to enter the cells and thus cannot bind to nuclear ER) at the following concentration (0.1 ; 1 and 10 nM) at three different time point (30 mn; 1h and 2h). The expression of PD-1, PD-L1, anti-TNF α and anti-TGF β by intracellular staining was analyzed by FACS. Q-PCR was used for RNA expression analysis for PD-1, PI3K, AKT isoforms and LepR used as marker of obesity.

RESULTS: To examine the cross-talk between ER and PD-1 through the non-genomic pathway of E2, Stimulation of UF cells with E2-BSA significantly induces the expression of PD-1 mRNA (5.7 ± 0.84) at the concentration of 0.1 nM after 1h compared to untreated control (2.2 ± 0.25) ($P = 0.016$). This effect reached a plateau and the concentrations of 1 and 10 nM doesn't induce further PD-1 induction. The ER-BSA treatment had no effect on the level of PD-L1 mRNA in UF cells. This observation was supported by FACS analysis based on the mean fluorescence intensity of PD-1 in UF cells (77136 ± 585.4) versus the untreated control (36183 ± 2917.5) ($P = 0.035$). Downstream of PD-1, the PI3K expression level was induced significantly after 30 mins at 0.1 nM of E2-BSA (0.084 ± 0.0014) vs. the control cells (0.029 ± 0.001) ($P = 0.0009$). For AKT, we analyzed the three isoforms AKT1, AKT2 and AKT3 separately. Surprisingly E2-BSA induced marked up-regulation (300 fold increase) of AKT3 after 30 mins of stimulation with 0.1 nM of E2-BSA (300.25 ± 106.6) vs. the unstimulated control (1.38 ± 0.24) ($P = 0.008$). E2 mediated modest induction of AKT1 and no effect on AKT2 ($P = 0.07$) compared to untreated control. E2-BSA induced a significant increase of LepR (14.68 ± 4.6) vs. (0.22 ± 0.01) under the same conditions. This results is suggesting the cross-talk of non-genomic ER, PD-1 and LepR through AKT3, which are eventually mediate proliferation of UF cells.

CONCLUSIONS: Our work presents novel immunomodulatory functions of estrogen in human UF. Our study introduces interconnection among three majors and important pathways in the pathogenesis of UF Targeting AKT3 directly or indirectly through PD-1, might represent a novel effective anti-fibroid immunotherapeutic strategy.

A CONTROLLED TRIAL ON UTERINE FIBROIDS TREATMENT COMPARING AROMATASE INHIBITOR PLUS GnRH ANALOGUE VERSUS ULIPRISTAL ACETATE. F. Scarpellini,^a M. Sbracia,^b ^aCERM, Rome, Italy; ^bCERM-Hungaria, Roma, Italy.

CrossMark

OBJECTIVE: We have previously showed that combined treatment of uterine fibroids with the aromatase inhibitor Anastrazole plus GnRH analogue (Goserelin) is an effective therapy in these women with a fast reduction of uterine volume and related symptoms especially uterine bleeding. In this controlled study we compared this treatment with Ulipristal acetate that recently has been introduced in the treatment of fibroids.

DESIGN: A controlled randomized trial on women with uterine fibroids

MATERIALS AND METHODS: 63 women with symptomatic uterine fibroids All patients did not undergo surgery and were medically treated. The mean age of women was 39.1 ± 2.0 . The women were assigned to the com-

bined treatment group or to the Ulipristal group by a computer generated sequence. 30 women were treated with Anastrazole 1 mg/die plus Goserelin 3.6 mg/month. 33 women were treated with Ulipristal acetate 5.0 mg/daily. The women of the two groups were followed up during the treatment, undergoing to serial the assessment ultrasound scan of uterine and fibroids dimensions as well as side effects record.

RESULTS: The two groups of patients did not show statistical significant differences for any of epidemiological data. The time of pain symptom disappearance was shorter in the group treated with the combined therapy than in the Ulipristal group (2.8 ± 0.9 vs 4.1 ± 1.2 , $P < 0.01$). After three months treatment there was a significantly bigger reduction in uterine and fibroids volume in the women treated with the combined therapy than in the Ulipristal group (41.8% vs 14.3% , $P < 0.01$). The side effects rate observed was significantly lower in the patients treated with the combined therapy than controls especially regarding uterine bleeding during treatment (3.3% vs 30.3% ; $P < 0.01$).

CONCLUSIONS: The combined treatment of uterine fibroids with Anastrazole plus GnRH analog showed better results than Ulipristal acetate group with a bigger fibroids reduction, in a shorter time and with lower side effects, especially for uterine bleeding. The combined treatment seems to be the treatment of choice in these women even though these data should be confirmed in larger study.

O-159 Tuesday, October 31, 2017 11:30 AM

SYNERGISTIC EFFECTS OF SIMVASTATIN AND ULIPRISTAL ACETATE ON UTERINE LEIOMYOMA. M. Malik,^a W. H. Catherino,^a

CrossMark

A. Laknaur,^b M. Ali,^b A. Al-Hendy,^b J. Segars,^c M. A. Borahay.^d ^aOB/GYN, Uniformed Services University of the Health Sciences, Bethesda, MD; ^bOB/GYN, Augusta University, Augusta, GA; ^cOB/GYN, Johns Hopkins School of Medicine, Baltimore, MD; ^dObstetrics and Gynecology, Johns Hopkins University, Baltimore, MD.

OBJECTIVE: Human fibroids are highly prevalent uterine tumors composed of proliferating transformed myometrial cells and excessive disordered extracellular matrix (ECM). The gonadal hormone progesterone is known to induce and maintain leiomyoma growth. Simvastatin, primarily used to treat hyperlipidemia, was recently shown to have anti-proliferative and pro-apoptotic effect on leiomyoma cells and xenograft model. Moreover, simvastatin is thought to modulate progesterone levels. Our objectives are to examine effect of simvastatin on ECM production and leiomyoma stem cells, and evaluate the combined effect of simvastatin and ulipristal acetate (UPA), a progesterone receptor modulator.

DESIGN: In-vitro laboratory study

MATERIALS AND METHODS: Patient-derived leiomyoma cell lines were treated with simvastatin at different concentrations for 24 and 48 hours. Expression of ECM proteins and regulating pathways was determined using western blot. Patient-derived stro-1 $^+$ /CD44 $^+$ tumor initiating stem cells were treated with simvastatin, UPA and combinations for 48 hours. Proliferation was examined using MTT assay.

RESULTS: Simvastatin affected the expression of collagen 1A (COL1A) in leiomyoma cells, as early as 24hrs of treatment. A clear concentration dependent effect was observed at 48hr of exposure, with leiomyoma cells demonstrating a 2.5-fold (0.4 ± 0.03) reduction in COL1A at 10^{-7} M simvastatin, compared to untreated controls. At similar concentration and time point, versican (VCAN) was reduced by 1.25-fold whereas fibronectin (FN1) protein did not demonstrate a significant change. Fibromodulin (FMOD) demonstrated significant change at higher concentrations of simvastatin. A significant 2-fold decrease in transforming growth factor beta3 (TGF β 3) protein indicated that simvastatin may affect the production of the ECM proteins by inhibition of the fibrosis-inducing pathway. Its pro-apoptotic role was supported by a concentration-dependent increase in cleaved caspase-3, in treated cells. We have previously demonstrated that leiomyoma cells exposed to UPA demonstrated a decrease in expression of ECM proteins and various components of the TGF pathway. Treatment of leiomyoma stem cells by simvastatin or UPA for 48 hours inhibited proliferation with effects significant at 10^{-7} M ($81 \pm 4\%$ of control) and lower. With simvastatin/UPA combination, proliferation was significantly inhibited to $39 \pm 25\%$ of control at 10^{-7} M concentrations.

CONCLUSIONS: Simvastatin inhibits production of leiomyoma ECM and inhibits proliferation of leiomyoma cells. Simvastatin/ulipristal acetate synergism appears to be a promising approach in leiomyoma therapy. To improve efficacy, combination therapy may work by focusing on different steps in leiomyoma cell stimulation.

Quality of Life of Women with Polycystic Ovary Syndrome

Natalia Ligocka [†], Karolina Chmaj-Wierzchowska ^{*,†}, Katarzyna Wszołek , Maciej Wilczak and Katarzyna Tomczyk 

Department of Maternal and Child Health, Poznan University of Medical Sciences, 60-701 Poznan, Poland

* Correspondence: karolinachmaj@poczta.onet.pl; Tel.: +48-61-8419-618

† These authors contributed equally to this work.

Abstract: *Background and Objectives:* Polycystic ovary syndrome (PCOS) is an endocrine disorder characterized by multiple hormonal and metabolic abnormalities, including insulin resistance, hyperandrogenism, and disturbances in lipid and carbohydrate metabolism. The objective of this study is to assess the quality of life of women diagnosed with polycystic ovary syndrome (PCOS) and to identify any factors within the study group that may impact the scores related to quality of life. *Materials and Methods:* This research was carried out among women diagnosed with PCOS. An original questionnaire, developed through an online Google Forms survey, was utilized as the research instrument and distributed through social networks and support groups to women facing PCOS. This study encompassed a participant pool of 200 women with PCOS, aged 24 years or older. For the analytical component, Pearson's χ^2 test was employed—a nonparametric test designed to assess the relationship between two variables measured on a qualitative scale. The chosen level of statistical significance was set at $p < 0.05$. *Results:* The analysis revealed that the quality of life of the women under study was not linked to the duration of the disease or comorbidities. However, a significant association was observed with the inconvenience caused by PCOS symptoms. Women experiencing very bothersome symptoms of PCOS reported a lower quality of life compared to those with symptoms rated as not very bothersome. Despite the majority of women with PCOS rating their quality of life as good or very good, they often find the associated symptoms of PCOS bothersome. Women reporting lower quality of life tend to acknowledge the impact of PCOS on their lives, experience a sense of lack of control over the disease, struggle with depression, and do not accept their physical appearance. *Conclusions:* Hence, the support from specialists like endocrinologists, gynecologists, and nutritionists becomes crucial for many women dealing with PCOS. Adopting a healthy lifestyle, incorporating a balanced diet, and engaging in regular physical activity can assist in managing the troublesome symptoms of PCOS, thereby enhancing overall quality of life. In instances of emotional difficulties, seeking psychological support is equally important, and the significance of support and acceptance from loved ones should not be overlooked.

1. Introduction

Polycystic ovary syndrome (PCOS) is an endocrine disorder characterized by multiple hormonal and metabolic abnormalities, including insulin resistance, hyperandrogenism, and disturbances in lipid and carbohydrate metabolism [1–7]. Dysbiosis of gut microbiota may play a pathogenic role in the development of PCOS [8]. Several criteria exist for diagnosing PCOS, such as the National Institutes of Health (NIH) criteria, Androgen Excess Society (AES) criteria, and Rotterdam criteria. Among these, the Rotterdam criteria are the most widely utilized [9–12]. To receive a diagnosis of PCOS, a minimum of two of the three Rotterdam criteria must be satisfied: ultrasound evidence of polycystic ovaries (presence of at least 20 Graff follicles measuring 2–9 mm in diameter and/or ovarian volume >10 mL),

infrequent ovulation or absence of ovulation, and clinical and/or biochemical indications of hyperandrogenism [13]. When employing these criteria for PCOS diagnosis, it is essential to simultaneously rule out other endocrine causes [13]. Women grappling with PCOS frequently contend with symptoms that can be personally challenging. Therefore, the paramount approach involves providing them with support and understanding, creating a sense of safety. This approach not only facilitates effective interviews but also contributes to formulating a treatment plan geared toward mitigating or addressing the prevailing symptoms and achieving the desired outcomes for the patient. Consequently, it is essential to delve into the quality of life experienced by women with PCOS and the prevalent challenges they encounter [14–20]. This includes exploring aspects such as family life, social interactions, sexual well-being, professional engagements, parenthood, fertility treatments, and potential feelings of helplessness linked to issues like hirsutism or accompanying metabolic conditions.

The objective of this study was to conduct a self-assessment of the quality of life of women with PCOS and to analyze the factors influencing the aforementioned quality of life scores.

2. Materials and Methods

The research was carried out among women diagnosed with PCOS. An original questionnaire entitled “Assessment of the quality of life of women with polycystic ovary syndrome”, developed through an online Google Forms survey, was utilized as the research instrument and distributed through social networks and support groups to women with verified PCOS. The study included a group of 200 participants with PCOS.

The questionnaire consisted of 28 questions (including 4 multiple-choice ones). The first part of the questionnaire had questions related to general demographic information (age, place of residence, marital status, education, professional status, and socioeconomic conditions). The next questions concerned PCOS (when was the disease diagnosed, what are the symptoms and other diseases, and what is the treatment used) and fertility. The third part of the survey included questions regarding the assessment of quality of life and experienced emotions (depression/anxiety/sadness, a feeling of lack of control or acceptance of physical appearance, and support from family).

Data analysis was conducted using TIBCO Software Inc. (2017) Statistica, version 13, and Microsoft Excel, version 2019 (Microsoft Office). The analysis of the gathered data took the form of both descriptive and analytical statistics. Descriptive statistics were conducted through a Microsoft Excel spreadsheet, which included the creation of graphs based on the collected data. For the analytical component, Pearson’s χ^2 test was employed—a nonparametric test designed to assess the relationship between two variables measured on a qualitative scale. The chosen level of statistical significance was set at $p < 0.05$.

3. Results

The study cohort comprised 200 women diagnosed with PCOS, aged 24 years or older.

3.1. Characteristics of the Study Group of Women with Polycystic Ovary Syndrome

The predominant segment of the study group consisted of women aged 24 to 29, making up 53% of the participants. Geographically, 34.5% resided in large cities with populations exceeding 100,000, while 32% lived in rural areas. Among the participants, 41% were married. In terms of education, 60% of the women held higher education degrees, and a majority, accounting for 71%, were economically active. Assessing socioeconomic conditions, 57% rated them as good (see Table 1). Within the study group, 18% of the women had children, while the remaining 82% did not. Among those attempting to conceive, 55% made no efforts, 41.5% encountered difficulties, and 3.5% reported no problems. For women with children, the duration of attempts to conceive varied, with 38.6% lasting 1–2 years, 31.3% up to a year, 21.7% spanning 3–5 years, and 8.4% extending beyond 5 years. The manifestation of PCOS primarily presented as irregular menstrual cycles (80.5%) and the

characteristic ultrasound image of polycystic ovaries (71.5%). Other common manifestations included infrequent or absent ovulation (61%), insulin resistance/hyperinsulinemia (60.5%), hirsutism (50%), overweight/obesity (47%), difficulties in getting pregnant (45%), acne (44%), and bloating (41.5%). Less frequently reported symptoms included amenorrhea (32%), hyperandrogenism (26.5%), infertility (24%), and androgenetic alopecia (17.5%). Regarding comorbidities, 30.5% of women had hypothyroidism/Hashimoto's disease, 9% had lipid disorders, 7.5% experienced hypertension, 5.5% had diabetes, and 1.5% had hyperthyroidism.

Table 1. Characteristics of the study group.

Variable	Subgroup	%
Age	24–29 years	53%
	18–23 years	24.5%
	30–35 years	18.5%
	above 35 years	4%
Residence	large cities, >100 thousand residents	34.5%
	medium-sized cities, 50–100 thousand residents	15.5%
	small cities, <50 thousand residents	18%
	country	32%
Marital status	married	41%
	informal relationship	30.5%
	unmarried—maidens	27%
	widows	1%
Education	divorced	0.5%
	higher	60%
	secondary	34.5%
	vocational	3.5%
Job status	primary	2%
	active—working	71%
	studying	19.5%
	nonactive	9.5%
Socio-economic conditions	good	57%
	very good	30%
	sufficient	12%
	poor	1%

The women surveyed typically rated the severity of their symptoms as bothersome (40.5%), moderately bothersome (26.5%), or very bothersome (24%). Less frequently, respondents rated their symptoms associated with PCOS as not very bothersome (8.5%) or not bothersome at all (0.5%). Of the women surveyed, 79% were undergoing treatment for PCOS-related symptoms, while 21% were not receiving treatment for PCOS. A total of 96% of the surveyed women were under the regular care of a gynecologist, and 50.5% were under the regular care of an endocrinologist. A smaller percentage of women surveyed were under the regular care of a nutritionist (13%), psychologist (11%), dermatologist (8.5%), psychiatrist (8%), or diabetologist (7.5%) (see Table 2).

Table 2. Clinical symptoms and treatment options for polycystic ovary syndrome.

Variable	Subgroup	%
Diagnosis of PCOS	1–3 years	31.5%
	up to 1 year	24%
	4–6 years	22%
	up to 10 years	10%
	above 10 years	12.5%
Severity of symptoms	bothersome	40.5%
	moderately bothersome	26.5%
	very bothersome	24%
	little bothersome	8.5%
	nondisruptive	0.5%
Under constant care	gynecologist	96%
	endocrinologist	50.5%
	dietician	13%
	psychologist	11%
	dermatologist	8.5%
Treatment undertaken	psychiatrist	8%
	diabetologist	7.5%
	yes	79%
	no	21
Forms of treatment	hormonal contraception/yes	26%
	no	74%
	metformin/yes	39.5%
	no	60.5%
	diet/yes	53.5%
	no	46.5%
	physical activity/yes	51%
	no	49%

3.2. Self-Assessment of Quality of Life of Women with Polycystic Ovary Syndrome

The women who participated in the survey generally assessed their quality of life as good (self-assessment of quality of life), rated by 61.5%. Following this, 20% rated their quality of life as very good, while 15% indicated a satisfactory quality of life. A small percentage of respondents, 2.5%, rated their quality of life poorly, and 1% rated it very poorly. The presence of PCOS affected “some sphere” of life for 84% of the surveyed women, whereas 16% acknowledged that PCOS had no impact on their lives. Within the study group, PCOS predominantly affected the sexual sphere for 79.2% and, to a lesser extent, the family (61.9%), social (50.6%), and occupational (24.4%) spheres. Sadness attributed to PCOS was reported by 79% of the surveyed women, with only 21% indicating that they experienced no sadness or anxiety due to PCOS. A feeling of being out of control due to PCOS was experienced by 75% of the women, and 26% struggled with depression. Acceptance of their physical appearance was noted by only 40.5% of the surveyed women, while 59.5% did not accept their appearance. Furthermore, 67.5% of the women admitted to having low self-esteem due to the presence of PCOS, with 32.5% reporting no perceived impact. Regarding family support, the surveyed women typically rated it as medium (43%)

or good (32%), with fewer respondents rating it as very good (14%), bad (9%), or very bad (2%) (see Table 3).

Table 3. Self-assessment of quality of life in women with polycystic ovary syndrome.

Variable	Subgroup	%
Self-assessment of quality of life	good quality of life	61.5%
	very good quality of life	15%
	poor quality of life	2.5%
	very bad quality of life	1%
Sadness	yes	79%
	no	21%
Depression	diagnosed	26%
	no depression	74%
Accept of their appearance	yes	40.5%
	no	59.5%
Self-esteem	low	67.5%
	not affected	32.5%
Influence on spheres of life	sexual sphere	79.2%
	family sphere	61.9%
	social sphere	50.6%
	professional sphere	24.4%

3.3. Assessment of Factors Affecting the Quality of Life of Women with Polycystic Ovary Syndrome

The analysis revealed that the quality of life of the women under study was not linked to the duration of the disease ($\chi^2 = 8.98; p = 0.344$) or comorbidities ($\chi^2 = 4.04; p = 0.401$). However, a significant association was observed with the inconvenience caused by PCOS symptoms ($\chi^2 = 22.25; p < 0.01$). Women experiencing very bothersome symptoms of PCOS reported a lower quality of life compared to those with symptoms rated as not very bothersome (refer to Table 4).

Table 4. Relationship between quality of life assessment, duration of illness, severity of symptoms, and comorbidities.

	How Is Your Quality of Life?			χ^2	<i>p</i>
	Very Good	Good	Sufficient/Poor		
How long ago were you diagnosed with polycystic ovarian syndrome (PCOS)?	Less than a year ago	25.0%	58.3%	16.7%	8.98 0.344
	1–3 years ago	11.1%	73.0%	15.9%	
	4–6 years ago	22.7%	61.4%	15.9%	
	7–10 years ago	20.0%	50.0%	30.0%	
	11 or more years ago	28.0%	48.0%	24.0%	

Table 4. Cont.

		How Is Your Quality of Life?			χ^2	<i>p</i>
		Very Good	Good	Sufficient/ Poor		
How do you assess the annoyance of the symptoms present?	Little bothersome	33.3%	66.7%	0.0%	22.25	0.001
	Moderately bothersome	24.5%	69.8%	5.7%		
	Bothersome	21.0%	58.0%	21.0%		
	Very bothersome	8.3%	56.3%	35.4%		
Have you been diagnosed with any of the conditions that accompany PCOS?	One	22.9%	61.8%	15.3%	4.04	0.401
	Two	12.2%	65.4%	22.4%		
	More	21.2%	54.6%	24.2%		

χ^2 : Chi-square statistics; *p*: statistical significance level.

Likewise, the correlation between the assessment of quality of life and factors such as treatment, adherence to diet, and physical activity was investigated through Pearson's χ^2 test analyses. The outcomes of these analyses are presented in Table 5, but they proved to be statistically insignificant (*p* > 0.05). Only the connection between quality of life and dietary adherence approached statistical significance ($\chi^2 = 5.67$; *p* = 0.059). Women following a diet tended to give lower ratings of their quality of life.

Table 5. Relationship between quality of life assessment, treatment, diet, and physical activity.

		How Is Your Quality of Life?			χ^2	<i>p</i>
		Very Good	Good	Sufficient/ Poor		
Are you being treated (for symptoms related to polycystic ovary syndrome?)	No	19.0%	57.2%	23.8%	1.00	0.607
	Yes	20.3%	62.6%	17.1%		
Do you use hormonal contraception?	No	23.0%	58.1%	18.9%	3.63	0.162
	Yes	11.5%	71.2%	17.3%		
Do you take metformin?	No	20.7%	61.1%	18.2%	0.09	0.956
	Yes	19.0%	62.0%	19.0%		
Do you follow any kind of diet?	No	14.0%	69.9%	16.1%	5.67	0.059
	Yes	25.2%	54.2%	20.6%		
Do you take care of regular physical activity (at least three times a week)?	No	16.3%	64.3%	19.4%	1.62	0.445
	Yes	23.5%	58.9%	17.6%		

χ^2 : Chi-square statistics; *p*: statistical significance level.

Additionally, through Pearson's χ^2 test analyses, the relationship between the assessment of quality of life and factors such as having children and experiencing negative emotions was explored. The results of these analyses are detailed in Table 6. No significant association was found between quality of life and having children ($\chi^2 = 1.66$; *p* = 0.436) or experiencing sadness ($\chi^2 = 3.40$; *p* = 0.183). However, quality of life was observed to be linked with the impact of the disease on one's life ($\chi^2 = 13.14$; *p* < 0.01), feeling out of control ($\chi^2 = 10.17$; *p* < 0.01), and depression ($\chi^2 = 19.16$; *p* < 0.001). Women who acknowledged that PCOS had an impact on their lives, those feeling out of control due to the disease, and those struggling with depression reported lower quality of life.

Table 6. Relationship between quality of life assessment, having children, and experiencing negative emotions.

	How Is Your Quality of Life?			χ^2	<i>p</i>
	Very Good	Good	Sufficient/ Poor		
Do you have any children?	No	18.3%	62.8%	18.9%	1.66 0.436
	Yes	27.8%	55.6%	16.8%	
Does the presence of PCOS affect any area of your life?	No	40.6%	56.3%	3.1%	13.14 0.001
	Yes	16.1%	62.5%	21.4%	
Do you experience anxiety/sadness due to PCOS?	No	26.2%	64.3%	9.5%	3.40 0.183
	Yes	18.4%	60.8%	20.8%	
Do you feel a lack of control over the situation with PCOS?	No	28.0%	68.0%	4.0%	10.17 0.006
	Yes	17.3%	59.4%	23.3%	
Do you have depression?	No	23.0%	65.5%	11.5%	19.16 0.000
	Yes	11.5%	50.0%	38.5%	

χ^2 : Chi-square statistics; *p*: statistical significance level.

This study also investigated whether the quality of life of women with PCOS was linked to the impact of the disease on self-esteem. To explore this, a series of analyses were conducted using Pearson's χ^2 test, and the results, detailed in Table 7, were found to be statistically significant (*p* < 0.05). The findings indicated that women who did not accept their physical appearance, had low self-esteem, and lacked family support tended to rate their quality of life as lower.

Table 7. Relationship between quality of life assessment and self-esteem.

	How Is Your Quality of Life?			χ^2	<i>p</i>
	Very Good	Good	Sufficient/ Poor		
Do you accept your appearance (physical)?	No	13.5%	58.8%	27.7%	20.19 0.000
	Yes	29.7%	65.4%	4.9%	
Do you have low self-esteem due to polycystic ovary syndrome?	No	27.7%	63.1%	9.2%	7.36 0.025
	Yes	16.3%	60.7%	23.0%	
How do you assess the support from your family?	Very good	39.3%	53.6%	7.1%	22.13 0.001
	Good	21.9%	67.2%	10.9%	
	Moderate	15.1%	64.0%	20.9%	
	Poor	9.0%	45.5%	45.5%	

χ^2 : Chi-square statistics; *p*: statistical significance level.

4. Discussion

PCOS stands as the most prevalent endocrine disorder among women of reproductive age. The range of clinical manifestations associated with PCOS are substantial, encompassing hormonal, metabolic, lipid, and carbohydrate metabolism disorders [16]. These conditions collectively exert a significant impact on the quality of life for affected women [1]. Given the diverse array of clinical symptoms and the associated dependencies on the occurrence of additional diseases, it is imperative to approach each patient with PCOS on an individual basis. Tailoring the treatment to encompass the patient's symptoms, concurrent conditions, and expectations for therapeutic outcomes is crucial for quality of life.

Women with PCOS suffer more from depression and sexual dysfunction than healthy patients [21,22]. In our study, the majority of women in the sample rated their quality of life (self-assessment of quality of life) as good, accounting for 61.5%, while 20% of respondents perceived themselves as having a very good quality of life. Unfortunately, a significant portion, 79% of the surveyed women, experienced feelings of sadness related to the disease. Additionally, 75% declared a lack of control over PCOS, and 26% of the women reported struggling with depression. Moreover, 67.5% of the surveyed women admitted to experiencing low self-esteem due to the presence of PCOS, with only 40.5% accepting their physical appearance.

Women dealing with PCOS contend with various health challenges that manifest to varying degrees across different aspects of their lives. The predominant symptoms of PCOS include irregular menstrual cycles [23] and hirsutism [16]. Sidra et al. [24] noted that irregular menstrual cycles (71.8%) and hirsutism (68.7%) were the most commonly mentioned symptoms by women with PCOS [24]. Hirsutism, identified by Bazarganipour et al. [25], is frequently reported by women with PCOS, with Mohammad et al. [16] stating that it affects nearly 70% of women, often impacting their sense of femininity [16]. Rzońca et al. [26] reported that the longer the duration of the PCOS, the lower the overall quality of life of affected women, affecting various spheres such as social, physical, and environmental well-being [26]. Conversely, Stańczyk et al. [27] observed a prevalence of lowered self-esteem among most women with PCOS, particularly those grappling with hirsutism and lacking robust social support [27]. Contrary to some previous findings, our study did not establish a correlation between the duration of illness or the presence of additional diseases and the quality of life. However, it did reveal a noteworthy association between the severity of PCOS symptoms and the overall quality of life. Women with highly bothersome PCOS symptoms tended to rate their quality of life as lower.

Struggling with issues such as excessive body hair, challenging-to-control acne, increased hair loss, or heightened sebum production can significantly diminish a woman's self-esteem, particularly in terms of her physical attractiveness, leading to embarrassment and potentially contributing to the development of psychosocial disorders [1,2]. Additionally, conditions like overweight, obesity, insulin resistance, and hyperinsulinemia can either be a cause or consequence of metabolic disorders, substantially impacting the deterioration of quality of life and self-perception [28,29]. For women with PCOS, excessive body weight and the prolonged effort to shed it can also negatively affect their self-esteem [27,30]. A study by Moghadam et al. [20] highlighted obesity as a significant contributor to poor quality of life, particularly due to its association with negative psychological symptoms [20]. In addressing most symptoms linked to PCOS, lifestyle modification is often recommended. This involves adopting a diet that supports weight maintenance or reduction, alongside regular exercise—considered the primary nonpharmacological treatment for women with PCOS. Lifestyle modifications yield substantial improvements in metabolism, reproductive function, and a reduction in insulin resistance [17,31]. A reduction in body weight has been found to primarily enhance insulin sensitivity in target tissues. This weight loss leads to increased sex hormone binding globulin (SHBG) and decreased testosterone levels, thereby alleviating symptoms of hyperandrogenism. This mechanism also contributes to rectifying endocrine dysfunction, regulating menstrual cycles, and enhancing ovulation frequency, thereby improving fertility [32–34]. In the context of lifestyle modification, maintaining an appropriate diet is crucial. This involves primarily reducing the intake of high glycemic index carbohydrates, adopting a low-calorie diet, increasing fiber and polyunsaturated fat consumption, and decreasing saturated fats [3,18,35,36]. Another vital aspect of modifying the lifestyle of women with PCOS is regular physical exercise, which, when combined with an appropriate diet, can lead to a reduction in excessive body weight and alleviate bothersome PCOS-related symptoms, ultimately contributing to enhanced well-being. Regular physical activity is recommended at least three times a week, with each session lasting at least 30 min. The selection of suitable physical activities depends on individual needs and preferences, ensuring alignment with a woman's current capabilities [29]. Although our

study did not confirm a direct correlation between physical activity and quality of life, it did highlight that women who did not accept their physical appearance, had low self-esteem, and lacked family support tended to rate their quality of life as lower. Intriguingly, there was a noteworthy trend in quality of life among those adhering to dietary recommendations, approaching statistical significance. Specifically, women on a diet tended to rate their quality of life more negatively.

Women with PCOS often face challenges in conceiving or may be diagnosed with infertility. This contributes to a decline in the quality of life for these women, as the desire to have a child holds significant importance in the lives of a certain proportion of women. It represents the realization of their dreams and a strengthening of family ties with their partners. According to Sulaiman et al. [29], infertility affects 38.4% of women with PCOS [29]. Additionally, Barnard et al. [23] associate PCOS with elevated levels of depression [23]. Sidra et al. [24] share a similar perspective, reporting an increasing incidence of depression among women with PCOS, with a result of 61.8% [24]. In our study, a slightly different result was obtained, with 26% of surveyed women confirming the presence of depression. Given the gravity of depression in the context of this condition, further investigation into its prevalence among women with PCOS, involving a larger sample, would be valuable. Our study did not establish a direct relationship between quality of life and the experience of having offspring or feelings of sadness. Instead, it revealed that lower quality of life was associated with women who acknowledged that PCOS was impacting their lives, women with a sense of lack of control over the disease, and women grappling with depression.

The treatment of PCOS is contingent upon the predominant symptoms and the individual patient's expectations regarding therapeutic outcomes. Consequently, PCOS treatment should be comprehensive and tailored to the specific needs of each woman. In cases of insulin resistance and hyperinsulinemia, when nonpharmacological approaches like a proper diet and regular exercise prove insufficient, pharmacological treatment becomes necessary. Metformin, a widely utilized drug, is commonly prescribed. It enhances insulin sensitivity in target tissues and has a positive impact on the lipid profile. Metformin's mechanism involves inhibiting hepatic gluconeogenesis, subsequently reducing intestinal glucose absorption, and later increasing peripheral glucose uptake and metabolism. Despite its side effects, metformin significantly improves tissue insulin sensitivity and contributes to weight loss. As an alternative to metformin, inositol supplementation is increasingly recommended [37–41]. Conversely, for women not planning to conceive but contending with irregular menstrual cycles and excessive hairiness, oral contraceptives are the preferred form of therapy. Their primary role is to regulate menstrual cycles and reduce hyperandrogenemia. Hormonal contraception inhibits excessive secretion of luteinizing hormone (LH) and lowers free androgens. It is crucial to note that the effects of hirsutism therapy may only become evident after 3–6 months due to the hair follicle development cycle. However, these effects may reverse upon discontinuation of treatment. Some women with PCOS are turning to cosmetic procedures like laser hair removal. Given the potential risk of embolic complications with oral contraceptives, it is essential to approach patients individually, selecting the safest contraception type while considering contraindications and assessing risk factors for heart disease [42–46]. Therefore, comprehensive care is vital, tailoring treatment based on accompanying symptoms, conditions, and expected outcomes. Early diagnosis and appropriately selected treatment can help prevent more serious consequences associated with untreated PCOS [1,27,29]. Unfortunately, in our study, we did not observe an impact of treatment on the assessed quality of life of women with PCOS.

5. Conclusions

Despite the majority of women with PCOS rating their quality of life as good or very good, they often find the associated symptoms of PCOS bothersome. Women reporting a lower quality of life tend to acknowledge the impact of PCOS on their lives, experience a sense of lack of control over the disease, struggle with depression, and do not accept

their physical appearance. Hence, the support from specialists like endocrinologists, gynecologists, and nutritionists becomes crucial for many women dealing with PCOS. Adopting a healthy lifestyle, incorporating a balanced diet, and engaging in regular physical activity can assist in managing the troublesome symptoms of PCOS, thereby enhancing overall quality of life. In instances of emotional difficulties, seeking psychological support is equally important, and the significance of support and acceptance from loved ones should not be overlooked.

Objective: To evaluate racial differences in the anxiety and depression prevalence and scores in women with polycystic ovary syndrome (PCOS).

Design: Cross-sectional.

Setting: Academic institution.

Patient(s): Reproductive-aged women with PCOS ($n = 272$) and controls ($n = 295$).

Intervention(s): Hospital anxiety and depression scale and modified PCOS quality-of-life survey (MPCOS-Q).

Main Outcome Measure(s): Differences in depression and anxiety scores and quality-of-life score measured using the hospital anxiety and depression scale and MPCOS-Q were determined between White and Black women with PCOS. Multivariable correlation regressions assessed the association of the Ferriman-Gallwey score, total testosterone, body mass index (BMI), and homeostatic model assessment of insulin resistance with anxiety, depression, and quality-of-life scores.

Result(s): Multivariable regression controlling for age, BMI, and socioeconomic status showed that White women with PCOS had a significantly higher prevalence of anxiety than Black women with PCOS (75.9% vs. 61.3%) and significantly higher anxiety scores (mean \pm SD, 10.3 ± 4.1 vs. 8.7 ± 4.6). The prevalence of depression (24.4% vs. 29%) and depression scores (4.8 ± 3.6 vs. 5.1 ± 4.0) was not significantly different. In multivariable correlation regressions, the interaction between BMI and race in its association with anxiety scores was significant. The association of race with Ferriman-Gallwey score, total testosterone, or homeostatic model assessment of insulin resistance was not significant. In multivariable models, although the total MPCOS-Q scores were similar, the infertility domain was significantly lower in Black women with PCOS (mean \pm SD, 12.6 ± 7.8 vs. 17.5 ± 6.8) indicating a lower quality of life related to infertility.

Conclusion: Racial differences identified in the prevalence of anxiety and MPCOS-Q domains suggest the importance of routine screening and provide an opportunity for targeted interventions based on race. (Fertil Steril Rep® 2021;■:■-■. ©2021 by American Society for Reproductive Medicine.)

Key Words: Anxiety, depression, PCOS, quality of life, racial differences

Discuss: You can discuss this article with its authors and other readers at <https://www.fertsterdialog.com/posts/xfre-d-20-00221>

Polycystic ovary syndrome (PCOS) is the most common endocrine disorder affecting reproductive-aged women (1). Its prev-

alence ranges from 8% to 13% depending on the diagnostic criteria used and the race and ethnicity of the population studied (2). For example, although the

prevalence of PCOS in the United States ranges from 5% to 7% (3), it is as low as 2.2% in China (4) and as high as 14.1% in Iran (5). The prevalence of different phenotypes of PCOS also varies depending upon race or ethnicity. In a cross-sectional retrospective study in the United Kingdom ($n = 1,310$), South Asian women were significantly more likely to have hyperandrogenic symptoms compared with White women (6). Similar differences in phenotypes have been described in other populations, including African Americans and Hispanics (7, 8), leading recent international guidelines to suggest

ethnicity-based cutoffs for Ferriman-Gallwey (FG) scores (2).

In addition, metabolic risk in women with PCOS also varies with ethnicity. In an international study, Norwegian women with PCOS were more likely to have metabolic syndrome, Indian women were more likely to have impaired glucose tolerance, and Brazilian women were more likely to have low high-density lipoprotein (HDL) compared with White women residing in the United States (9). In the United States, Black adolescents and young adults have been reported to have a higher prevalence of metabolic syndrome and its components compared with their White counterparts (relative risk 2.65, 95% confidence interval [CI]: 1.29–5.4) (10, 11).

Although racial disparities in phenotype and metabolic risk have been studied, there is no data on racial differences in emotional wellness in the PCOS population. It is important to consider the effect of racial disparities and differences on mental health, including the emerging evidence that racial experiences in minority populations can affect multiple aspects of mental health care, including distress due to anxiety, access to care, and the use of treatment (12–16). In the US general population, the lifetime prevalence of generalized anxiety disorder (GAD) is higher in White women (8.6%) compared with that in Black women (5.1%) (17). A survey-based study reported higher 12-month odds of GAD diagnosis (odds ratio [OR] 2.9, 95% CI: 2.1–4.1) and social anxiety disorders diagnosis (OR 2.4, 95% CI: 1.8–3.2) in White adults compared with African Americans after controlling for socio-demographic variables (18). Another survey of 43,093 adults found that Black adults had significantly lower lifetime odds of social anxiety disorder compared with White adults (OR 0.6, 95% CI: 0.5–0.73) (19). The prevalence of depression has also been shown to be influenced by race, although the 2013–2016 National Health and Nutrition Examination Survey found no significant differences in the prevalence of major depression between White ($10.5\% \pm 0.9\%$) and Black ($11.0\% \pm 0.8\%$) women (20). Despite the evidence in the non-PCOS population, there are no studies directly comparing the racial differences in anxiety and depression within the PCOS population. Understanding these differences is important as it could influence screening guidelines, counseling tools, or allocation of resources when evaluating mental health in PCOS.

Therefore, the aim of our study was to evaluate the racial differences in the prevalence of anxiety and depression between Black and White women with PCOS and to determine if physical and biochemical attributes of PCOS correlate with anxiety, depression, and quality of life.

MATERIALS AND METHODS

Subjects

This was a retrospective, cross-sectional study conducted at the University of Pennsylvania from November 2015 to October 2018 that included nonpregnant women of 18–50 years of age. Women seen at the Penn PCOS center meeting the Rotterdam criteria (21) were approached for participation. Data on clinical and biochemical measures related to PCOS were obtained by chart review. The homeostatic model

assessment of insulin resistance (HOMA-IR) was calculated by multiplying fasting glucose levels (mg/dL) times fasting insulin levels (mIU/mL) divided by 405. Women without PCOS were recruited from the gynecology clinic as controls and were excluded if they reported both hirsutism and irregular menses on the demographic questionnaires. The University of Pennsylvania Institutional Review Board approved this study.

Surveys

Demographic questionnaires containing items on race, socioeconomic status (SES), and psychiatric, menstrual, and pregnancy history, the hospital anxiety and depression scale (HADS) survey, and the modified-PCOSQ (MPCOS-Q) survey were administered. White or Black race was self-reported. The HADS is a validated 14-item questionnaire with 7 questions dedicated to the assessment of anxiety and 7 to the assessment of depressive symptoms (22, 23). HADS is scored on a Likert scale, and scores ≥ 8 were considered clinical cutoffs as described in other studies (24). The MPCOS-Q is a 30-item questionnaire containing the following domains: emotions, body hair, weight, infertility, menstruation, and acne (25). Questions relate to the impact of each domain on the quality of life, with answers presented on Likert scales, for example, none of the time to all of the time. Higher values in each domain and in total scores indicate a higher quality of life. The study data were collected and managed using REDCap (Vanderbilt University, Nashville, TN) (26) electronic data capture tools.

Outcomes

The primary outcome was the differences in the prevalence of anxiety and depression in women with PCOS as well as differences in anxiety, depression, and quality-of-life scores between White and Black women with PCOS. The secondary outcomes included the same comparisons in White and Black controls and correlations between anxiety, depression, quality-of-life scores and FG scores, body mass index (BMI), testosterone levels, and HOMA-IR between races in women with PCOS.

Statistical Analyses

Continuous outcomes were compared using either rank-sum or student *t*-test as dictated by normality assessments. Normality assessments were based on graphical displays as well as quantitatively through the Shapiro-Wilk test. Categorical outcomes were compared using Pearson chi-square tests or Fisher's exact test. For correlation analyses, FG score, BMI, total testosterone levels, and HOMA-IR were included.

Multivariable logistic regression modeling was used to examine differences in the prevalence of anxiety and depression between White and Black women with PCOS. Multivariable linear regression modeling was used to examine differences in continuous HADS scores and MPCOS-Q scores between White and Black women with PCOS. Covariates to include in the model were determined

TABLE 1**Demographic characteristics of women with PCOS and controls.**

	PCOS (n = 272)			Controls (n = 295)

Note: BMI = body mass index; PCOS = polycystic ovary syndrome.

Alur-Gupta. PCOS race differences in anxiety. *Fertil Steril Rep* 2021.

a priori as well as assessment of confounding using a backward elimination strategy and included patient age, BMI, and SES. Linear regression with interaction terms as well as Pearson's correlation were employed to evaluate racial differences in association between FG scores, BMI, testosterone levels, and HOMA-IR, HADS, and MPCOS-Q scores. For comparative purposes, the preceding analyses were replicated for the controls, including examining for interactive effects for race between women with PCOS and controls.

RESULTS

Demographic Characteristics

The demographic characteristics of the 272 women with PCOS and 295 controls are shown in Table 1. Black women with PCOS had a significantly higher BMI ($P < .001$), were less likely to have a college degree or higher ($P = .006$), had lower incomes ($P < .001$), and were less likely to be married or in a domestic partnership ($P = .034$) than White women with PCOS. FG score, total testosterone, and free testosterone did not differ significantly between Black and White women with PCOS (Table 2).

Racial Differences in Anxiety and Depression Prevalence

White women with PCOS had a significantly higher prevalence of anxiety (defined as HADS > 8) than Black women

(75.9% vs. 61.3%), and the odds of anxiety in multivariable logistic regression models controlling for age, BMI, and SES (adjusted odds ratio [aOR] 2.21, 95% CI: 1.17–4.19) was also higher in White versus Black women with PCOS ($P = .014$). However, the prevalence of depression (defined as HADS > 8) and the odds of depression were not significantly different (White women 24.4% vs. Black women 29.0%) in adjusted models (aOR 1.03, 95% CI: 0.50–2.14, $P = .933$) (Table 3, Fig. 1A).

In multivariable logistic regression models controlling for age, BMI, and SES, White controls had a significantly higher prevalence of anxiety and odds of anxiety than Black controls (59.6% vs. 47.1%; aOR 2.04, 95% CI: 1.17–3.53, $P = .011$). The prevalence of depression and odds of depression were not significantly different between White and Black controls in models adjusted for age, BMI, and SES (18.5% vs. 13.2%; aOR 1.46, 95% CI: 0.65–3.28, $P = .361$) (Table 3, Fig. 1B).

Thus, in both women with PCOS and controls, a higher prevalence of anxiety was seen among White women compared with Black women. To determine if the differences between White women and Black women varied significantly between women with PCOS and controls, the data were combined and the above models extended to include the interaction between groups. Both interaction models were nonsignificant ($P = .839$ for anxiety prevalence; $P = .514$ for depression prevalence) indicating that there were no racial differences in prevalence when comparing the PCOS cohort with the control cohort.

TABLE 2**Phenotypic characteristics and biochemical data in White versus Black women with PCOS.**

	White women with PCOS (n = 202)	Black women with PCOS (n = 70)	P value
Measures of androgen excess			
FG score	10 (4–15)	12 (5–17)	.128
Total testosterone (ng/dL)	49 (32–60)	48 (44–74)	.055
Free testosterone (pg/mL)	4.9 (2.5–8)	6.3 (3.7–9.7)	.086
DHEAS (μ g/dL)	222.5 (136.0–307.0)	177.5 (118.0–264.8)	.036
SHBG (nmol/L)	53.5 (31.6–100.9)	38 (24–67)	.031
Measures of hyperlipidemia			
Total cholesterol (mg/dL)	179.5 (162–204)	164 (149–177)	<.001
Triglycerides (mg/dL)	103.5 (75.5–163.5)	68 (51–92)	<.001
LDL (mg/dL)	100 (83–118)	97 (86–110)	.584
HDL (mg/dL)	54 (45–67)	50 (41.5–59)	.043
Measures of insulin resistance			
HgbA1c	5.3 \pm 0.4	5.6 \pm 0.4	<.001
HOMA-IR	2.8 (1.5–5.6)	3.7 (1.8–6.2)	.334
Fasting glucose	85 (78–91)	85 (81–90)	.730
Measures of ovarian reserve			
AMH (ng/mL)	6.0 (3.1–9.1)	7.0 (4.4–10.4)	.251
Total AFC	37 (27–40)	40 (31–55)	.044

Note: Data are presented as median (IQR) and mean \pm SD. AFC = antral follicle count; AMH = antimüllerian hormone; DHEAS = dehydroepiandrosterone sulfate; FG = Ferriman-Gallwey score; HDL = high-density lipoprotein; HgbA1c = hemoglobin A1c; HOMA-IR = homeostatic model assessment of insulin resistance; IQR = interquartile range; LDL = low-density lipoprotein; PCOS = polycystic ovary syndrome; SHBG = sex hormone-binding globulin.

Alur-Gupta. PCOS race differences in anxiety. *Fertil Steril Rep* 2021.

Racial Differences in Anxiety and Depression Scores

In multivariable linear regression models controlling for age, BMI, and SES, White women with PCOS had significantly higher anxiety scores (mean \pm SD 10.3 \pm 4.1 vs. 8.7 \pm 4.6, β = 1.80, P = .006). Depression scores were not significantly different in adjusted models for comparisons of White and Black women with PCOS (mean 4.8 \pm 3.6 vs. 5.1 \pm 4.0, β = 0.23, P = .659) (Table 3).

In multivariable linear regression models adjusted for age, BMI, and SES, White controls did not have significantly different anxiety scores compared with those of Black controls (mean 8.1 \pm 3.8 vs. 7.5 \pm 4.8, β = 1.03, P = .083). In models adjusted for age, BMI, and SES, White controls did not have significantly different depression scores compared with those of Black controls (mean 3.6 \pm 3.3 vs. 4.1 \pm 3.5, β = 0.77, P = .105) (Table 3).

Combining the PCOS and controls data, interaction models yielded nonsignificant interactions for both anxiety (P = .363) and depression (P = .425) scores, indicating that there were no racial differences in scores when comparing the PCOS cohort with the controls.

Correlation Between Anxiety, Depression, and FG Scores, Total Testosterone, BMI, and HOMA-IR

In multivariable correlation regressions of anxiety and depression, within the PCOS sample, the interaction term between BMI and race in its association with anxiety scores was significant (P = .031), indicating that the relationship between BMI and anxiety varied differentially between White and Black women. Further evaluation of correlation estimates separately within White and Black women with PCOS revealed a direct relationship in White women in whom higher

TABLE 3**Racial differences in anxiety and depression in White versus Black women with PCOS and controls.**

	White vs. Black PCOS (n = 272)		White vs. Black controls (n = 295)		
	aOR ^b	P value	aOR ^b	P value	Interaction P value
HADS anxiety prevalence ^a	2.21 (1.17, 4.19)	.014	2.04 (1.17, 3.53)	.011	.839
HADS depression prevalence ^a	1.03 (0.50, 2.14)	.933	1.46 (0.65, 3.28)	.361	.514
Mean HADS anxiety score	Coefficient	P value	Coefficient	P value	
Mean HADS depression score	1.80 (0.51, 3.10)	.006	1.03 (−0.13, 2.19)	.083	.363
	0.23 (−0.80, 1.27)	.659	0.77 (−0.16, 1.70)	.105	.425

Note: aOR = adjusted odds ratio; BMI = body mass index; HADS = hospital anxiety and depression scale; PCOS = polycystic ovary syndrome.

^a Defined as HADS score >8.

^b Adjusted for age, BMI, and socioeconomic status variables.

FIGURE 1

(A) Racial differences in the prevalence of anxiety and depression symptoms in women with PCOS. (B) Racial differences in the prevalence of anxiety and depression symptoms in controls. (C) Racial differences in the quality-of-life domain scores in women with PCOS. PCOS = polycystic ovary syndrome.

Alur-Gupta. PCOS race differences in anxiety. *Fertil Steril Rep* 2021.

BMI was associated with higher anxiety scores ($r = 0.11, P = .147$) but an inverse relationship in Black women in whom higher BMI was associated with lower anxiety scores ($r = -0.17, P = .184$). The interaction term between race and FG score, total testosterone, and HOMA-IR was not significant.

Racial Differences in Quality-of-Life Scores

In unadjusted analyses, Black women with PCOS had significantly lower total MPCOS-Q scores compared with those of White women (98.6 vs. 110.7, $P = .009$). In multivariable linear regression models adjusted for age, BMI, and SES, there was no difference in the total MPCOS-Q score ($\beta = 2.75, P = .572$). When broken down by domain, in unadjusted analyses the emotions domain and infertility domain scores were significantly lower in Black women with PCOS compared with those in White women with PCOS ($P = .002$ and $P < .001$, respectively), meaning that Black women had lower quality of life related to emotional well-being and infertility concerns. In multivariable linear regression models adjusted for age, BMI, and SES, the infertility domain score remained significantly lower in Black women with PCOS (mean 12.6

vs. 17.5, $\beta = 3.51, P = .001$) (Fig. 1C). In correlation regressions of total quality-of-life scores in women with PCOS, the interaction terms between race and FG score, total testosterone, and HOMA-IR were not significant ($P = .644$, $P = .276$, and $P = .300$, respectively).

DISCUSSION

Racial differences in PCOS phenotypes and long-term metabolic risk are well recognized. In our study, the prevalence of anxiety after adjusting for age, BMI, and SES and the anxiety levels were significantly higher in adult White women with PCOS compared with those in Black women with PCOS. There were no significant differences in the prevalence of depression or depressive symptoms between the 2 groups.

In keeping with the literature, we found that White controls had a significantly higher prevalence of anxiety compared with that of Black controls, with no difference in the prevalence of depression. In addition, although the finding that higher BMI was associated with higher anxiety in White women with PCOS but lower anxiety in Black women with PCOS did not reach statistical significance, this

may relate in part to a lack of power and warrants further investigation. Examination of quality-of-life scores showed that infertility had the most significant impact on lowering quality of life, with Black women with PCOS having lower infertility domain scores compared with those of White women with PCOS.

Anxiety disorders contribute significantly to the financial burden related to health care (27) such that GAD is associated with 1.5–5.4 days of work impairment in 1 month and 5 times greater likelihood of moderate/severe occupational dysfunction and physical disability (28, 29). Women with PCOS are at an increased risk of anxiety compared with controls as seen in a large meta-analysis of >1,400 women (OR 5.62; 95% CI: 3.22–9.80) (30). Thus, understanding the risk factors that mediate the relationship between PCOS and anxiety is vital.

Although our study was not designed to determine causative factors, potential causes for the lower anxiety scores in Black women include greater resilience to stressors secondary to strong social support and religiosity (18). Also, preexisting substance-abuse disorders, known to be more common in White adults, may contribute to an increase in certain forms of anxiety (18). Further, higher body image dissatisfaction in White compared with Black adults (31) has also been linked to mood disorders (32–34). Of note, body image dissatisfaction is a known mediator for anxiety in women with PCOS. In contrast, other studies have emphasized that sociocultural differences in beliefs and attitudes may affect the expression and assessment of anxiety in Black adults, thus advising caution in the interpretation of observed differences (35). The impact of racial experiences on mental health cannot be understated. Unconscious bias and other race-related factors have been associated with differences in access to care, the use of treatment, and stress (12–16). It is possible that differences in mental health are also driven by cultural and systemic differences as well as structural racism (36). Although our study was not constructed to evaluate this, the contribution and interplay of these factors must not be ignored.

The underlying etiology for increased anxiety and depression in women with PCOS is unclear; in 1 study, women with PCOS and concurrent depression had higher BMI and hirsutism scores, whereas women with PCOS and concurrent anxiety had higher BMI, hirsutism scores, and free testosterone levels, although the effect sizes were small (30). The association between BMI and anxiety has been studied in the general population (37), with a recent meta-analysis of 25 studies reporting increased anxiety in obese individuals (pooled OR 1.30, 95% CI: 1.20–1.41) (38). Dysregulated biological pathways, including neurotransmitter imbalances, oxidative stress, and hypothalamus-pituitary-adrenal axis disturbances, have been implicated in the association between psychiatric disorders and obesity (39). In addition, anxiety has been associated with disordered eating, which can affect obesity, and obese women may be at a higher risk of facing stigma and discrimination leading to dissatisfaction (38). Another study demonstrated that insulin resistance was associated with increased odds of depression in women with PCOS after controlling for age and BMI (40). To understand

the etiology for increased anxiety in White women with PCOS, we examined the association with the previously described risk factors and found a significant interaction between race and BMI as it associates with anxiety scores.

Racial differences in the health-related quality of life in women with PCOS have been described with varying results (41, 42). In our study, Black women with PCOS were noted to have significantly lower scores on the emotion and infertility domains of the quality-of-life survey. With regards to the relationship between infertility and quality of life, several studies have shown that infertile women suffer from poor quality of life scores. An Iranian matched case-control study of 180 infertile and 540 fertile women found that infertility affected the women's physical health, mental health, and social health significantly (43). A cross-sectional study of US women veterans also found that of the 996 veterans studied, those reporting a history of infertility had worse perceived physical health and higher rates of depression in analyses adjusted for age (44). In a meta-analysis of studies comparing racial differences in in vitro fertilization treatment outcomes in the general infertile population, Black women had lower live birth rates compared with those of White women, although there was considerable heterogeneity (45). In addition to differences in access to infertility services, Black and Hispanic women use infertility services far less frequently compared with White women (46). Black women have a higher prevalence of uterine fibroids and tubal disease, which affect miscarriage and live birth rates even in equal access settings (47). These studies underscore the complex relationship between infertility and race and may provide insights into our findings of lower quality-of-life scores related to infertility. In our population, Black women were less likely to be married or in a domestic partnership, which could have also contributed to lower quality-of-life scores related to fertility. As the majority of women with anovulatory infertility have PCOS (48), practitioners should be sensitive to the impact that infertility has on overall quality of life, particularly in Black populations.

Cognitive behavioral therapy combined with nutritional counseling, lifestyle changes and the use of continuous hormonal contraceptives improve anxiety scores in women with PCOS (49, 50). Cognitive behavioral therapy is a form of psychotherapy that focuses on changing the dysfunctional thoughts that lead to negative mood states and is recommended by the American Psychological Association as a first-line treatment for several mental health disorders (51, 52). Although most of these studies were small, they suggested that targeting weight and hyperandrogenism improved anxiety symptoms. Our findings of an interaction between race and BMI also suggested that BMI may play a role in the differences observed. As it is estimated that 80% of women with PCOS in the United States are obese (53), future trials should examine if the impact of lifestyle modifications and hormonal contraceptives on anxiety and depression symptoms is modified by race.

Our study is the first to examine differences in anxiety and depressive symptoms and health-related quality-of-life scores between White and Black women with PCOS residing in the United States. Relatively large sample sizes and

interaction assessment with clinical parameters in women with PCOS add to the strengths of this study. We were unable to examine racial differences in anxiety and depression based on PCOS phenotypes, and our findings may not be generalizable to adolescents. Although women with hirsutism and irregular menses were excluded from the control group, it is possible that some controls were incorrectly labeled; however, we would expect this to result in more conservative estimates. Hormonal contraceptive use data, which can impact mood, was not available, although antidepressant use was not significantly different between the populations. In addition, although the focus of this paper was on Black and White women, exploration of other races is also necessary. Although there were insufficient numbers and power to evaluate additional races in this analysis, future studies evaluating a larger cohort of races should be conducted. They should also examine the impact of factors such as substance abuse or body image distress on the relationship between race and anxiety in these populations.

CONCLUSION

White women with PCOS are more likely to have anxiety symptoms and higher anxiety scores compared with Black women. Black women with PCOS also had lower quality-of-life scores, particularly in the infertility domain, compared with those of White women with PCOS. The Androgen Excess-Polycystic Ovary Syndrome Society recommends screening all women with PCOS for anxiety and depression and having adequate resources for follow-up, referral, and ongoing care (54). Understanding the factors that contribute to differences in the prevalence of anxiety may provide an opportunity for improved individualized counseling. Currently, there appears to be a role for recommending lifestyle management as studies in the general population suggest that exercise, such as resistance training or Pilates, can lead to significant reductions in anxiety levels both in obese individuals and those with anxiety disorders (55–57). Further, routine management of women with PCOS must include assessment of quality-of-life symptoms, and research trials should continue to evaluate the contribution of race and race-related factors to these findings. Management of long-term comorbidities in this young, reproductive age population may be best addressed by multidisciplinary teams, including physicians, nutritionists, mental health therapists, and psychologists, as proposed in the international guidelines (2).

ABSTRACT

STUDY QUESTION: What is the recommended assessment and management of those with polycystic ovary syndrome (PCOS), based on the best available evidence, clinical expertise, and consumer preference?

SUMMARY ANSWER: International evidence-based guidelines address prioritized questions and outcomes and include 254 recommendations and practice points, to promote consistent, evidence-based care and improve the experience and health outcomes in PCOS.

WHAT IS KNOWN ALREADY: The 2018 International PCOS Guideline was independently evaluated as high quality and integrated multidisciplinary and consumer perspectives from six continents; it is now used in 196 countries and is widely cited. It was based on best available, but generally very low to low quality, evidence. It applied robust methodological processes and addressed shared priorities. The guideline transitioned from consensus based to evidence-based diagnostic criteria and enhanced accuracy of diagnosis, whilst promoting consistency of care. However, diagnosis is still delayed, the needs of those with PCOS are not being adequately met, evidence quality was low and evidence-practice gaps persist.

STUDY DESIGN, SIZE, DURATION: The 2023 International Evidence-based Guideline update reengaged the 2018 network across professional societies and consumer organizations, with multidisciplinary experts and women with PCOS directly involved at all stages. Extensive evidence synthesis was completed. Appraisal of Guidelines for Research and Evaluation-II (AGREEII)-compliant processes were followed. The Grading of Recommendations, Assessment, Development, and Evaluation (GRADE) framework was applied across evidence quality, feasibility, acceptability, cost, implementation and ultimately recommendation strength and diversity and inclusion were considered throughout.

PARTICIPANTS/MATERIALS, SETTING, METHODS: This summary should be read in conjunction with the full Guideline for detailed participants and methods. Governance included a six-continent international advisory and management committee, five guideline development groups, and paediatric, consumer, and translation committees. Extensive consumer engagement and guideline experts informed the update scope and priorities. Engaged international society-nominated panels included paediatrics, endocrinology, gynaecology, primary care, reproductive endocrinology, obstetrics, psychiatry, psychology, dietetics, exercise physiology, obesity care, public health and other experts, alongside consumers, project management, evidence synthesis, statisticians and translation experts. Thirty-nine professional and consumer organizations covering 71 countries engaged in the process. Twenty meetings and five face-to-face forums over 12 months addressed 58 prioritized clinical questions involving 52 systematic and 3 narrative reviews. Evidence-based recommendations were developed and approved via consensus across five guideline panels, modified based on

international feedback and peer review, independently reviewed for methodological rigour, and approved by the Australian Government National Health and Medical Research Council (NHMRC).

MAIN RESULTS AND THE ROLE OF CHANCE: The evidence in the assessment and management of PCOS has generally improved in the past five years, but remains of low to moderate quality. The technical evidence report and analyses (~6000 pages) underpins 77 evidence-based and 54 consensus recommendations, with 123 practice points. Key updates include: i) further refinement of individual diagnostic criteria, a simplified diagnostic algorithm and inclusion of anti-Müllerian hormone (AMH) levels as an alternative to ultrasound in adults only; ii) strengthening recognition of broader features of PCOS including metabolic risk factors, cardiovascular disease, sleep apnea, very high prevalence of psychological features, and high risk status for adverse outcomes during pregnancy; iii) emphasizing the poorly recognized, diverse burden of disease and the need for greater healthcare professional education, evidence-based patient information, improved models of care and shared decision making to improve patient experience, alongside greater research; iv) maintained emphasis on healthy lifestyle, emotional wellbeing and quality of life, with awareness and consideration of weight stigma; and v) emphasizing evidence-based medical therapy and cheaper and safer fertility management.

LIMITATIONS, REASONS FOR CAUTION: Overall, recommendations are strengthened and evidence is improved, but remains generally low to moderate quality. Significantly greater research is now needed in this neglected, yet common condition. Regional health system variation was considered and acknowledged, with a further process for guideline and translation resource adaptation provided.

WIDER IMPLICATIONS OF THE FINDINGS: The 2023 International Guideline for the Assessment and Management of PCOS provides clinicians and patients with clear advice on best practice, based on the best available evidence, expert multidisciplinary input and consumer preferences. Research recommendations have been generated and a comprehensive multifaceted dissemination and translation program supports the Guideline with an integrated evaluation program.

STUDY FUNDING/COMPETING INTEREST(S): This effort was primarily funded by the Australian Government via the National Health Medical Research Council (NHMRC) (APP1171592), supported by a partnership with American Society for Reproductive Medicine, Endocrine Society, European Society for Human Reproduction and Embryology, and European Society for Endocrinology. The Commonwealth Government of Australia also supported Guideline translation through the Medical Research Future Fund (MRFCRI000266). HJT and AM are funded by NHMRC fellowships. JT is funded by a Royal Australasian College of Physicians (RACP) fellowship. Guideline development group members were volunteers. Travel expenses were covered by the partnering organizations. Disclosures of interest were strictly managed according to NHMRC policy and are available with the full guideline, technical evidence report, peer review and responses (www.monash.edu/medicine/mchri/pcos). Of named authors HJT, CTT, AD, LM, LR, JBoyle, AM have no conflicts of interest to declare. JL declares grant from Ferring and Merck; consulting fees from Ferring and Titus Health Care; speaker's fees from Ferring; unpaid consultancy for Ferring, Roche Diagnostics and Ansh Labs; and sits on advisory boards for Ferring, Roche Diagnostics, Ansh Labs, and Gedeon Richter. TP declares a grant from Roche; consulting fees from Gedeon Richter and Organon; speaker's fees from Gedeon Richter and Exeltis; travel support from Gedeon Richter and Exeltis; unpaid consultancy for Roche Diagnostics; and sits on advisory boards for Roche Diagnostics. MC declares travels support from Merck; and sits on an advisory board for Merck. JBoivin declares grants from Merck Serono Ltd.; consulting fees from Ferring B.V; speaker's fees from Ferring Arzneimittel GmbH; travel support from Organon; and sits on an advisory board for the Office of Health Economics. RJJ has received speaker's fees from Merck and sits on an advisory board for Ferring. AJoham has received speaker's fees from Novo Nordisk and Boehringer Ingelheim. The guideline was peer reviewed by special interest groups across our 39 partner and collaborating organizations, was independently methodologically assessed against AGREEII criteria and was approved by all members of the guideline development groups and by the NHMRC.

Keywords: Polycystic ovary syndrome / guideline / evidence-based / assessment / management / GRADE

What does this mean for those with PCOS?

Building on the 2018 International Evidence-based Guideline for the Assessment and Management of Polycystic Ovary Syndrome (PCOS), this Guideline updates and expands clinical questions, aiming to ensure that women with PCOS receive optimal, evidence-based care that meets their needs and improves health outcomes. The guideline and translation program were developed with full consumer participation at all stages including priority topics and outcomes for those with PCOS. The aim is to support women and their healthcare providers to optimize diagnosis, assessment and management of PCOS. There is an emphasis on improved education and awareness of healthcare professionals, partnership in care, and empowerment of women with PCOS. Personal characteristics, preferences, culture and values are considered, in addition to resource availability across different settings. With effective translation, the Guideline will address priorities identified by women with PCOS, upskill healthcare professionals, empower consumers, improve care and outcomes, identify key research gaps, and promote vital future research.

Introduction

Polycystic ovary syndrome (PCOS) is the most common endocrinopathy affecting reproductive-aged women, with impacts across the lifespan from adolescence to post menopause. PCOS prevalence is between 10 to 13%, as confirmed in the guideline process (Teede et al., 2010; Azziz et al., 2016). PCOS aetiology is complex; and clinical presentation is heterogeneous with reproductive,

metabolic, and psychological features (Teede et al., 2010; Azziz et al., 2016). Women internationally experience delayed diagnosis and dissatisfaction with care (Gibson-Helm et al., 2017; Dokras et al., 2017; Teede et al., 2014). Clinical practice in the assessment and management of PCOS remains inconsistent, with ongoing key evidence-practice gaps. Following on from the 2018 International Evidence-based Guideline for the Assessment and

Management of Polycystic Ovary Syndrome (Teede et al., 2018a; Teede et al., 2018b), independently evaluated as high quality, this extensive update integrates current literature with previous systematic reviews and extends to new clinical questions prioritized by consumers. Ultimately, we aim to update, extend and translate rigorous, comprehensive evidence-based guidelines for diagnosis, assessment and treatment, to improve the lives of those with PCOS worldwide.

To do so, the Guideline leverages substantive government and society investment and brings together extensive consumer engagement and international collaboration with leading societies and organizations, multidisciplinary experts, and primary care representatives. This comprehensive evidence-based Guideline is constructed from a rigorous, Appraisal of Guidelines for Research and Evaluation-II (AGREE-II)-compliant, evidence-based guideline development process. It provides a single source of international evidence-based recommendations to guide clinical practice, with the opportunity for adaptation in relevant health systems. Together with an extensive translation program, the aim is to reduce worldwide variation in care and promote high quality clinical service provision to improve health outcomes and quality of life in women with PCOS. The Guideline is supported by a multi-faceted international translation program with co-designed resources to enhance the skills of healthcare professionals and to empower women with PCOS, with an integrated comprehensive evaluation program. Here, we summarize recommendations from the 2023 International Evidence-based Guideline for the Assessment and Management of PCOS.

Materials and methods

Best practice evidence-based guideline development methods were applied and are detailed in the full Guideline and the technical report, which are available online (www.monash.edu/medicine/mchri/pcos) (Misso and Teede, 2012). In brief, extensive healthcare professional and consumer or patient engagement informed the Guideline priority areas. International society-nominated panels from across three leading entities, four partner organizations and thirty-two collaborating entities, included consumers and experts in paediatrics, endocrinology, gynaecology, primary care, reproductive endocrinology, psychology, dietetics, exercise physiology, sleep, bariatric/metabolic surgery, public health, other co-opted experts, project management, evidence synthesis and translation. Governance included an international advisory and a management committee, five guideline development groups (GDGs) with 56 members, and paediatric, consumer, and translation committees. The five GDGs covered i) Screening, diagnostic and risk assessment and life stage; ii) Psychological features and models of care; iii) Lifestyle management; iv) Management of nonfertility features; and v) Assessment and management of infertility. The leading entities; the Australian National Health and Medical Research Council (NHMRC) Centres for Research Excellence in Women's Health in Reproductive Life and in Polycystic Ovary Syndrome, led by Monash University, partnered with the American Society for Reproductive Medicine, the Endocrine Society, the European Society of Endocrinology and the European Society of Human Reproduction and Embryology and collaborated with 32 other entities. With international meetings over 12 months fifty-five prioritized clinical questions involved 52 systematic and three narrative reviews, generating evidence-based and consensus recommendations with accompanying practice points. Committee members nominated by partner and collaborator organizations provided international peer

review, and independent experts reviewed methods, which were then submitted to NHMRC for independent review. The target audience includes multidisciplinary healthcare professionals, consumers or patients, policy makers, and educators. The Guideline includes a focus on equity, cultural and ethnic diversity, avoidance of stigma and inclusivity (see full guideline for details).

Processes aligned with all elements of the AGREE-II tool for quality guideline assessment (Brouwers et al., 2010), with extensive evidence synthesis and meta-analysis. Integrity assessment was integrated into guideline evidence synthesis processes and followed the Research Integrity in Guideline Development (RIGID) framework, with studies assessed against criteria from the Research Integrity Assessment (RIA) tool and the Trustworthiness in Randomised Controlled Trials (TRACT) checklist (Mousa et al., 2023; Weibel et al., 2023; Mol et al., 2023). Evidence synthesis methods are outlined in the full guideline and followed best practice (Brouwers et al., 2010; National Health and Medical Research Council, 2009; National Health and Medical Research Council, 2007). Guideline recommendations are presented by category, terms used, evidence quality and Grading of Recommendations, Assessment, Development and Evaluation (GRADE) framework considerations. Category includes evidence-based (sufficient evidence in PCOS) or consensus (insufficient evidence in PCOS, also evidence in general or relevant populations was considered) recommendations and accompanying practice points (implementation considerations) (Table 1).

The terms include "should", "could" and "should not", which are informed by the nature of the recommendation (evidence or consensus), the GRADE framework and the evidence quality and are independent descriptors reflecting GDG judgement. They refer to overall interpretation and practical application of the recommendation, balancing benefits and harms. "Should" is used where benefits of the recommendation exceed harms and where the recommendation can be trusted to guide practice. Conditional recommendations are reflected using the terms "could" or "should/could consider" which are used where evidence quality was limited or available studies demonstrate little clear advantage of one approach over another, or the balance of benefits to harms was unclear. "Should not" applies when there is a lack of appropriate evidence, or harms may outweigh benefits.

Evidence quality was categorized according to the GRADE framework, with judgments about the quality of the included studies and/or synthesized evidence incorporating risk of bias, inconsistency, indirectness, imprecision and any other considerations (e.g., publication bias) that may influence evidence quality. These judgments considered study number and design, statistical data and importance of outcomes (Table 2). The quality of evidence reflects the confidence that the estimate of the effect is

Table 1. Categories of PCOS guideline recommendations

EBR	Evidence Based Recommendations: Evidence sufficient to inform a recommendation made by the guideline development group.
CR	Consensus Recommendations: In the absence of adequate evidence, a consensus recommendation has been made by the guideline development group, also informed by evidence from the general population.
PP	Practice Points: Evidence not sought. A practice point has been made by the guideline development group where important issues arose from discussion of evidence-based or consensus recommendations.

PCOS, polycystic ovary syndrome.

Table 2. Quality (certainty) of evidence categories (adapted from GRADE)

High	⊕⊕⊕⊕	Very confident that the true effect lies close to that of the estimate of the effect.
Moderate	⊕⊕⊕○	Moderate confidence in the effect estimate. The true effect is likely to be close to the estimate of the effect, but there is a possibility that it is different.
Low	⊕⊕○○	Limited confidence in the effect estimate. The true effect may be substantially different from the estimate of the effect.
Very Low	⊕○○○	Very little confidence in the effect estimate. The true effect is likely to be substantially different from the estimate of the effect.

GRADE, Grading of Recommendations, Assessment, Development, and Evaluation.

adequate to support each recommendation (National Health and Medical Research Council, 2009), largely determined by the expert evidence synthesis team. GRADE acknowledges that evidence quality is a continuum; any discrete categorization involves some arbitrary decisions; nevertheless, the advantages of simplicity, transparency, and clarity outweigh these limitations (National Health and Medical Research Council, 2009).

The GRADE framework enabled structured and transparent consideration across evidence quality, feasibility, acceptability, cost, implementation, and ultimately recommendation strength (National Health and Medical Research Council, 2009) and was completed at face to face guideline group meetings for all clinical questions (Table 3) (GRADE).

Notably, certainty of evidence varied across outcomes within each question. Here evidence certainty reflects the lowest certainty for the critical outcomes. Evidence was often stronger for the top ranked outcome, and high quality randomized controlled trials (RCTs) were often present, despite overall low quality of evidence. These nuances were considered by the GDG for all question as per the technical report, with any apparent discrepancy between recommendation strength and evidence certainty justified in the full Guideline. Finally, we note that this is a living Guideline with annual evidence review in rapidly evolving areas.

The recommendations (Table 4) apply the category, descriptive terms, GRADE of the recommendations and the quality of the evidence. The full Guideline, technical evidence and administrative reports are available online (www.monash.edu/medicine/mchri/pcos). The Guideline outlines the clinical need for the question, the clinical question, the evidence summary, the recommendations and practice points, and a summary of the justification developed by the GDGs using the GRADE framework. Extensive international peer review from across the 39 organizations was then considered by each GDG and recommendations were reconsidered applying the GRADE framework if justified. The comprehensive evidence reviews, profiles, and GRADE frameworks supporting each recommendation can be found in the Technical Report. The administrative report on guideline development, disclosure of interest process and declarations, peer review feedback and responses can also be found online. Here, we present the evidence-based and consensus recommendations and practice points (Table 4). This summary, the full Guideline and technical reports are supported by a comprehensive co-designed translation program to optimize dissemination and impact with resources freely available online (www.monash.edu/medicine/mchri/pcos).

Table 3. The Grading of Recommendations, Assessment, Development, and Evaluation (GRADE) framework recommendation strength

❖	Conditional recommendation against the option.
❖❖	Conditional recommendation for either the option or the comparison.
❖❖❖	Conditional recommendation for the option.
❖❖❖❖	Strong recommendation for the option.

Two algorithms are provided to support recommendations on diagnosis (Figure 1) and infertility management (Figure 2).

Discussion

The International Evidence-based Guideline for the Assessment and Management of PCOS and the related translation program aims to provide a high quality, reliable source of international evidence-based recommendations to guide consistent clinical practice and to empower women with evidence-based information. All recommendations were formulated after an assessment of the best available evidence, multidisciplinary clinical expertise, consumer preferences and structured review by five GDGs. The guideline provides 77 evidence-based and 54 consensus recommendations, with 123 practice points underpinned by a technical report on evidence synthesis and GRADE detailed considerations (~6000 pages). The evidence has generally improved over the past five years but remains of low to moderate quality, requiring significant research investment into this neglected, yet common condition.

Key recommendations and updates include that PCOS should be diagnosed using the 2018 International Evidence-based Guideline criteria, which built on the consensus based 2003 Rotterdam criteria. This requires the presence of two of the following: i) clinical/biochemical hyperandrogenism; ii) ovulatory dysfunction; and iii) polycystic ovaries on ultrasound; and here in 2023, alternatively anti-Müllerian hormone (AMH) can now be used instead of ultrasound. Exclusion of other aetiologies is needed. Importantly, where irregular menstrual cycles and hyperandrogenism are present, diagnosis is simplified and ultrasound or AMH are not required for diagnosis. In adolescents, both hyperandrogenism and ovulatory dysfunction are required, with ultrasound and AMH not recommended due to poor specificity. AMH was highlighted as a rapidly evolving area in 2018 and evidence is now strong enough to make this new recommendation. This will significantly change practice and offers women a low cost, convenient option, without evidence of overdiagnosis.

Insulin resistance is recognized as a key feature of PCOS, yet routinely available measures of insulin resistance are inaccurate and clinical measurement is not currently recommended. Once diagnosed, assessment and management should address reproductive, metabolic, cardiovascular, dermatologic, sleep, and psychological features. A lifelong health plan is recommended including a focus on healthy lifestyle, prevention of excess weight gain, optimization of fertility and preconception risk factors, and prevention and treatment of diverse clinical features. These include metabolic risk factors, diabetes, cardiovascular disease, and sleep disorders, which are all increased in PCOS. PCOS should be considered a high-risk condition in pregnancy with women identified and monitored. An increased premenopausal risk of endometrial cancer should also be recognized, whilst absolute risks remain low.

Table 4. Recommendations for the assessment and management of polycystic ovary syndrome (PCOS). © Monash University on behalf of the NHMRC Centre for Research Excellence in Women's Health in Reproductive Life 2023.

NO.	TYPE	RECOMMENDATION	GRADE/QUALITY
1		Screening, diagnostic and risk assessment and life-stages	
		General principles	
	PP	All diagnostic assessments are recommended for use in accordance with the diagnostic algorithm (Algorithm 1).	
1.1		Irregular cycles and ovulatory dysfunction	
1.1.1	CR	Irregular menstrual cycles are defined as:	♦♦♦♦
		<ul style="list-style-type: none"> • Normal in the first year post menarche as part of the pubertal transition. • 1 to < 3 years post menarche: < 21 or > 45 days. • 3 years post menarche to perimenopause: < 21 or > 35 days or < 8 cycles per year. • 1 year post menarche > 90 days for any one cycle. • Primary amenorrhea by age 15 or > 3 years post thelarche (breast development). <p>When irregular menstrual cycles are present a diagnosis of PCOS should be considered and assessed according to these PCOS Guidelines.</p>	
1.1.2	PP	The mean age of menarche may differ across populations.	
1.1.3	PP	In adolescents with irregular menstrual cycles, the value and optimal timing of assessment and diagnosis of PCOS should be discussed with the patient and their parent/s or guardian/s, considering diagnostic challenges at this life stage and psychosocial and cultural factors.	
1.1.4	PP	For adolescents who have features of PCOS, but do not meet diagnostic criteria, an "increased risk" could be considered and reassessment advised at or before full reproductive maturity, 8 years post menarche. This includes those with PCOS features before combined oral contraceptive pill (COC) commencement, those with persisting features and those with significant weight gain in adolescence.	
1.1.5	PP	Ovulatory dysfunction can still occur with regular cycles and if anovulation needs to be confirmed serum progesterone levels can be measured.	
1.2		Biochemical hyperandrogenism	
1.2.1	EBR	Healthcare professionals should use total and free testosterone to assess biochemical hyperandrogenism in the diagnosis of PCOS; free testosterone can be estimated by the calculated free androgen index.	♦♦♦♦ ⊕○○○
1.2.2	EBR	If testosterone or free testosterone is not elevated, healthcare professionals could consider measuring androstenedione and dehydroepiandrosterone sulfate (DHEAS), noting their poorer specificity and greater age associated decrease in DHEAS.	♦♦♦ ⊕○○○
1.2.3	EBR	Laboratories should use validated, highly accurate tandem mass spectrometry (LC-MS/MS) assays for measuring total testosterone and if needed, for androstenedione and DHEAS. Free testosterone should be assessed by calculation, equilibrium dialysis or ammonium sulfate precipitation.	♦♦♦♦ ⊕⊕○○
1.2.4	EBR	Laboratories should use LC-MS/MS assays over direct immunoassays (e.g., radiometric, enzyme-linked, etc.) for assessing total or free testosterone, which have limited accuracy and demonstrate poor sensitivity and precision for diagnosing hyperandrogenism in PCOS.	♦♦♦♦ ⊕⊕○○
1.2.5	PP	For the detection of hyperandrogenism in PCOS, the assessment of biochemical hyperandrogenism is of greatest value in patients with minimal or no clinical signs of hyperandrogenism (i.e., hirsutism).	
1.2.6	PP	It is very difficult to reliably assess for biochemical hyperandrogenism in women on the combined oral contraceptive pill (COC) as the pill increases sex hormone-binding globulin and reduces gonadotrophin-dependent androgen production. If already on the COCP, and assessment of biochemical androgens is imperative, the pill should be withdrawn for a minimum of three months and contraception should be managed otherwise during this time.	
1.2.7	PP	Repeated androgen measures for the ongoing assessment of PCOS in adults have a limited role.	
1.2.8	PP	In most adolescents, androgen levels reach adult ranges at 12-15 years of age	
1.2.9	PP	If androgen levels are markedly above laboratory reference ranges, causes of hyperandrogenaemia other than PCOS, including ovarian and adrenal neoplastic growths, congenital adrenal hyperplasia, Cushing's syndrome, ovarian hyperthecosis (after menopause), iatrogenic causes, and syndromes of severe insulin resistance, should be considered. However, some androgen-secreting neoplasms are associated with only mild to moderate increases in androgen levels. The clinical history of time of onset and/or rapid progression of symptoms is critical in assessing for an androgen-secreting tumour.	

Table 4. Continued

NO.	TYPE	RECOMMENDATION	GRADE/QUALITY
1.2.10	PP	Reference ranges for different methods and laboratories vary widely, and are often based on an arbitrary percentile or variances of the mean from a population that has not been fully characterized and is highly likely to include women with PCOS. Normal values should be determined either by the range of values in a well characterized healthy control population or by cluster analysis of general population values.	
1.2.11	PP	Laboratories involved in androgen measurements in females should consider: <ul style="list-style-type: none"> Determining laboratory normal values by either the range of values in a well characterized healthy control population or by cluster analysis of the values of a large general population. Applying the most accurate methods where available. Using extraction/chromatography immunoassays as an alternative to mass spectrometry only where adequate expertise is available. Future improvements may arise from measurement of 11-oxygenated androgens, and from establishing cut-off levels or thresholds based on large-scale validation in populations of different ages and ethnicities. 	
1.3 Clinical hyperandrogenism			
1.3.1	EBR	The presence of hirsutism alone should be considered predictive of biochemical hyperandrogenism and PCOS in adults.	♦♦♦ ⊕○○○
1.3.2	EBR	Healthcare professionals could recognize that female pattern hair loss and acne in isolation (without hirsutism) are relatively weak predictors of biochemical hyperandrogenism.	♦♦♦ ⊕○○○
1.3.3	CR	A comprehensive history and physical examination should be completed for symptoms and signs of clinical hyperandrogenism, including acne, female pattern hair loss and hirsutism in adults, and severe acne and hirsutism in adolescents.	♦♦♦♦
1.3.4	CR	Healthcare professionals should be aware of the potential negative psychosocial impact of clinical hyperandrogenism and should consider the reporting of unwanted excess hair growth and/or female pattern hair loss as being important, regardless of apparent clinical severity.	♦♦♦
1.3.5	CR	A modified Ferriman Gallwey score (mFG) of 4 – 6 should be used to detect hirsutism, depending on ethnicity, acknowledging that self-treatment is common and can limit clinical assessment.	♦♦♦♦
1.3.6	CR	Healthcare professionals should consider that the severity of hirsutism may vary by ethnicity but the prevalence of hirsutism appears similar across ethnicities.	♦♦♦
1.3.7	PP	Healthcare professionals should: <ul style="list-style-type: none"> Be aware that standardized visual scales are preferred when assessing hirsutism, such as the mFG scale in combination with a photographic atlas. Consider the Ludwig or Olsen visual scales for assessing female pattern hair loss. Note that there are no universally accepted visual instruments for assessing the presence of acne. Recognize that women commonly treat clinical hyperandrogenism cosmetically, diminishing their apparent clinical severity. Appreciate that self-assessment of unwanted excess hair growth, and possibly acne and female pattern hair loss, has a high degree of validity and merits close evaluation, even if overt clinical signs of hyperandrogenism are not readily evident on examination. Note that only terminal hairs need to be considered in defining hirsutism, and these can reach >5 mm if untreated, vary in shape and texture, and are generally pigmented. Note that new-onset severe or worsening hyperandrogenism, including hirsutism, requires further investigation to rule out androgen-secreting tumours and ovarian hyperthecosis. Monitor clinical signs of hyperandrogenism, including hirsutism, acne and female pattern hair loss, for improvement or treatment adjustment during therapy. 	
1.4 Ultrasound and polycystic ovarian morphology			
1.4.1	EBR	Follicle number per ovary (FNPO) should be considered the most effective ultrasound marker to detect polycystic ovarian morphology (PCOM) in adults.	♦♦♦♦ ⊕○○○
1.4.2	EBR	Follicle number per ovary (FNPO), follicle number per cross-section (FNPS) and ovarian volume (OV) should be considered accurate ultrasound markers for PCOM in adults.	♦♦♦♦ ⊕○○○
1.4.3	CR	PCOM criteria should be based on follicle excess (FNPO, FNPS) and/or ovarian enlargement.	♦♦♦♦
1.4.4	CR	Follicle number per ovary (FNPO) ≥ 20 in at least one ovary should be considered the threshold for PCOM in adults.	♦♦♦♦

(continued)

Table 4. Continued

NO.	TYPE	RECOMMENDATION	GRADE/QUAITY
1.4.5	CR	Ovarian volume (OV) ≥ 10 ml or follicle number per section (FNPS) ≥ 10 in at least one ovary in adults should be considered the threshold for PCOM if using older technology or image quality is insufficient to allow for an accurate assessment of follicle counts throughout the entire ovary.	♦♦♦♦
1.4.6	PP	There are no definitive criteria to define polycystic ovary morphology (PCOM) on ultrasound in adolescents, hence it is not recommended in adolescents.	
1.4.7	PP	When an ultrasound is indicated, if acceptable to the individual, the transvaginal approach is the most accurate for the diagnosis of PCOM.	
1.4.8	PP	Transabdominal ultrasound should primarily report ovarian volume (OV) with a threshold of ≥ 10 ml or follicle number per section (FNPS) ≥ 10 in either ovary in adults given the difficulty of assessing follicle counts throughout the entire ovary with this approach.	
1.4.9	PP	In patients with irregular menstrual cycles and hyperandrogenism, an ovarian ultrasound is not necessary for PCOS diagnosis.	
1.4.10	PP	Thresholds for PCOM should be revised regularly with advancing ultrasound technology, and age-specific cut-off values for PCOM should be defined.	
1.4.11	PP	There is a need for training in careful and meticulous follicle counting per ovary and clear standardized protocols are recommended for PCOM reporting on ultrasound including at a minimum: <ul style="list-style-type: none"> • Last menstrual period (or stage of cycle). • Transducer bandwidth frequency. • Approach/route assessed. • Total number of 2–9 mm follicles per ovary. • Measurements in three dimensions (in cm) or volume of each ovary. • Other ovarian features and/or pathology including ovarian cysts, corpus lutea, dominant follicles (≥ 10 mm) (which should not be included in ovarian volume calculations). • Reliance on the contralateral ovary FNPO for diagnosis of PCOM, where a dominant follicle is noted. • Uterine features and/or pathology including endometrial thickness and pattern. 	
1.5	Anti-Müllerian Hormone in the diagnosis of PCOS		
1.5.1	EBR	Serum anti-Müllerian hormone (AMH) could be used for defining PCOM in adults.	♦♦♦ ⊕⊕⊕○
1.5.2	EBR	Serum AMH should only be used in accordance with the diagnostic algorithm, noting that in patients with irregular menstrual cycles and hyperandrogenism, an AMH level is not necessary for PCOS diagnosis.	♦♦♦♦ ⊕⊕⊕○
1.5.3	EBR	We recommend that serum AMH should not be used as a single test for the diagnosis of PCOS.	♦♦♦♦ ⊕⊕⊕○
1.5.4	EBR	Serum AMH should not yet be used in adolescents.	♦♦♦♦ ⊕⊕⊕○
1.5.5	PP	Either serum AMH or ultrasound may be used to define PCOM; however, both tests should not be performed to limit overdiagnosis.	
1.5.6	PP	Laboratories and healthcare professionals need to be aware of factors that influence AMH in the general population including: <ul style="list-style-type: none"> • Age: Serum AMH generally peaks between the ages of 20–25 years in the general population. • Body mass index (BMI): Serum AMH is lower in those with higher BMI in the general population. • Hormonal contraception and ovarian surgery: Serum AMH may be suppressed by current or recent COCP use. • Menstrual cycle day: Serum AMH may vary across the menstrual cycle. 	
1.5.7	PP	Laboratories involved in AMH measurements in females should use population and assay specific cut-offs.	
1.6	Ethnic variation		
1.6.1	EBR	Healthcare professionals should be aware of the high prevalence of PCOS in all ethnicities and across world regions, ranging from 10–13% globally using the Rotterdam criteria.	♦♦♦♦ ⊕⊕○○
1.6.2	EBR	Healthcare professionals should be aware that PCOS prevalence is broadly similar across world regions, but may be higher in South East Asian and Eastern Mediterranean regions.	♦♦♦♦ ⊕⊕○○

(continued)

Table 4. Continued

NO.	TYPE	RECOMMENDATION	GRADE/QUALITY
1.6.3	PP	Healthcare professionals should be aware that the presentation of PCOS may vary across ethnic groups.	
1.7	Menopause life stage		
1.7.1	CR	A diagnosis of PCOS could be considered as enduring / lifelong.	♦♦♦
1.7.2	CR	Healthcare professionals could consider that both clinical and biochemical hyperandrogenism persist in the postmenopause for women with PCOS.	♦♦♦
1.7.3	CR	PCOS diagnosis could be considered postmenopause if there is a past diagnosis, or a long-term history of oligo-amenorrhoea with hyperandrogenism and/or PCOM, during the earlier reproductive years (age 20–40).	♦♦♦
1.7.4	CR	Further investigations should be considered to rule out androgen-secreting tumours and ovarian hyperthecosis in postmenopausal women presenting with new-onset, severe or worsening hyperandrogenism including hirsutism.	♦♦♦
1.8	Cardiovascular disease risk		
1.8.1	EBR	Women with PCOS should be considered at increased risk of cardiovascular disease and potentially of cardiovascular mortality, acknowledging that the overall risk of cardiovascular disease in pre-menopausal women is low.	♦♦♦ ⊕○○○
1.8.2	EBR	All women with PCOS should be assessed for cardiovascular disease risk factors.	♦♦♦♦ ⊕○○○
1.8.3	CR	All women with PCOS, regardless of age and BMI, should have a lipid profile (cholesterol, low density lipoprotein cholesterol, high density lipoprotein cholesterol and triglyceride level) at diagnosis. Thereafter, frequency of measurement should be based on the presence of hyperlipidaemia and additional risk factors or global cardiovascular risk.	♦♦♦♦
1.8.4	CR	All women with PCOS should have blood pressure measured annually and when planning pregnancy or seeking fertility treatment, given the high risk of hypertensive disorders in pregnancy and the associated comorbidities.	♦♦♦♦
1.8.5	CR	Funding bodies should recognize that PCOS is highly prevalent with multisystem effects including cardiometabolic disease and should diversify and increase research support accordingly.	♦♦♦♦
1.8.6	CR	Cardiovascular general population guidelines could consider the inclusion of PCOS as a cardiovascular risk factor.	♦♦♦
1.8.7	CR	Healthcare professionals, women with PCOS and other stakeholders should all prioritize preventative strategies to reduce cardiovascular risk.	♦♦♦♦
1.8.8	PP	Consideration should be given to the differences in cardiovascular risk factors, and cardiovascular disease, across ethnicities (see 1.6.1) and age, when determining frequency of risk assessment.	
1.9	Impaired glucose tolerance and type 2 diabetes risk		
1.9.1	EBR	Healthcare professionals and women with PCOS should be aware that, regardless of age and BMI, women with PCOS have an increased risk of impaired fasting glucose, impaired glucose tolerance and type 2 diabetes.	♦♦♦♦ ⊕○○○
1.9.2	EBR	Glycaemic status should be assessed at diagnosis in all adults and adolescents with PCOS.	♦♦♦♦ ⊕○○○
1.9.3	CR	Glycaemic status should be reassessed every one to three years, based on additional individual risk factors for diabetes.	♦♦♦♦
1.9.4	CR	Healthcare professionals, women with PCOS and other stakeholders should prioritize preventative strategies to reduce type 2 diabetes risk.	♦♦♦♦
1.9.5	CR	Funding bodies should recognize that PCOS is highly prevalent, has significantly higher risk for diabetes, and should be funded accordingly.	♦♦♦♦
1.9.6	CR	Diabetes general population guidelines should consider the inclusion of PCOS as an independent risk factor for diabetes.	♦♦♦♦
1.9.7	PP	Healthcare professionals, adults and adolescents with PCOS and their first-degree relatives, should be aware of the increased risk of diabetes and the need for regular glycaemic assessment.	
1.9.8	PP	Women with type 1 and type 2 diabetes have an increased risk of PCOS and screening should be considered in individuals with diabetes.	

(continued)

Table 4. Continued

NO.	TYPE	RECOMMENDATION	GRADE/QUAITY
Glycaemic testing			
1.9.9	EBR	Healthcare professionals and women with PCOS should recommend the 75-g oral glucose tolerance test (OGTT) as the most accurate test to assess glycaemic status in PCOS, regardless of BMI.	♦♦♦♦ ⊕○○○
1.9.10	EBR	If an OGTT cannot be performed, fasting plasma glucose and/or glycated haemoglobin (HbA1c) could be considered, noting significantly reduced accuracy.	♦♦♦ ⊕○○○
1.9.11	EBR	An OGTT should be considered in all women with PCOS and without pre-existing diabetes, when planning pregnancy or seeking fertility treatment, given the high risk of hyperglycaemia and the associated comorbidities in pregnancy. If not performed preconception, an OGTT could be offered at the first prenatal visit and all women with PCOS should be offered the test at 24–28 weeks gestation.	♦♦♦ ⊕○○○
1.9.12	PP	Insulin resistance is a pathophysiological factor in PCOS, however, clinically available insulin assays are of limited clinical relevance and are not recommended in routine care (refer to 3.1.10).	
1.10 Obstructive Sleep Apnea			
1.10.1	EBR	Healthcare professionals should be aware that women with PCOS have significantly higher prevalence of obstructive sleep apnea compared to women without PCOS, independent of BMI.	♦♦♦♦ ⊕⊕⊕○
1.10.2	EBR	Women with PCOS should be assessed for symptoms of obstructive sleep apnea (i.e., snoring in combination with waking unrefreshed from sleep, daytime sleepiness or fatigue) and if present, screen with validated tools or refer for assessment.	♦♦♦♦ ⊕⊕⊕○
1.10.3	PP	Simple obstructive sleep apnea screening questionnaires (such as the Berlin questionnaire, validated in the general population) can assist in identifying obstructive sleep apnea in women with PCOS, noting that diagnosis requires a formal sleep study.	
1.10.4	PP	Goals of treatment should target obstructive sleep apnea related symptom burden.	
1.11 Endometrial hyperplasia and cancer			
1.11.1	EBR	Healthcare professionals should be aware that premenopausal women with PCOS have markedly higher risk of developing endometrial hyperplasia and endometrial cancer.	♦♦♦♦ ⊕○○○
1.11.2	PP	Women with PCOS should be informed about the increased risk of endometrial hyperplasia and endometrial cancer, acknowledging that the overall chance of developing endometrial cancer is low, therefore routine screening is not recommended.	
1.11.3	PP	Long-standing untreated amenorrhea, higher weight, type 2 diabetes and persistent thickened endometrium are additional to PCOS as risk factors for endometrial hyperplasia and endometrial cancer.	
1.11.4	PP	Women with PCOS should be informed of preventative strategies including weight management, cycle regulation and regular progestogen therapy.	
1.11.5	PP	When excessive endometrial thickness is detected, consideration of a biopsy with histological analysis and withdrawal bleed is indicated.	
1.12 Risks in first degree relatives			
1.12.1	EBR	Healthcare professionals could consider that fathers and brothers of women with PCOS may have an increased prevalence of metabolic syndrome, type 2 diabetes, and hypertension.	♦♦♦ ⊕○○○
1.12.2	PP	The cardiometabolic risk in female first degree relatives of women with PCOS remains inconclusive.	
2 Prevalence, screening and management of psychological features and models of care			
General principles			
PP Psychological features are common and important components of PCOS that all healthcare professionals should be aware of.			
PP Funding bodies should recognize that PCOS is highly prevalent, and has significantly higher psychological disorders which should be prioritized and funded accordingly.			
2.1 Quality of Life			
2.1.1	EBR	Healthcare professionals and women should recognize the adverse impact of PCOS and/or PCOS features on quality of life in adults.	♦♦♦♦ ⊕⊕○○

Table 4. Continued

NO.	TYPE	RECOMMENDATION	GRADE/QUALITY
2.1.2	PP	Women with PCOS should be asked about their perception of PCOS related-symptoms, impact on quality of life, key concerns, and priorities for management.	
2.2	Depression and Anxiety		
2.2.1	EBR	Healthcare professionals should be aware of the high prevalence of moderate to severe depressive symptoms and depression in adults and adolescents with PCOS and should screen for depression in all adults and adolescents with PCOS, using regionally validated screening tools.	♦♦♦♦ ⊕⊕⊕⊕
2.2.2	EBR	Healthcare professionals should be aware of the high prevalence of moderate to severe anxiety symptoms and anxiety disorders in adults and should screen for anxiety in all adults with PCOS, using regionally validated screening tools.	♦♦♦♦ ⊕⊕⊕⊕
2.2.3	CR	If moderate or severe depressive or anxiety symptoms are detected, practitioners should further assess, refer appropriately, or offer treatment.	♦♦♦♦
2.2.4	PP	Severity of symptoms and clinical diagnosis of depression or anxiety should guide management. The optimal interval for anxiety and depression screening is not known. A pragmatic approach could include screening at diagnosis with repeat screening based on clinical judgement, risk factors, comorbidities, and life events, including the perinatal period. Screening for mental health disorders comprises assessment of risk factors, symptoms, and risk of self-harm and suicidal intent.	
2.3	Psychosexual function		
2.3.1	CR	Healthcare professionals could consider the multiple factors that can influence psychosexual function in PCOS including higher weight, hirsutism, mood disorders, infertility and PCOS medications.	♦♦♦
2.3.2	CR	Permission to discuss psychosexual function should be sought noting that the diagnosis of psychosexual dysfunction requires both low psychosexual function combined with related distress.	♦♦♦♦
2.4	Body Image		
2.4.1	EBR	Healthcare professionals should be aware that features of PCOS can have a negative impact on body image.	♦♦♦♦ ⊕⊕○○
2.5	Eating disorders		
2.5.1	EBR	Eating disorders and disordered eating should be considered in PCOS, regardless of weight, especially in the context of weight management and lifestyle interventions (see sections 2.4 and 3.6).	♦♦♦ ⊕⊕○○
2.5.2	PP	If disordered eating or eating disorders are suspected, appropriately qualified practitioners should further assess via a full diagnostic interview. If an eating disorder or disordered eating is detected, appropriate management and support should be offered.	
2.6	Information resources, models of care, cultural and linguistic considerations		
2.6.1	Information needs		
2.6.1.1	EBR	Tailored information, education and resources that are high-quality, culturally appropriate and inclusive should be provided to all with PCOS.	♦♦♦♦ ⊕⊕⊕○
2.6.1.2	EBR	Information, education and resources are a high priority for patients with PCOS and should be provided in a respectful and empathic manner.	♦♦♦♦ ⊕⊕⊕○
2.6.1.3	CR	Entities responsible for healthcare professional education should ensure that information and education on PCOS is systemically embedded at all levels of healthcare professional training to address knowledge gaps.	♦♦♦♦
2.6.1.4	PP	The diversity of the population should be considered when adapting practice paradigms. Healthcare professional education opportunities should be optimised at all stages of graduate and postgraduate training and continuing professional development and in practice support resources.	
2.6.1.5	PP	Women should be counselled on the risk of misinformation and guided to evidence-based resources.	
2.6.2	Models of care		
2.6.2.1	CR	Models of care should prioritize equitable access to evidence-based primary care with pathways for escalation to integrated specialist and multidisciplinary services as required.	♦♦♦♦

Table 4. Continued

NO.	TYPE	RECOMMENDATION	GRADE/QUAITY
2.6.2.2	PP	Strategies to deliver optimal models of care could include healthcare professional education, care pathways, virtual care, broader health professional engagement (e.g., nurse practitioners) and coordination tools.	
2.6.3	Support to manage PCOS		
2.6.3.1	CR	Public health actors should consider increasing societal awareness and education on PCOS to reduce stigma and marginalization.	❖❖❖
2.6.3.2	PP	Culturally appropriate resources and education on PCOS across the life span for families of those with the condition should be considered.	
2.6.4	Patient care		
2.6.4.1	EBR	Healthcare professionals should employ shared decision-making and support patient agency or ability to take independent actions to manage their health and care.	❖❖❖ ⊕⊕⊕○
2.6.4.2	EBR	The importance of being knowledgeable about PCOS, of applying evidence-based practices when sharing news on diagnosis, treatment, and health implications, and of ascertaining and focusing on patient priorities, should be recognized.	❖❖❖ ⊕⊕⊕○
2.6.4.3	CR	Healthcare system leaders should enable system wide changes to support healthcare professional training, knowledge and practice in sharing news optimally, shared decision making and patient agency, including ensuring adequate consultation time and accessible resources.	❖❖❖
2.6.4.4	PP	Evidence-based strategies for shared decision making and for sharing news (such as the SPIKES framework) are readily available and should be used to inform PCOS care. All healthcare professionals partnering with women with PCOS should be knowledgeable in sharing news, in shared decision-making, and in supporting patient self-management. Evidence-based strategies and resources can be used to support patient activation, which refers to modifiable knowledge, skills, ability, confidence, and willingness to self-manage one's own health and care.	
2.7	Psychological therapy		
2.7.1	CR	Women with PCOS diagnosed with depression, anxiety, and/or eating disorders should be offered psychological therapy guided by regional general population guidelines and the preference of the woman with PCOS.	❖❖❖
2.7.2	CR	Women with PCOS with disordered eating, body image distress, low self-esteem, problems with feminine identity, or psychosexual dysfunction should be offered evidence-based treatments (e.g., cognitive behaviour therapy) where appropriate.	❖❖❖
2.8	Antidepressant and anxiolytic treatment		
2.8.1	CR	Psychological therapy could be considered first-line management, and antidepressant medications considered in adults where mental health disorders are clearly documented and persistent, or if suicidal symptoms are present, based on general population guidelines.	❖❖
2.8.2	PP	Lifestyle intervention and other therapies (e.g., COCP, metformin, laser hair removal) that target PCOS features should be considered, given their potential to improve psychological symptoms. Where pharmacological treatment for anxiety and depression is offered in PCOS, healthcare professionals should apply caution: <ul style="list-style-type: none"> • to avoid inappropriate treatment with antidepressants or anxiolytics. • to limit use of agents that exacerbate PCOS symptoms, including weight gain. Healthcare professionals should be aware that not managing anxiety and depression may impact adherence to PCOS treatment / management.	
3	Lifestyle management		
3.1		Effectiveness of lifestyle interventions	
3.1.1	EBR	Lifestyle intervention (exercise alone or multicomponent diet combined with exercise and behavioural strategies) should be recommended for all women with PCOS, for improving metabolic health including central adiposity and lipid profile.	❖❖❖ ⊕○○○
3.1.2	CR	Healthy lifestyle behaviours encompassing healthy eating and/or physical activity should be recommended in all women with PCOS to optimize general health, quality of life, body composition and weight management (maintaining weight, preventing weight gain and/or modest weight loss).	❖❖❖

Table 4. Continued

NO.	TYPE	RECOMMENDATION	GRADE/QUALITY
3.1.3	PP	Healthcare professionals should be aware that lifestyle management is a core focus in PCOS management.	
3.1.4	PP	Lifestyle management goals and priorities should be co-developed in partnership with women with PCOS, and value women's individualized preferences.	
3.1.5	PP	There are benefits to a healthy lifestyle even in the absence of weight loss.	
3.1.6	PP	In those with higher weight, weight management can be associated with significant clinical improvements and the following key points need to be considered including:	
		<ul style="list-style-type: none"> • A lifelong focus on prevention of further weight gain. • If the goal is to achieve weight loss, a tailored energy deficit could be prescribed for women, considering individual energy requirements, body weight and physical activity levels. • The value of improvement in central adiposity (e.g., waist circumference, waist-hip ratio) or metabolic health. • The need for ongoing assessment and support. 	
3.1.7	PP	Healthcare professionals should be aware of weight stigma when discussing lifestyle management with women with PCOS (see 3.6).	
3.1.8	PP	Healthy lifestyle and optimal weight management, in the context of structured, intensive, and ongoing clinical support, appears equally effective in PCOS as in the general population.	
3.1.9	PP	In those who are not overweight, in the adolescent and at key life points, the focus should be on healthy lifestyle and the prevention of excess weight gain.	
3.1.10	PP	Insulin resistance is a pathophysiological factor in PCOS, however, clinically available insulin assays are of limited clinical relevance and should not be used in routine care (refer to 1.9.12).	
3.2 Behavioural Strategies			
3.2.1	CR	Lifestyle interventions could include behavioural strategies such as goal-setting, self-monitoring, problem solving, assertiveness training, reinforcing changes, and relapse prevention, to optimize weight management, healthy lifestyle and emotional wellbeing in women with PCOS.	♦♦♦
3.2.2	PP	Behavioural support could include: goal-setting, problem solving, self-monitoring and reviewing, or SMART goals (Specific, Measurable, Achievable, Realistic and Timely).	
3.2.3	PP	Comprehensive healthy behavioural or cognitive behavioural interventions could be considered to increase support, engagement, retention, adherence, and maintenance of healthy lifestyle and improve health outcomes in women with PCOS.	
3.3 Dietary Intervention			
3.3.1	EBR	Healthcare professionals and women should consider that there is no evidence to support any one type of diet composition over another for anthropometric, metabolic, hormonal, reproductive or psychological outcomes.	♦♦♦ ⊕〇〇〇
3.3.2	CR	Any diet composition consistent with population guidelines for healthy eating will have health benefits and, within this, healthcare professionals should advise sustainable healthy eating tailored to individual preferences and goals.	♦♦♦♦
3.3.3	PP	Tailoring of dietary changes to food preferences, allowing for a flexible, individual and co-developed approach to achieving nutritional goals, and avoiding unduly restrictive and nutritionally unbalanced diets, are important, as per general population guidelines.	
3.3.4	PP	Barriers and facilitators to optimize engagement and adherence to dietary change should be discussed, including psychological factors, physical limitations, socioeconomic and sociocultural factors, as well as personal motivators for change. The value of broader family engagement should be considered. Referral to suitably trained allied healthcare professionals needs to be considered when women with PCOS need support with optimizing their diet.	
3.4 Exercise Intervention			
3.4.1	EBR	Healthcare professionals and women could consider that there is a lack of evidence supporting any one type and intensity of exercise being better than another for anthropometric, metabolic, hormonal, reproductive or psychological outcomes.	♦♦♦ ⊕〇〇〇

(continued)

Table 4. Continued

NO.	TYPE	RECOMMENDATION	GRADE/QUAITY
3.4.2	CR	Any physical activity consistent with population guidelines will have health benefits and, within this, healthcare professionals should advise sustainable physical activity based on individual preferences and goals.	♦♦♦♦
3.4.3	CR	Healthcare professionals should encourage and advise the following in concordance with general population physical activity guidelines: <ul style="list-style-type: none"> • All adults should undertake physical activity as doing some physical activity is better than none. • Adults should limit the amount of time spent being sedentary (e.g., sitting, screen time) as replacing sedentary time with physical activity of any intensity (including light intensity) provides health benefits. • For the prevention of weight gain and maintenance of health, adults (18–64 years) should aim for a minimum of 150 to 300 minutes of moderate intensity activities or 75 to 150 minutes of vigorous intensity aerobic activity per week or an equivalent combination of both spread throughout the week, plus muscle strengthening activities (e.g., resistance/flexibility) on two non-consecutive days per week. • For promotion of greater health benefits including modest weight-loss and prevention of weight-regain, adults (18–64 years) should aim for a minimum of 250 min/week of moderate intensity activities or 150 min/week of vigorous intensities or an equivalent combination of both, plus muscle strengthening activities (e.g., resistance/flexibility) ideally on two non-consecutive days per week. • Adolescents should aim for at least 60 minutes of moderate- to vigorous-intensity physical activity per day, including activities that strengthen muscle and bone at least three times per week. 	♦♦♦♦
3.4.4	PP	Physical activity is any bodily movement produced by skeletal muscles that requires energy expenditure. It includes leisure time physical activity, transportation (e.g., walking or cycling), occupational (i.e., work), household chores, playing games, sports or planned exercise, or activities in the context of daily, family and community activities.	
3.4.5	PP	Aerobic activity is best performed in bouts of at least 10 minutes duration, aiming to achieve at least 30 minutes daily on most days.	
3.4.6	PP	Barriers and facilitators to optimize engagement and adherence to physical activity should be discussed, including psychological factors (e.g., body image concerns, fear of injury, fear of failure, mental health), personal safety concerns, environmental factors, physical limitations, socioeconomic factors, sociocultural factors, and personal motivators for change. The value of broader family engagement should be considered. Referral to suitably trained allied healthcare professionals needs to be considered for optimizing physical activity in women with PCOS.	
3.4.7	PP	Self-monitoring, including with fitness tracking devices and technologies for step count and exercise intensity, could be considered as an adjunct to support and promote active lifestyles and minimize sedentary behaviours.	
3.5 Factors affecting weight gain in PCOS			
3.5.1	EBR	Healthcare professionals and women with PCOS could consider that there is a lack of consistent evidence of physiological or behavioural lifestyle differences, related to weight, in women with PCOS compared to women without PCOS.	♦♦♦ ⊕○○
3.5.2	PP	Whilst the specific mechanisms are unclear, it is recognized that many women with PCOS will have underlying mechanisms that drive greater longitudinal weight gain and higher BMI which may: <ul style="list-style-type: none"> • Underpin greater challenges with weight management. • Highlight the importance of lifelong healthy lifestyle strategies and prevention of excess weight gain. • Assist women with PCOS and healthcare professionals in forming realistic, tailored life-style goals. 	
3.6 Weight Stigma			
3.6.1	EBR	Many women with PCOS experience weight stigma in healthcare and other settings and the negative biopsychosocial impacts of this should be recognized.	♦♦♦♦ ⊕○○
3.6.2	CR	Healthcare professionals should be aware of their weight biases and the impact this has on their professional practice and on women with PCOS.	♦♦♦♦
3.6.3	CR	Health policy makers, managers and educators should promote awareness of weight stigma and invest in weight stigma education and minimization strategies.	♦♦♦♦

(continued)

Table 4. Continued

NO.	TYPE	RECOMMENDATION	GRADE/QUALITY
3.6.4	PP	<p>Healthcare professionals should be aware of weight-inclusive practices which promote acceptance of and respect for body size diversity and focus on improvement of health behaviours and health outcomes for people of all sizes. In PCOS this includes:</p> <ul style="list-style-type: none"> Acknowledging that whilst higher weight is a risk factor for PCOS and its complications, it is only one indicator of health and broader factors should be assessed. Asking permission to discuss and measure weight and using strategies to minimize discomfort (e.g., blind weighing). Recognizing that the terms "overweight" and "obese/obesity" can be stigmatizing with suggested alternatives including "higher weight". If weighing, explaining how weight information will be used to inform risks, prevention and treatment and how not knowing may impact on recommendations. Ensuring appropriate equipment is available for women of all sizes. Offering options of weight-centric care (promoting intentional weight loss) or weight-inclusive care (promoting healthy lifestyle change without focusing on intentional weight loss) tailored to individual goals and preferences. Offering all women best practice assessment, treatment and support regardless of weight, acknowledging that weight may be a non-modifiable risk factor when using lifestyle modification alone. 	
3.6.5	PP	Increasing awareness of weight stigma among family members of women and adolescents with PCOS should be considered.	
4 Management of non-fertility features			
4.1 Pharmacology treatment principles in PCOS			
	PP	Shared decision making between the patient (and parent/s or guardian/s, if the patient is a child) and the healthcare professional is required.	
	PP	An individual's characteristics, preferences and values must be elicited and considered when recommending any intervention alone or in combination.	
	PP	Understanding how individual adults and adolescents value treatment outcomes is essential when prescribing medications.	
	PP	Medical therapy is generally not approved for use specifically in PCOS and recommended use is therefore evidence-based, but off-label. Healthcare professionals need to inform adults, adolescents and their parents/s or guardian/s and discuss the evidence, possible concerns and side effects. Regulatory agencies should consider approval of evidence-based medications for use in PCOS.	
4.2 Combined Oral Contraceptive Pills			
4.2.1	EBR	Combined oral contraceptive pills (COCP) could be recommended in reproductive age adults with PCOS for management of hirsutism and/or irregular menstrual cycles.	❖❖❖ ⊕○○○
4.2.2	EBR	The COCP could be considered in adolescents at risk or with a clear diagnosis of PCOS for management of hirsutism and/or irregular menstrual cycles.	❖❖❖ ⊕○○○
4.2.3	EBR	Healthcare professionals could consider that there is no clinical advantage of using high dose ethinylestradiol ($\geq 30 \mu\text{g}$) versus low dose ethinylestradiol ($< 30 \mu\text{g}$) when treating hirsutism in adults with PCOS.	❖❖❖ ⊕○○○
4.2.4	EBR	General population guidelines should be considered when prescribing COCP in adults and adolescents with PCOS as specific types or doses of progestins, estrogens or combinations of COCP cannot currently be recommended.	❖❖❖ ⊕○○○
4.2.5	EBR	The 35 μg ethinyl estradiol plus cyproterone acetate preparations should be considered as second-line therapy, versus other COCPs, balancing benefits and adverse effects, including venous thromboembolic risks.	❖❖❖ ⊕○○○
4.2.6	EBR	Progestin only oral contraceptives may be considered for endometrial protection, based on general population guidelines, acknowledging that evidence in women with PCOS is limited.	❖❖❖ ⊕○○○
4.2.7	PP	<p>When prescribing COCPs in adults and adolescents with PCOS, and adolescents at risk of PCOS</p> <ul style="list-style-type: none"> It is important to address main presenting symptoms and consider other treatments such as cosmetic therapies. Shared decision-making (including accurate information and reassurance on the efficacy and safety of COCP) is recommended and likely to improve adherence. Natural estrogen preparations and the lowest effective estrogen doses (such as 20–30 μg of ethinyl estradiol or equivalent), need consideration, balancing efficacy, metabolic risk profile, side effects, cost, and availability. 	

(continued)

Table 4. Continued

NO.	TYPE	RECOMMENDATION	GRADE/QUAITY
		<ul style="list-style-type: none"> The relatively limited evidence on COCPs specifically in PCOS needs to be appreciated with practice informed by general population guidelines. The relative and absolute contraindications and side effects of COCPs need to be considered and be the subject of individualized discussion. PCOS specific features, such as higher weight and cardiovascular risk factors, need to be considered. 	
4.3		Metformin	
4.3.1	EBR	Metformin alone should be considered in adults with PCOS and a BMI $\geq 25 \text{ kg/m}^2$ for anthropometric, and metabolic outcomes including insulin resistance, glucose, and lipid profiles.	♦♦♦ ⊕○○○
4.3.2	EBR	Metformin alone could be considered in adolescents at risk of or with PCOS for cycle regulation, acknowledging limited evidence.	♦♦♦ ⊕○○○
4.3.3	CR	Metformin alone may be considered in adults with PCOS and BMI $< 25 \text{ kg/m}^2$, acknowledging limited evidence.	♦♦♦
4.3.4	PP	Where metformin is prescribed the following need to be considered: <ul style="list-style-type: none"> Shared decision making needs to consider feasibility and effectiveness of active lifestyle intervention. Women should be informed that metformin and active lifestyle intervention have similar efficacy. Mild adverse effects, including gastrointestinal side-effects are generally dose dependent and self-limiting. Starting at a low dose, with 500 mg increments 1–2 weekly and extended-release preparations may minimize side effects and improve adherence. Suggested maximum daily dose is 2.5 g in adults and 2g in adolescents. Use appears safe long-term, based on use in other populations, however indications for ongoing requirement needs to be considered. Use may be associated with low vitamin B12 levels, especially in those with risk factors for low vitamin B12 (e.g., diabetes, post bariatric / metabolic surgery, pernicious anaemia, vegan diet etc.), where monitoring should be considered. 	
4.4		Metformin and combined oral contraceptive pills	
4.4.1	EBR	COCP could be used over metformin for management of hirsutism in irregular menstrual cycles in PCOS.	♦♦♦ ⊕○○○
4.4.2	EBR	Metformin could be used over COCP for metabolic indications in PCOS.	♦♦♦ ⊕○○○
4.4.3	EBR	The combination of COCP and metformin could be considered to offer little additional clinical benefit over COCP or metformin alone, in adults with a BMI $\leq 30 \text{ kg/m}^2$.	♦♦♦ ⊕○○○
4.4.4.	PP	In combination with the COCP, metformin may be most beneficial in high metabolic risk groups including those with a BMI $>30 \text{ kg/m}^2$, diabetes risk factors, impaired glucose tolerance or high-risk ethnic groups.	
4.4.5	PP	Where COCP is contraindicated, not accepted or not tolerated, metformin may be considered for irregular menstrual cycles. For hirsutism, other interventions may be needed.	
4.5		Anti-obesity pharmacological agents	
4.5.1	CR	Anti-obesity medications including liraglutide, semaglutide, both glucagon-like peptide-1 (GLP-1) receptor agonists and orlistat, could be considered, in addition to active lifestyle intervention, for the management of higher weight in adults with PCOS as per general population guidelines.	♦♦♦
4.5.2	PP	Healthcare professionals should ensure concurrent effective contraception when pregnancy is possible for women who take GLP-1 receptor agonists, as pregnancy safety data are lacking.	
4.5.3	PP	Gradual dose escalation for GLP-1 receptor agonists is recommended to reduce gastrointestinal adverse effects.	
4.5.4	PP	Shared decision making, when discussing GLP-1 receptor agonist use with women with PCOS, needs to consider side effects, and the potential need for long-term use in weight management, given the high risk for weight regain after discontinuation, and the lack of long-term safety data.	
4.6		Anti-androgen pharmacological agents	
4.6.1	EBR	In combination with effective contraception, anti-androgens could be considered to treat hirsutism in women with PCOS, if there is a suboptimal response after a minimum of six months of COCP and/or cosmetic therapy.	♦♦♦ ⊕○○○

(continued)

Table 4. Continued

NO.	TYPE	RECOMMENDATION	GRADE/QUALITY
4.6.2	CR	Given the negative psychological impact of female pattern hair loss, anti-androgens in combination with COCP could be trialed, acknowledging the lack of evidence in the PCOS population.	❖❖❖
4.6.3	PP	Whenever pregnancy is possible, healthcare professionals must educate and counsel women and adolescents, parents/s or guardian/s, regarding the risks of incomplete development of external genital structures of male fetuses (undervirilization) when anti-androgens are used. To prevent this, women who can get pregnant should be strongly counselled to use effective contraception (e.g., intrauterine device or COCPs).	
4.6.4	PP	Anti-androgens could be considered to treat hirsutism, in the presence of another effective form of contraception, for women with contraindications for COCP therapy or when COCPs are poorly tolerated.	
4.6.5	PP	When prescribing anti-androgens, based on general population recommendations, healthcare professionals should consider that: <ul style="list-style-type: none"> • Spironolactone at 25–100 mg/day appears to have lower risks of adverse effects. • Cyproterone acetate at doses ≥ 10 mg is not advised due to an increased risk including for meningioma. • Finasteride has an increased risk of liver toxicity. • Flutamide and bicalutamide have an increased risk of severe liver toxicity. • The relatively limited evidence on anti-androgens in PCOS needs to be appreciated with small numbers of studies and limited numbers of participants. 	
4.7	Inositol		
4.7.1	EBR	Inositol (in any form) could be considered in women with PCOS based on individual preferences and values, noting limited harm, potential for improvement in metabolic measures, yet with limited clinical benefits including in ovulation, hirsutism or weight.	❖❖ ⊕○○○
4.7.2	EBR	Metformin should be considered over inositol for hirsutism and central adiposity, noting that metformin has more gastrointestinal side effects than inositol.	❖❖ ⊕○○○
4.7.3	PP	Women taking inositol and other complementary therapies are encouraged to advise their healthcare professional.	
4.7.4	PP	Specific types, doses or combinations of inositol cannot currently be recommended in adults and adolescents with PCOS, due to a lack of quality evidence.	
4.7.5	PP	Shared decision making should include discussion that regulatory status and quality control of inositol in any form (like other nutrient supplements) can differ from those for pharmaceutical products and doses and qualities may vary.	
4.7.6	PP	Policy makers and healthcare professionals have a responsibility to ensure women have access to unconflicted, evidence-based information to inform shared-decision making, whilst also acknowledging and respecting individual values and preferences, including for complementary therapies.	
4.8	Mechanical laser and light therapies for hair reduction		
4.8.1	EBR	Mechanical laser and light therapies should be considered for reducing facial hirsutism and for related depression, anxiety, and quality of life in women with PCOS.	❖❖ ⊕○○○
4.8.2	EBR	A greater number of laser treatment sessions may be required in women with PCOS, compared to women with idiopathic hirsutism, to achieve hair reduction.	❖❖ ⊕○○○
4.8.3	CR	Adverse effects appear limited in the hands of experienced and suitably qualified providers, and women should be encouraged to seek hair reduction therapies from such providers.	❖❖❖
4.8.4	PP	Where laser hair removal is prescribed, the following need to be considered: <ul style="list-style-type: none"> • Wavelength and delivery of laser treatment varies by skin and hair colour. • Laser is relatively ineffective in women with blond, grey or white hair. • The addition of combined oral contraceptive pills (COCP), with or without anti-androgens, to laser treatment may provide greater hair reduction and maintenance compared to laser alone. • Low and high fluence laser appear to have similar efficacy in reducing facial hair, while low fluence laser has reduced associated pain. 	
4.8.5	PP	Mechanical hair removal with Intense Pulse Light (IPL) could be considered, albeit benefits may be less pronounced compared to laser treatment. There is no evidence to support the efficacy of home-based IPL kits.	
4.8.6	PP	Policy makers should consider funding this evidence-based effective therapy for women with PCOS to alleviate distressing symptoms of hirsutism, and related negative impact on quality of life, body image, and psychological health.	

(continued)

Table 4. Continued

NO.	TYPE	RECOMMENDATION	GRADE/QUAITY
4.9	Bariatric/ metabolic surgery		
4.9.1	CR	Bariatric/ metabolic surgery could be considered to improve weight loss, hypertension, diabetes (prevention and treatment), hirsutism, irregular menstrual cycles, ovulation, and pregnancy rates in women with PCOS.	♦♦♦
4.9.2	CR	Bariatric/ metabolic surgery in women with PCOS should be informed by general population guidelines.	♦♦♦♦
4.9.3	CR	PCOS is a metabolic condition and could be considered an indication at a lower BMI threshold for bariatric/ metabolic surgery similarly to other metabolic conditions including diabetes.	♦♦♦
4.9.4	CR	Women should be strongly counselled on the likelihood of rapid return of fertility and the need to commit to effective contraception, ideally prior to surgery. Even when pregnancy is desired, contraception should be continued until a stable weight is achieved, usually after one year, to avoid significantly increased risk of growth restriction, prematurity, small for gestational age, pregnancy complications, and prolonged hospitalization of the infant.	♦♦♦♦
4.10	Pregnancy outcomes		
4.10.1	EBR	Women with PCOS have higher risk pregnancies, and healthcare professionals should ensure that PCOS status is identified during antenatal care, and appropriate monitoring and support is provided.	♦♦♦♦ ⊕○○○
4.10.2	EBR	Healthcare professionals should recognize that pregnant women with PCOS have an increased risk of: <ul style="list-style-type: none"> • Higher gestational weight gain. • Miscarriage. • Gestational diabetes. • Hypertension in pregnancy and preeclampsia. • Intrauterine growth restriction, small for gestational age babies and low birth weight. • Preterm delivery. • Caesarean section. 	♦♦♦♦ ⊕○○○
4.10.3	EBR	Assisted reproductive technology in women with PCOS should be considered as not conferring additional risk of miscarriage, preterm birth, impaired fetal growth, and caesarean section, over that observed in women without PCOS.	♦♦♦ ⊕○○○
4.10.4	EBR	Women with PCOS should be considered as not having an increased risk of large for gestational age babies, macrosomia and instrumental delivery.	♦♦♦ ⊕○○○
4.10.5	PP	Early lifestyle intervention should be offered to pregnant women with PCOS, given the risk of higher baseline weight, excess gestational weight gain and pregnancy complications.	
4.10.6	PP	Blood pressure measurement should be performed when planning pregnancy or seeking fertility treatment, given the high risk of hypertensive disorders in pregnancy and the associated comorbidities in women with PCOS.	
4.10.7	PP	An OGTT should be offered to all women with PCOS when planning pregnancy or seeking fertility treatment, given the high risk of hyperglycaemia and the associated comorbidities in pregnancy. If not performed in the preconception phase, an OGTT should be offered at the first antenatal visit and repeated at 24–28 weeks gestation.	
4.11	Metformin in pregnancy		
4.11.1	EBR	Healthcare professionals should be aware that metformin in pregnant women with PCOS has not been shown to prevent: <ul style="list-style-type: none"> • Gestational diabetes. • Late miscarriage (12 weeks + 1 day to 21 weeks + 6 days gestational age). • Hypertension in pregnancy. • Pre-eclampsia. • Macrosomia or birthweight ≥ 4000 g. 	♦♦♦♦ ⊕○○○
4.11.2	EBR	Metformin could be considered in some circumstances (e.g., risk for preterm birth) to reduce preterm delivery and limit excess gestational weight gain, in pregnant women with PCOS.	♦♦♦ ⊕⊕○○
4.11.3	PP	Women should be counselled that the consequences of metformin exposure on long-term offspring health remain unclear and there is a suggestion of increased childhood weight, although causality is not certain.	
4.11.4	PP	Side effects of metformin are mostly mild, transient gastrointestinal symptoms and are not worse in pregnancy.	

Table 4. Continued

NO.	TYPE	RECOMMENDATION	GRADE/QUALITY
5		Assessment and treatment of infertility	
		General principles	
	PP	All fertility treatment in PCOS should be guided by the fertility treatment algorithm (Algorithm 2).	
	PP	Those with PCOS should be reassured that pregnancy can often be successfully achieved either naturally or with assistance.	
	PP	Prenatal vitamins supplementation should be commenced with ovulation induction therapy aligned to routine preconception care.	
	PP	Pregnancy should be excluded prior to ovulation induction therapy.	
	PP	The use of ovulation induction agents, including letrozole, metformin and clomiphene citrate, is off-label in many countries. Where off-label use of ovulation induction agents is allowed, healthcare professionals need to inform women and discuss the evidence, possible concerns, and side effects.	
	PP	There should be ongoing monitoring of patients for adverse effects, and infants for congenital anomalies, in all studies conducted with ovulation induction agents and these should be reported in any published papers.	
5.1		Preconception risk factors	
5.1.1	EBR	Women with PCOS should be counselled on the adverse impact of excess weight on clinical pregnancy, miscarriage, and live birth rates, following infertility treatment.	♦♦♦♦ ⊕○○○
5.1.2	CR	Consistent with routine preconception care, in women with PCOS planning pregnancy, weight, blood pressure, smoking, alcohol, diet and nutritional status, folate supplementation (higher dose in those with BMI >30 kg/m ²), exercise, sleep and mental, emotional and sexual health should be considered and optimized to improve reproductive and pregnancy outcomes and overall health.	♦♦♦♦
5.1.3	PP	A reproductive life plan and age-appropriate education on optimizing reproductive health is recommended in adolescents and women with PCOS, including healthy lifestyle, prevention of excess weight gain, and optimizing preconception risk factors.	
5.1.4	PP	Healthcare professionals are encouraged to seek permission and, if given, to assess weight and BMI and initiate a dialogue on the importance of weight and lifestyle on women's health before pregnancy. This requires caution to avoid weight stigma and needs to consider the cultural, social, and environmental determinants of health (see 3.6).	
5.1.5	PP	Chronic conditions such as diabetes, high blood pressure, anxiety, depression and other mental health conditions, should be optimally managed and women should be counselled regarding the risk of adverse pregnancy outcomes.	
5.2		Tubal patency testing	
5.2.1	CR	In women with PCOS and infertility due to anovulation alone with normal semen analysis, the risks, benefits, costs and timing and techniques of tubal patency testing in relation to the cost and complexity of the treatment, should be considered on an individual basis, depending on personal history and population prevalence, prior to starting ovulation induction with timed intercourse or intrauterine insemination.	♦♦♦
5.3		Letrozole	
5.3.1	EBR	Letrozole should be the first-line pharmacological treatment for ovulation induction in infertile anovulatory women with PCOS, with no other infertility factors.	♦♦♦♦ ⊕○○○
5.3.2	PP	The use of letrozole is still off-label in many countries. Where it is not allowed, clinicians could use other ovulation induction agents.	
5.3.3	PP	Letrozole should not be given where there is any possibility of a pre-existing pregnancy, though there is no evidence for increased teratogenicity compared to other ovulation induction agents.	
5.4		Clomiphene citrate and metformin	
5.4.1		Metformin versus placebo	
5.4.1.1	EBR	Metformin could be used alone, in women with PCOS with anovulatory infertility and no other infertility factors, to improve clinical pregnancy and live birth rates, whilst informing women that there are more effective ovulation agents.	♦♦♦ ⊕○○○

(continued)

Table 4. Continued

NO.	TYPE	RECOMMENDATION	GRADE/QUAITY
5.4.1.2	PP	Women should be counselled as to potential mild gastrointestinal side-effects with metformin.	
5.4.1.3	PP	Healthcare and resource burden including monitoring, travel and costs are lower with metformin.	
5.4.1.4	PP	Consideration of age and screening for other fertility factors needs to be discussed before prescribing metformin.	
5.4.2 Clomiphene citrate verses metformin			
5.4.2.1	EBR	Clomiphene citrate could be used in preference to metformin in women with PCOS with anovulatory infertility and no other infertility factors, to improve ovulation, clinical pregnancy and live birth rates.	♦♦♦ ⊕○○
5.4.2.2	PP	The risk of multiple pregnancy is increased with clomiphene citrate use (alone or in combination with metformin) and therefore clomiphene cycles may require ultrasound monitoring.	
5.4.3 Clomiphene citrate and metformin verses clomiphene citrate alone			
5.4.3.1	EBR	Clomiphene citrate combined with metformin could be used rather than clomiphene citrate alone in women with PCOS with anovulatory infertility and no other infertility factors to improve ovulation and clinical pregnancy rates.	♦♦♦ ⊕○○
5.4.4 Clomiphene citrate and metformin versus metformin alone			
5.4.4.1	EBR	Clomiphene citrate combined with metformin could be used rather than metformin alone in women with PCOS with anovulatory infertility and no other infertility factors to improve live birth rates.	♦♦♦ ⊕○○
5.4.4.2	PP	Monitoring of combined cycles will need to be equivalent to clomiphene citrate alone.	
5.4.5 Clomiphene citrate versus Letrozole			
5.4.5.1	EBR	Letrozole should be used rather than clomiphene citrate in women with PCOS with anovulatory infertility and no other infertility factors to improve ovulation, clinical pregnancy and live birth rates.	♦♦♦♦ ⊕○○
5.4.5.2	PP	Current evidence demonstrates no difference in fetal abnormality rates between letrozole or clomiphene citrate ovulation induction or natural conception.	
5.5 Gonadotrophins			
5.5.1	EBR	Gonadotrophins alone could be considered rather than clomiphene citrate in therapy naïve women with PCOS with anovulatory infertility and no other infertility factors to improve ovulation, clinical pregnancy and live birth rates (refer to PP 5.5.6).	♦♦♦ ⊕○○
5.5.2	EBR	Gonadotrophins alone could be used over gonadotrophins combined with clomiphene citrate in women with PCOS who are anovulatory and infertile with clomiphene citrate resistance or failure, and no other infertility factors.	♦♦♦ ⊕○○
5.5.3	EBR	Gonadotrophins could be considered rather than the combination of clomiphene citrate and metformin in women with PCOS who are anovulatory and infertile, with clomiphene citrate-resistance and no other infertility factors.	♦♦♦ ⊕○○
5.5.4	EBR	Either gonadotrophins or laparoscopic ovarian surgery could be used in women with PCOS who are anovulatory and infertile, with clomiphene citrate-resistance and no other infertility factors, following counselling on higher live birth rate and higher multiple pregnancy rates with gonadotrophins.	♦♦ ⊕○○
5.5.5	EBR	Gonadotrophins could be second-line pharmacological therapy for women with PCOS who are anovulatory and infertile, with no other infertility factors and who have failed first line oral ovulation induction.	♦♦♦ ⊕○○
5.5.6	PP	Where gonadotrophins are to be prescribed, the following should be considered: <ul style="list-style-type: none"> • Cost of the intervention for ovulation induction. • Expertise required for the use of the intervention for ovulation induction. • The degree of intensive ultrasound monitoring that is required. • A low dose step-up gonadotrophin protocol should be used to optimize the chance of monofollicular development. • Implications of potential multiple pregnancy. 	
5.5.7	PP	There appears to be no difference in the clinical efficacy of the available gonadotrophin preparations.	
5.5.8	PP	When using gonadotrophins, best clinical practice is to avoid multiple pregnancy. Considerations here include cancelling cycles when there is more than a total of two follicles greater than 14mm in diameter and advising avoidance of unprotected intercourse.	

(continued)

Table 4. Continued

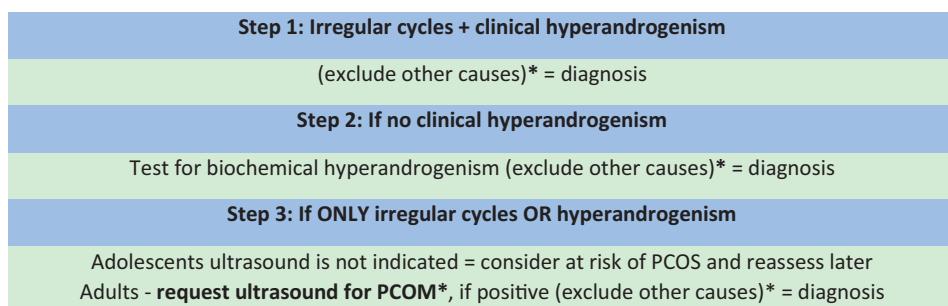

NO.	TYPE	RECOMMENDATION	GRADE/QUALITY
5.5.9	PP	Live birth rate, clinical pregnancy rate per patient and ovulation rate per cycle are higher with gonadotrophins than with clomiphene citrate.	
5.5.10	PP	A low dose gonadotrophin protocol should be used to optimize the chance of monofollicular growth and minimize multiple pregnancy.	
5.5.11	PP	Cycle monitoring and drug costs coupled with multiple injection will influence choice in gonadotrophin use.	
5.6		Laparoscopic ovarian surgery	
5.6.1	EBR	Laparoscopic ovarian surgery could be second-line therapy for women with PCOS who are anovulatory and infertile, with clomiphene citrate resistance and no other infertility factors.	♦♦♦ ⊕○○
5.6.2	PP	When using laparoscopic ovarian surgery, the following should be considered: <ul style="list-style-type: none"> Comparative cost of the intervention for ovulation induction. Expertise required for the safe use of the intervention for ovulation induction. Both intraoperative and postoperative risks, which are higher in women who are above healthy weight. 	
5.7		In vitro fertilization and in vitro maturation	
5.7.0.1	CR	In the absence of an absolute indication for in vitro fertilization (IVF)/intracytoplasmic sperm injection (ICSI), IVF could be offered in women with PCOS and anovulatory infertility, if first- or second-line ovulation induction therapies have failed.	♦♦♦
5.7.0.2	PP	In women with anovulatory PCOS, the use of IVF is effective and when elective single embryo transfer is used, multiple pregnancies can be minimized.	
5.7.0.3	PP	Women with PCOS undergoing IVF/ICSI treatment should be counselled prior to starting treatment about the increased risk of ovarian hyperstimulation syndrome and options to reduce the risk should be offered.	
5.7.1		Gonadotrophin releasing hormone protocol	
5.7.1.1	PP	Gonadotrophin releasing hormone (GnRH) antagonist protocol cannot be recommended over GnRH agonist long protocol for women with PCOS undergoing IVF/ICSI to improve clinical pregnancy or live birth rate.	
5.7.1.2	PP	The use of a GnRH antagonist protocol for women with PCOS undergoing IVF/ICSI is recommended as it enables the use of an agonist trigger, with the freezing of all embryos generated if required, without compromising the cumulative live birth rate, to reduce the risk of significant ovarian hyperstimulation syndrome.	
5.7.2		Trigger type	
5.7.2.1	CR	Triggering final oocyte maturation with a GnRH agonist and freezing all suitable embryos is recommended, in an IVF/ICSI cycle with a GnRH antagonist protocol, where a fresh embryo transfer is not intended or where there is an increased risk of ovarian hyperstimulation syndrome.	♦♦♦♦
5.7.3		Choice of follicle stimulating hormone	
5.7.3.1	CR	Either urinary or recombinant follicle stimulating hormone (FSH) could be used in women with PCOS undergoing (controlled) ovarian (hyper) stimulation for IVF/ICSI, with insufficient evidence to recommend a particular type of FSH preparation.	♦♦♦
5.7.4		Exogenous luteinising hormone	
5.7.4.1	CR	Exogenous recombinant luteinising hormone (LH) treatment should not be routinely used in combination with FSH therapy in women with PCOS undergoing controlled ovarian hyperstimulation for IVF/ ICSI.	♦
5.7.5		Adjunct metformin	
5.7.5.1	EBR	Adjunct metformin therapy could be used before and/or during FSH ovarian stimulation in women with PCOS undergoing IVF/ICSI treatment with GnRH agonist long protocol, to reduce the risk of developing ovarian hyperstimulation syndrome and miscarriage.	♦♦♦ ⊕○○
5.7.5.2	PP	Good practice in PCOS and IVF is the use of a GnRH antagonist protocol as it gives the flexibility of using a GnRH agonist trigger, freeze all strategy to reduce the risk of ovarian hyperstimulation syndrome. However, if using a GnRH agonist long protocol then metformin could be considered. If using metformin, the following could be considered: <ul style="list-style-type: none"> Commence metformin at the start of GnRH agonist treatment. Gradually titrate metformin up to a dose of between 1000mg to 2500mg daily in order to minimize side effects. Stopping metformin therapy at the time of the pregnancy test or period, unless the metformin therapy is otherwise indicated. 	

Table 4. Continued

NO.	TYPE	RECOMMENDATION	GRADE/QUAITY
5.7.6	In vitro maturation		
5.7.6.1	EBR	The use of in vitro maturation (IVM) and ICSI could be considered in women with PCOS as an alternative to a stimulated IVF/ICSI cycle, where an embryo is frozen and replaced in a subsequent embryo transfer cycle, acknowledging there is no risk of ovarian hyperstimulation syndrome, but a lower cumulative live birth rate.	❖❖ ⊕⊕⊕○
5.7.6.2	CR	The use of IVM and ICSI could be considered prior to stimulated IVF/ ICSI cycles acknowledging both benefits and limitations.	❖❖
5.7.6.3	PP	IVM should only be considered in services with sufficient expertise, and advocacy is needed for regional or national centres of expertise.	
5.7.6.4	PP	IVM could be offered as an option in women with prior severe ovarian hyperstimulation syndrome and where the risk of severe ovarian hyperstimulation syndrome is deemed unacceptably high, provided that expertise in IVM techniques exists.	
5.7.6.5	PP	Evidence suggests that IVM/ICSI is less effective than standard IVF/ICSI in terms of clinical pregnancy per patient and live birth rate per patient.	
5.8	Inositol		
5.8.1	EBR	Inositol in any form alone, or in combination with other therapies, should be considered experimental therapy in women with PCOS with infertility, with benefits and risks currently too uncertain to recommend the use of these agents as fertility therapies.	❖❖ ⊕○○○
5.8.2	PP	There is limited evidence with uncertain results, on the effect of inositol on ovulation, clinical pregnancy and live birth rates.	
5.8.3	PP	Side effects and safety are not known for inositol.	
5.8.4	PP	Women need to be aware that these agents can have limited regulation with variable dose, quality, consistency, and combination with other agents.	
5.8.5	PP	Women's personal goals and preferences should be considered when discussing complementary therapies.	
5.9	Anti-obesity pharmacological agents		
5.9.1	CR	We recommend using anti-obesity agents in PCOS for reproductive outcomes only in research settings to establish efficacy and safety.	

See [Table 1](#) for definition of CR, EBR and PP. © International evidence-based guideline for the assessment and management of polycystic ovary syndrome 2023, Helena Teede et al. Symptoms of depression and anxiety are significantly increased and should be screened for in all women with PCOS, with psychological assessment and therapy as indicated. Greater awareness of psychological features including eating disorders and impacts on body image and quality of life is needed.

Dissatisfaction with PCOS diagnosis and care is high and significant improvement in education and awareness is

strongly recommended for women and healthcare professionals including high quality, evidence-based resources. Shared decision making and self-empowerment are fundamental and integrated models of care should be codesigned, funded and evaluated.

Supported healthy lifestyle remains vital throughout the lifespan in PCOS, with a strong focus on overall health, prevention of

weight gain and, if required, on weight management. Recognizing the benefits of many diet and physical activity regimens, there is no one specific regimen that has benefits over others in PCOS. Weight bias and stigma should be minimized and healthcare professionals should seek permission to weigh women, with explanation of weight-related risks.

Combined oral contraceptive pills are the first line pharmacological treatment for menstrual irregularity and hyperandrogenism, with no specific recommended preparation and a preference for lower ethinyl estradiol dose preparations and those with less side-effects. Metformin is recommended primarily for metabolic features and has greater efficacy than inositol, which offers limited clinical benefits in PCOS. Metformin is not routinely recommended for use in pregnant women with PCOS. Mechanical laser therapy is effective for hair reduction in some subgroups, whilst anti-androgens have a limited role where other therapies are ineffective or contraindicated. Anti-obesity agents and bariatric/metabolic surgery may be considered based on general population guidelines, balancing potential for benefits and side effects.

Letrozole is the preferred first line pharmacological infertility therapy, with clomiphene in combination with metformin; gonadotrophins or ovarian surgery primarily having a role as second line therapy. *In vitro* fertilization (IVF) could be offered, potentially with *in vitro* maturation, as third line therapy, where other ovulation induction therapies have failed and in the absence of an absolute indication for IVF in women with PCOS and anovulatory infertility. Given the underlying risk for pregnancy complications in PCOS, single embryo transfer should be preferred.

Overall, evidence in PCOS is low to moderate quality. Based on high prevalence and significant health impact, greater priority, education, models of care, funding, and research are recommended. Guideline translation will be extensive including multilingual education outputs and evidence-based resources for consumers (the ASKPCOS app), healthcare professionals and policy makers.

The guideline recommendations are protected under copyright, however a clear process for adaption of guideline recommendations to regional context is available by contacting the author for correspondence (www.monash.edu/medicine/mchri/pcos). The translation program will be free and internationally accessible, building on the existing range of codesigned resources including the patient focused, evidence-based PCOS APP (AskPCOS), used in 186 countries and based on a rigorously developed question prompt list. Multi-faceted patient codesigned resources will aim to enhance health literacy with comprehensive PCOS-related health information available in multiple formats and in 15-20 languages. Internationally accessible resources include education modules for healthcare professionals at different career stages and disciplines, healthcare professional accredited courses, practice resources and tools, webinars with international expert panels, and e-health information resources that will be available online (www.monash.edu/medicine/mchri/pcos). Importantly, the Guideline and translation of the Guideline is expected to improve patient experiences through the provision of timely and accurate diagnosis, of accessible evidence-based information and of improved multi-disciplinary support. Ultimately, this international initiative may serve as an exemplar for large scale collaborative engagement, pooling of resources, avoidance of duplication and inconsistency with consensus-based statements, and codesign of best quality consistent guidelines with processes for local adaption and healthcare impact. Key elements include extensive collaboration, broad stakeholder representation, consumer partnership, distributive leadership, adequate

funding, robust project management and governance, adherence to best practice and integrated comprehensive translation, and evaluation. We sincerely thank the partner and collaborating organizations, consumer groups and members of the GDGs for their substantive commitment to the international partnership to optimize health outcomes for women with this common, heterogeneous, and much neglected condition.

Data availability

All data extracted and analyzed in the guideline is available in a repository and can be accessed via <https://doi.org/10.26180/23625288.v1>

Authors' roles

HJT led the guidelines from funding, engaging partners, coordinating processes, prioritizing clinical questions, co-chairing guideline meetings, coordinating peer review responses and leading writing, approval and publication processes. Listed authors held senior leadership roles as chair or deputy chair of the five GDGs or leadership of the evidence team with roles from the management committee, chair/co-chair of GDG or the early career evidence network, involvement at all stages, responding to feedback, providing input into and endorsing the guideline. All other included authors were actively engaged as partner nominees and multidisciplinary GDG or consumer experts. The evidence synthesis network was led by CTT and AM across search strategies, training, Covidence processes, quality appraisal and GRADE, meta-analysis, evidence integrity processes (with BM) and preparing the technical report. The listed members of this network led evidence synthesis across the clinical questions and had input into the technical report.

Funding

The Australian National Health Medical Research Council (NHMRC) (APP1171592) primarily funded this work. The American Society for Reproductive Medicine, Endocrine Society, the European Society of Human Reproduction and Embryology and the European Society for Endocrinology provided partnership funding. Collaborating organizations provided in-kind support. The Commonwealth Government of Australia also supported Guideline Translation through the Medical Research Future Fund (MRFCRI000266). HJT and AM are funded by NHMRC fellowships and CTT by an RACP fellowship.

Conflict of interest

Disclosures of interest were declared at the outset and updated throughout the guideline process, aligned with National Health Medical Research Council (NHMRC) guideline processes. These are available online (www.monash.edu/medicine/mchri/pcos). Of named authors HJT, CTT, AD, LM, LR, JBoyle, AM have no conflicts of interest to declare. JL declares grant from Ferring and Merck; consulting fees from Ferring and Titus Health Care; speaker's fees from Ferring; unpaid consultancy for Ferring, Roche Diagnostics and Ansh Labs; and sits on advisory boards for Ferring, Roche Diagnostics, Ansh Labs, and Gedeon Richter. TP declares a grant from Roche; consulting fees from Gedeon Richter and Organon; speaker's fees from Gedeon Richter and Exeltis; travel support from Gedeon Richter and Exeltis; unpaid consultancy for Roche Diagnostics; and sits on advisory boards for

Roche Diagnostics. MC declares travels support from Merck; and sits on an advisory board for Merck. JBoivin declares grants from Merck Serono Ltd.; consulting fees from Ferring B.V; speaker's fees from Ferring Arzneimittell GmbH; travel support from Organon; and sits on an advisory board for the Office of Health Economics. RJP has received speaker's fees from Merck and sits on an advisory board for Ferring. AJoham has received speaker's fees from Novo Nordisk and Boehringer Ingelheim.

Appendix

Members of the PCOS Network

The international advisory panel, guideline technical team, paediatric, consumer and translation committees, the Indigenous cultural advisor and the extended early career support network who assisted with evidence synthesis, can be found online (www.monash.edu/medicine/mchri/pcos).

doi:10.1016/j.fertnstert.2003.10.004

Since the 1990 National Institutes of Health-sponsored conference on polycystic ovary syndrome (PCOS), it has become appreciated that the syndrome encompasses a broader spectrum of signs and symptoms of ovarian dysfunction than those defined by the original diagnostic criteria. The 2003 Rotterdam consensus workshop concluded that PCOS is a syndrome of ovarian dysfunction along with the cardinal features hyperandrogenism and polycystic ovary (PCO) morphology. PCOS remains a syndrome, and as such no single diagnostic criterion (such as hyperandrogenism or PCO) is sufficient for clinical diagnosis. Its clinical manifestations may include menstrual irregularities, signs of androgen excess, and obesity. Insulin resistance and elevated serum LH levels are also common features in PCOS. PCOS is associated with an increased risk of type 2 diabetes and cardiovascular events. (Fertil Steril® 2004;81:19–25. ©2004 by American Society for Reproductive Medicine.)

Nearly 15 years have passed since the first international conference on polycystic ovary syndrome (PCOS) was held. During that initial meeting at the National Institutes of Health (NIH) in Bethesda, Maryland, there was considerable discussion with little consensus, although a questionnaire led to the current diagnostic criteria that stand today (see Table 1). Based on the majority opinion rather than clinical trial evidence, the following diagnostic criteria were put forth: clinical or biochemical evidence of hyperandrogenism, chronic anovulation, and exclusion of other known disorders (1). These criteria were an important first step toward standardizing diagnosis and led to a number of landmark randomized multicenter clinical trials in PCOS (2, 3). Since that time and as outlined during a number of subsequent international conferences (4), there has been a gradually increasing awareness that the clinical expression of PCOS may be broader than that defined by the 1990 NIH criteria.

Rotterdam Consensus on Diagnostic Criteria for PCOS

PCOS is a syndrome of ovarian dysfunction. Its cardinal features are hyperandrogenism and polycystic ovary morphology (5). Its clinical manifestations may include menstrual irregularities, signs of androgen excess, and obesity.

PCOS is associated with an increased risk of type 2 diabetes (6, 7). Since the 1990 NIH-sponsored conference on PCOS, it has become appreciated that the syndrome encompasses a broader spectrum of signs and symptoms of ovarian dysfunction than those defined by the original diagnostic criteria (Table 1). It is now recognized that women with regular cycles and hyperandrogenism and/or polycystic ovaries (PCO) may have the syndrome (8–10). It has also been recognized that some women with the syndrome will have PCO without clinical evidence of androgen excess but will display evidence of ovarian dysfunction.

PCOS remains a syndrome and as such no single diagnostic criterion (such as hyperandrogenism or PCO) is sufficient for clinical diagnosis. PCOS also remains a diagnosis of exclusion. Known disorders that mimic the PCOS phenotype should be excluded.

Diagnostic Criteria for Clinical Trials and Familial Studies

The above-mentioned diagnostic criteria may not be suitable for trials focusing on clinical outcomes in women with PCOS. For instance, trials focusing on pregnancy as an outcome may place greater emphasis on anovulation as the identifying symptom, rather

TABLE 1

Revised diagnostic criteria of polycystic ovary syndrome.

1990 Criteria (both 1 and 2)
1. Chronic anovulation and
2. Clinical and/or biochemical signs of hyperandrogenism and exclusion of other etiologies.
Revised 2003 criteria (2 out of 3)
1. Oligo- or anovulation,
2. Clinical and/or biochemical signs of hyperandrogenism,
3. Polycystic ovaries and exclusion of other etiologies (congenital adrenal hyperplasia, androgen-secreting tumors, Cushing's syndrome)

Note: Thorough documentation of applied diagnostic criteria should be done (and described in research papers) for future evaluation.

2003 Rotterdam PCOS consensus. *Fertil Steril* 2004.

than the presence of PCO or clinical hyperandrogenism. Similarly, trials seeking an improvement in hirsutism may deemphasize baseline ovulatory function and require some pathological terminal hair growth for entry. Moreover, women with chronic anovulation and hyperandrogenism and/or PCO appear to be at substantially greater risk for insulin resistance than those with hyperandrogenism and regular cycles (11, 12). Accordingly, it is essential that studies of the metabolic features of PCOS stratify affected women according to ovulatory function (i.e., chronic oligo-/amenorrhea vs. regular cycles).

Family studies are critical for understanding the spectrum of phenotypes and for identifying susceptibility genes for PCOS. More narrow diagnostic criteria may be used in family studies to identify affected individuals, such as the presence of PCO alone (13) or hyperandrogenemia per se (14). A rigid definition of PCOS based on the present or past proposed diagnostic criteria may hamper our understanding of this heterogeneous disorder.

Exclusion of Related Disorders

To establish the diagnosis of PCOS, it is important to exclude other disorders with a similar clinical presentation, such as congenital adrenal hyperplasia, Cushing's syndrome, and androgen-secreting tumors. Exclusion of 21-hydroxylase deficient nonclassic adrenal hyperplasia (NCAH) can be performed using a basal morning 17-hydroxyprogesterone level, with cutoff values ranging between 2 and 3 ng/mL (15). Some participants felt that the routine screening of hyperandrogenic patients for NCAH should take into account the prevalence of this autosomal recessive disorder in the population under study.

The routine exclusion of thyroid dysfunction in patients deemed to be hyperandrogenic was felt to have limited value, as the incidence of this disorder among these patients is no higher than that in normal women of reproductive age. However, because screening for thyroid disorders may be advisable in all women of reproductive age, the routine

measurement of TSH in the hyperandrogenic patient need not be discouraged.

The initial workup in women presenting with oligo-anovulation may also include the assessment of serum FSH and E₂ levels to exclude hypogonadotropic hypogonadism (i.e., central origin of ovarian dysfunction) or premature ovarian failure characterized by low E₂ and high FSH concentrations, according to World Health Organization (WHO) classification (16, 17). PCOS is part of the spectrum of normogonadotropic normoestrogenic anovulation (WHO 2) (5, 18). It should be emphasized, however, that serum LH concentrations are frequently elevated in these patients, as will be discussed later.

Most participants felt that the routine measurement of PRL in the evaluation of hyperandrogenic patients should be performed to exclude hyperprolactinemia, with a caveat that many hyperandrogenic patients may have PRL levels in the upper normal limit or slightly above normal.

Finally, syndromes of severe insulin resistance (e.g., for the diagnosis of the hyperandrogenic-insulin resistant-acanthosis nigricans, or HAIRAN, syndrome) (19), Cushing's syndrome (20), androgen-secreting neoplasms (20, 21), or high-dose exogenous androgens (22) should be excluded if clinically suspected.

Hyperandrogenism

Clinical phenotyping of PCOS involves determining the presence of clinical and/or biochemical androgen excess (hyperandrogenism), while excluding related disorders.

Clinical Hyperandrogenism: Most participants felt that the primary clinical indicator of androgen excess is the presence of hirsutism (23). However, the following issues should be emphasized:

- Normative data in large populations are still lacking.
- The assessment of hirsutism is relatively subjective.
- Few physicians in clinical practice actually use standardized scoring methods.
- Hirsutism is often treated well before the patient is ever evaluated endocrinologically.
- Hirsutism may be significantly less prevalent in hyperandrogenic women of East Asian origin (24) or in adolescence (25).

The sole presence of acne was also felt to be a potential marker for hyperandrogenism, although studies are somewhat conflicting regarding the exact prevalence of androgen excess in these patients (26). The sole presence of androgenic alopecia as an indicator of hyperandrogenism has been less well studied. However, it appears to be a relatively poor marker of androgen excess, unless present in the oligo-ovulatory patient (27). Overall, the clinical evidence of hyperandrogenism is an important feature of patients with PCOS, notwithstanding the above-mentioned limitations.

Biochemical Hyperandrogenism: Most patients with PCOS have evidence of hyperandrogenemia, and recent ob-

servations suggest that circulating androgen levels may also represent an inherited marker for androgen excess (14). However, it was clearly denoted that a proportion of patients with PCOS may not demonstrate an overt abnormality in circulating androgens (5, 28–31).

The limitations of defining androgen excess by the measurement of circulating androgen levels were felt to be due in part to the inaccuracy and variability of the laboratory methods of measurement that are often used (32–34):

- There are multiple androgens that may not be considered (35).
- There is wide variability in the normal population.
- Normative ranges have not been well-established using well-characterized control populations.
- Age and body mass index (BMI) have not been considered when establishing normative values for androgen levels (36, 37).
- Little normative data are present on adolescent and older women.
- Androgens are suppressed more rapidly by hormonal suppression than other clinical features and may remain suppressed even after discontinuation of hormonal treatment.

Notwithstanding these limitations, it was felt that the measurement of free T or the free T (free androgen) index (34) were the more sensitive methods of assessing hyperandrogenemia (38, 39). Recommended methods for the assessment of free T included equilibrium dialysis (33, 34), calculation of free T from the measurement of sex hormone-binding globulin and total T, or ammonium sulfate precipitation (40). It was the uniform impression that currently available direct assays for free T have limited value, particularly in the evaluation of the hyperandrogenic woman.

It was noted that measurement of total T only may not be a very sensitive marker of androgen excess. A small fraction of patients with PCOS may have isolated elevations in dehydroepiandrosteronesulphate (DHEAS) levels. Some felt that the measurement of total T and DHEAS had some value in detecting a patient with an androgen-secreting tumor (41), although more recent data suggest that the best predictor of these neoplasms is the clinical presentation (42).

Finally, little data are available on the value of routinely measuring androstenedione in hyperandrogenic patients (5), although it was noted that it might be somewhat more elevated in patients with 21-hydroxylase-deficient nonclassic adrenal hyperplasia than in patients with PCOS. Nonetheless, the paucity of normative and clinical data with androstenedione precluded its recommendation for the routine assessment of hyperandrogenemia.

Polycystic Ovaries (PCO)

Workshop participants felt that PCO should now be considered as one of the possible criteria for PCOS (see Table 1). According to the available literature (18, 43, 44), the criteria having sufficient specificity and sensitivity to define

PCO are the following: “Presence of 12 or more follicles in each ovary measuring 2–9 mm in diameter, and/or increased ovarian volume (>10 mL)” (for a review, see 45). The subjective appearance of PCO should not be substituted for this definition. The follicle distribution should be omitted as well as the increase in stromal echogenicity and volume. Although increased stromal volume is a feature of PCO (46), it has been shown that the measurement of the ovarian volume is a good surrogate for the quantification of stromal volume in clinical practice (47). This definition does not apply to women taking the oral contraceptive pill, since its use modifies ovarian morphology in normal women and putatively in women with PCO (48). Only one ovary fitting this definition is sufficient to define PCO. If there is evidence of a dominant follicle (>10 mm) or a corpus luteum, the scan should be repeated during the next cycle. The presence of an abnormal cyst or ovarian asymmetry (which may suggest a homogeneous cyst) necessitates further investigation.

A woman having PCO in the absence of an ovulatory disorder or hyperandrogenism (“asymptomatic” PCO) should not be considered as having PCOS until more is known regarding the clinical presentation (49). In addition to its role in the definition of PCOS, ultrasound is helpful to predict fertility outcome of clomiphene citrate (50) and the risk of ovarian hyperstimulation syndrome (OHSS) and to assist in deciding whether the in vitro maturation of oocytes is desirable (51).

It is recognized that the appearance of PCO may be seen in women before undergoing ovarian stimulation for IVF in the absence of overt signs of the PCOS. These ovaries, when stimulated, behave like the ovaries of women with PCOS and are at increased risk for hyperstimulation and OHSS (52).

In addition, ultrasound provides the opportunity to screen for endometrial hyperplasia in these patients. The following technical recommendations should be highlighted:

- State-of-the-art equipment is required and should be operated by appropriately trained personnel.
- Whenever possible, the transvaginal approach should be used, particularly in obese patients.
- Regularly menstruating women should be scanned in the early follicular phase (cycle days 3–5). Oligo-/amenorrhoeic women should be scanned either at random or between days 3 and 5 after a progestin-induced withdrawal bleeding.
- Calculation of ovarian volume is performed using the simplified formula for a prolate ellipsoid ($0.5 \times \text{length} \times \text{width} \times \text{thickness}$) (53).
- Follicle number should be estimated both in longitudinal and antero-posterior cross-sections of the ovaries. The size of follicles <10 mm should be expressed as the mean of the diameters measured on the two sections.

TABLE 2

Summary of 2003 polycystic ovary syndrome (PCOS) consensus regarding screening for metabolic disorders.

Summary of consensus

- No tests of insulin resistance are necessary to make the diagnosis of PCOS, nor are they needed to select treatments.
- Obese women with PCOS should be screened for the metabolic syndrome, including glucose intolerance with an oral glucose tolerance test.
- Further studies are necessary in nonobese women with PCOS to determine the utility of these tests, although they may be considered if additional risk factors for insulin resistance, such as a family history of diabetes, are present.

2003 Rotterdam PCOS consensus. *Fertil Steril* 2004.

TABLE 3

Criteria for the metabolic syndrome in women with polycystic ovary syndrome. (Three of five qualify for the syndrome.)

Risk factor	Cutoff
1. Abdominal obesity (waist circumference)	>88 cm (>35 inch)
2. Triglycerides	≥150 mg/dL
3. HDL-C	<50 mg/dL
4. Blood pressure	≥130/≥85
5. Fasting and 2-h glucose from oral glucose tolerance test	110–126 mg/dL and/or 2-h glucose 140–199 mg/dL

2003 Rotterdam PCOS consensus. *Fertil Steril* 2004.

Insulin Resistance

Insulin resistance is associated with reproductive abnormalities in women with PCOS (see also Table 2). Improving insulin sensitivity through both lifestyle and pharmacological intervention can ameliorate these abnormalities. Insulin resistance, defined as decreased insulin-mediated glucose utilization, is commonly found in the larger population (10%–25%) when sophisticated dynamic studies of insulin action are performed (54). However, the criteria for selecting an abnormal cutoff point vary. Insulin resistance in women with PCOS appears even more common (up to 50%), both in obese and nonobese women (55). Reports of the prevalence on insulin resistance in women with PCOS vary depending on the sensitivity and specificity of the tests employed and the heterogeneity of PCOS.

There is currently no validated clinical test for detecting insulin resistance in the general population. Dynamic invasive tests such as the euglycemic clamp and frequently sampled glucose tolerance test are research procedures because of their intensive use of time and resources. Calculated indices based on fasting levels of insulin and glucose correlate well with dynamic tests of insulin action. However, there are multiple flaws that limit their widespread clinical use, including changes in beta-cell function with the development of diabetes (which alters the sensitivity of the tests), normal physiologic fluctuation in insulin levels, and the lack of a standardized universal insulin assay.

Other consensus conferences also recommended against screening for insulin resistance in both the general population and in high-risk populations because of these concerns and concerns regarding the value of these tests to predict clinical events (56). Instead, criteria have been developed for defining a metabolic syndrome, which includes components associated with the insulin resistance syndrome, including centripetal obesity, hypertension, fasting hyperglycemia, and dyslipidemia (Table 3) (57).

Other groups have recommended adding an oral glucose tolerance test (OGTT) to these fasting blood tests to evaluate

the 2-hour glucose level after a 75-g oral glucose challenge for glucose intolerance (WHO criteria, impaired glucose tolerance [IGT] >140 mg/dL to 199 mg/dL) (58, 59). IGT has long been recognized as a major risk factor for diabetes (60), and recent studies have shown that progression to diabetes in individuals with IGT can be delayed by lifestyle changes and pharmacological intervention (61, 62). Additionally, IGT identifies individuals at risk for excess mortality, especially women (63, 64). Given the high prevalence of IGT and type 2 diabetes as diagnosed by the OGTT among obese women with PCOS, it is prudent to screen obese women ($BMI >27 \text{ kg/m}^2$) with PCOS with an OGTT (6, 65). Further studies of the prevalence of features of the metabolic syndrome are necessary in both lean and obese women with PCOS.

Currently, there are scant data to indicate that markers of insulin resistance predict responses to treatment (3, 39, 66). Therefore, the role of these markers in the diagnosis of PCOS, as well as in selecting specific treatments, is uncertain. Tests of insulin sensitivity are of greatest interest in research studies of [1] the pathophysiology of PCOS, [2] young adolescents with a combined history of low birth weight and excessive postnatal catch-up, [3] mechanisms of response to therapy, and [4] family phenotypes. Further studies to identify predictive factors or early response factors to treatments of PCOS are needed.

Luteinizing Hormone

Both the absolute level of circulating LH as well as its relation to FSH levels are significantly elevated in women with PCOS as compared with controls (67, 68). This is due to an increased amplitude and frequency of LH pulses (69). Elevated LH concentrations (above the 95th percentile of normal) can be observed in approximately 60% of women with PCOS (5, 18), whereas the LH/FSH ratio may be elevated in up to 95% of subjects (68) if women who have recently ovulated are excluded. LH levels may be influenced by the temporal relation to ovulation, which transiently nor-

malizes LH, by BMI (being higher in lean women with PCOS), as well as by the assay system used.

The potential negative actions of LH on human reproduction are highly controversial. Some investigators have suggested that high LH levels could have detrimental effects on oocyte maturity and fertilization (70), as well as result in lower pregnancy and higher miscarriage rates (71). However, other studies have shown no untoward actions of LH on oocyte and embryo quality or on fertilization, implantation, and pregnancy rates (72, 73). Reduction of endogenous LH levels with GnRH agonists also provided conflicting results as some studies have suggested that this maneuver could reduce miscarriage rates (74), while others have questioned this therapeutic effect (75, 76). LH levels or the administration of exogenous LH activity were not found to affect the chances of ovulation or achievement of pregnancy using clomiphene citrate (39, 49) or exogenous gonadotropins (77, 78).

Based on the aforementioned data, the panel felt that measurement of serum LH levels should not be considered necessary for the clinical diagnosis of PCOS. LH levels could be useful as a secondary parameter (especially in lean women with amenorrhea or in research). Additional research is needed to further clarify the clinical relevance of LH in PCOS and the potential effects of LH suppression with GnRH analogs or its enhancement through LH activity administration at different stages of follicular maturation.

Long-Term Health Risks

Women with PCOS have multiple risk factors for diabetes including obesity, a family history of type 2 diabetes, and abnormalities in insulin action (both insulin resistance and beta-cell dysfunction). There is now clear evidence that women with PCOS are at increased (3–7 times) risk of developing type 2 diabetes (6, 7, 11, 79, 80). There are several lines of evidence suggesting that women with PCOS are also at increased risk of cardiovascular disease (81). Insulin-resistant states are associated with greater than normal susceptibility to coronary heart disease, and women with PCOS have evidence of dyslipidemia (82–85) and markers of abnormal vascular function (86–88). However, limited epidemiological studies have shown no direct evidence of an increased incidence of coronary heart disease in middle-aged women with a history of PCOS (although the incidence of stroke is slightly increased) (89).

Women with PCOS are also thought to be at increased risk for endometrial cancer through chronic anovulation with unopposed estrogen exposure of the endometrium. However, epidemiological evidence to support this hypothesis is limited (90).

Currently, no firm conclusions can be drawn, but the following statements represent the consensus view that PCOS is associated with an increased risk of type 2 diabetes:

- The risk is greater in anovulatory women with PCO, in obese subjects, and in those with a family history of type 2 diabetes.
- The risk of cardiovascular disease is uncertain at present (89, 91). Limited epidemiological data have shown no increase in cardiovascular events, but two factors need to be borne in mind: The young age of the cohorts studied so far (around 55 years) and the possibility that unknown factor(s) may be present in PCOS that protect the heart in the face of other risk factors.

More research is required to [1] assess the level of risk, [2] enable identification of patients at risk, [3] provide longitudinal follow-up of PCOS cohorts into their sixties and beyond, and [4] determine the place, timing, and efficacy of interventional measures.

Although many questions remain to be answered, lifestyle changes (diet and exercise) should be strongly encouraged to reduce the risk of both type 2 diabetes and cardiovascular disease (37, 92–95).

The Role of Life style Modification in Management of Polycystic Ovary Syndrome

Kalpana Sharma¹, S.K Srivastava²

¹Research scholar, Department of Psychology, Gurukul Kangri Vishwavidyalaya, Haridwar, India (corresponding author), ²Professor, Department of Psychology, Dean Faculty of Humanities, Gurukul Kangri Vishwavidyalaya, Haridwar, India

Abstract

Polycystic ovary syndrome is a common endocrine disorder affecting women of reproductive age group characterized by various metabolic and reproductive dysfunctions. There are evidences that environmental toxins play a potential role in disrupting reproductive health. In this review we summarized existing research on a variety of environmental factors involved in the etiology, prevalence and management of polycystic ovary syndrome. Pubmed, PsycINFO and Google Scholar were searched for the reviews and studies from last five years included in this study. All searches were limited to human studies. We concluded that symptoms of polycystic ovary syndrome are reduced with certain dietary supplement, restricted diet and exercise. Health related quality of life along with weight, body hair, infertility, acne score improves well with an intervention of about 24-weeks of lifestyle modification. That is why a healthy lifestyle is usually recommended to improve overall health and fertility.

Key words: Polycystic ovary syndrome, dietary habits and exercise

Introduction

Polycystic ovary syndrome is most common endocrine-metabolic disorders affecting 8% to 13% women of reproductive age group and is associated with ovulatory dysfunction, hyperandrogenism and cardiometabolic risk. Due to sedentary lifestyle and stress incidence of metabolic disorders like PCOS are increasing day by day. Polycystic ovary syndrome is characterized by insulin resistance, elevated circulating leukocytes, and hypothesized to have higher adipose tissue inflammation. The condition is marked by presence of cysts on the ovaries leading to their obstructed functioning. Amenorrhea, infrequent menstruation & anovulation, imbalanced hormonal levels, chronic pelvic pain and irregular bleeding are the common symptoms of Polycystic Ovary Syndrome. Women with polycystic ovary syndrome have higher prevalence of infertility compared with women without PCOS. ‘The overweight-obese women having PCOS appears to have exacerbated reproductive dysfunction and cardio metabolic risk.¹ Early diagnosis and treatment may reduce the risk of long-term complications such as metabolic disorders,

obesity, diabetes, and coronary disease, and malignancies such as breast and endometrial cancer. Obesity worsens the presentation of PCOS and weight management is supposed to be an initial treatment strategy. Khademi 2010 et.al found that ‘Obese PCOS women show more difficulty in losing weight by exercise than lean women with PCOS’.¹ Though this target can be achieved through lifestyle modifications, by incorporating restricted diet, exercise and behavioral interventions. That is why a healthy lifestyle is usually recommended to improve overall health and fertility.

The actual cause of PCOS is unknown but environmental factors such as dietary habits play an important role in prevention and treatment of this syndrome. ‘Weight reduction even of about 5% can improve problems such as insulin resistance, high level of androgens, reproductive system dysfunctions in women with PCOS. Thus, lifestyle modification can be used as therapeutic strategies in these patients’.² Lifestyle intervention may improves secondary reproductive outcome, free androgen index, may reduce weight and BMI. Women inducing lifestyle intervention shows

significant improvement in cardio respiratory fitness and reduces resting heart rate. It may also be used for improvement of health related quality of life and other psychological complications in women with PCOS. This can make enormous difference and relieve symptoms like eating habits, participating in regular physical activity, maintaining healthy weight, reducing androgen level, reducing risk of DM and CVD. ‘Lifestyle intervention helps improving body composition parameters including BMI, waist circumference, waist hip ratio, body fat, total cholesterol, C-reactive protein and peak VO₂ MD’.³ Knowledge about these interventions increases healthy eating, active living, health care satisfaction, feelings and experiences about intervention and health concerns.⁴ Losing just 5-10% of your body weight helps regulating menstrual cycle and improving symptoms of polycystic ovary syndrome. Thirty minutes of moderate to vigorous intensity exercise at least 4 days a week along with healthy diet can help women with PCOS lose weight.

Effect of Exercise on Polycystic Ovary Syndrome

Healthy lifestyle including nutritious and balanced diet, yoga & exercise are found effective in management of polycystic ovary syndrome. Weight loss programs hold promise and efficient hospital or community-based programs may prove beneficial in women with PCOS. Regular exercise also increases quality of life in these women. In overweight and obese women with or without PCOS exercise contributes to lower insulin and free androgen levels which helps restoring hypothalamic-pituitary-gonadal axis regulation of ovulation. The mechanism by which exercise affects ovulation is probably via modulation of hypothalamic-pituitary-gonadal axis. ‘Despite various researches supporting weight loss as primary measure for PCOS management there is lack of studies comparing types of physical activity, intensity and settings. These gaps may be responsible for delaying an efficient and effective use of exercise as a therapeutic modality to treat anovulatory infertility including PCOS. Exercise with or without diet can lead to resumption of ovulation. Regular exercise for 30-60 min is associated with reduced risk of anovulatory infertility’.⁵ Moderate aerobic exercise intervention for more than or equals to a period of three months have favorable effects on various cardio-metabolic risk factors in women with polycystic ovary syndrome.

Some of these factors include total cholesterol level, fasting glucose, waist circumference and waist to-hip ratio, testosterone, sex hormone, C-reactive protein and systolic blood pressure.⁶ Continuous aerobic training and intermittent aerobic training both helps in reduction of anxiety and depression. After approximately four months or sixteen weeks of aerobic training significant reduction in testosterone level are found. ‘CAT significantly increases the total score of Female Sexual Function Index, improves FSFI domains of satisfaction and pain and reduced WHR. Intermittent aerobic training increases total FSFI score and improves desires, excitation, lubrication, orgasm and satisfaction in women with polycystic ovary syndrome’.⁷ Beneficial effects of exercise are found for a range of metabolic, anthropometric and cardio respiratory fitness related outcomes. ‘Short duration and aerobic exercise significantly affects fasting insulin level, total cholesterol, low density cholesterol, and triglycerides. Exercise also improves VO₂ max, waist circumference and body fat percentage’.⁸ Moderate intensity exercise independent of substantial weight loss improves endothelial function in women with PCOS by reducing circulating CD105+MP.⁹ Physical resistance exercise alone can improve hyperandrogenism, reproductive function, and body composition by decreasing visceral fat and increasing lean muscle mass. ‘PRT reduces plasma testosterone and fasting glucose, increased androstenedione concentration and sex hormone binding globulin concentration decreases in women with PCOS’.¹⁰ Regular physical activity is associated with better anthropometric and androgenic profile in women with PCOS. As compared to sedentary women with PCOS active women have lower waist circumference, lipid accumulation product and low androgen levels.¹¹

When compared to oral contraceptives which treat hyperandrogenism and menstrual disturbances structured exercise training program is helpful in effective management of anthropometric measures, insulin sensitivity indexes, lipid profile, cardiopulmonary function, inflammatory marker and frequency of menstrual cycle in women with PCOS.¹² ‘Obese adolescents having PCOS who have experienced childhood trauma can lose weight and acquire its health benefits when intervened with weight loss, mood, and sleep’.¹³ Weight loss, fertility hormones, FSH, prolectin, oestrogen, antral follicle count, baseline anti-mullerian

hormone and adiponectine are significantly correlated with reproductive function. Physical activity changes the level of anti-mullerian hormone and adiponectin. Moderate aerobic exercise for around twelve weeks had significant effect on reproductive functions by modulating adiposity, levels of adiponectine anti-mullerian hormones and fertility hormones. 'Participants who respond to aerobic exercise intervention show significant improvement in reproductive function, with lower baseline anti-mullerian hormone level, weight loss and increased adiponectine level. These women also shows significant improvement in ovarian process and a restoration of menstrual cycle'.¹⁴ Resistance training has beneficial effects on morphology of the ovaries and the glycemic index in women with PCOS. It has good effect on insulin resistance index, improves ovaries volume, body composition indices including weight, body mass index and body fat.¹⁵

Polycystic ovary syndrome is characterized by insulin resistance, elevated circulating leukocytes and more tissue inflammation. In obese individuals aerobic exercise reduces circulating leukocytes and improves insulin sensitivity. Women with polycystic ovary syndrome have higher circulating leukocytes. This condition can be reversed by aerobic exercise and is associated with improvement in insulin sensitivity. WBC is found higher and total adiponectin level is lower in PCOS women performing regular exercises. 'Regular aerobic exercise for four weeks reduces serum leptin; ratio of leptin to high molecular weight adiponectine after eight weeks and significantly increases serum dehydroepiandrosterone sulfate after sixteen weeks'.¹⁶ Exercise may normalize amino acid metabolite in women with PCOS. 'If regular exercise is performed, Leucine, glutamate, methionine, ornithine, phenylalanine, tyrosine and proline in women with PCOS may normalize and become equal to women without PCOS'.¹⁷

'Aerobic exercise increase vagal modulation, decrease sympathetic modulation and increases parasympathetic modulation, decrease resting heart rates and systolic blood pressure irrespective changes in BMI, fasting insulin and testosterone level'.¹⁸ Women with PCOS who meet department of health and human services guidelines for exercise have superior metabolic health parameters. Vigorous exercise is associated with reduced metabolic dysfunctions independent of age,

BMI and total energy expenditure. 'When compared with inactive women and moderate exercisers, it was found that vigorous exercisers had lower body mass index, higher level of HDL and sex hormone binding globulin and reduced prevalence of the metabolic syndrome'.¹⁹ Homeostatic assessment of insulin resistance improves after high intensity interval training, high density lipoprotein increases, endothelial function increases and body fat decrease.²⁰ Progressive aerobic exercise improves health related quality of life, cardio respiratory fitness and cardio metabolic profile of overweight/ obese women with polycystic ovary syndrome. While glancing psychological aspects 'exercise improves following domains of health related quality of life - physical functioning, general health and mental health'.²¹

Effect of Yoga on Polycystic Ovary Syndrome

Women with PCOS also suffer from emotional ill health, anxiety and depression. Medical yoga therapy is emerging as an effective modality in the management of much non-communicable disease. Yoga therapy also addresses psychological morbidity. Yoga has calming effect on the mind and body through balancing sympathetic and parasympathetic nervous system. Lifestyle modification including diet, exercise and weight loss is very important component of management of PCOS. 'Thus yoga results in multiple beneficial effects on neuroendocrine axis and facilitates adoption of healthier lifestyle addressing underlying hyperandrogenemia and insulin resistance in PCOS'.²² Due to disturbance in hypothalamo-pituitary-ovarian axis various symptoms like anxiety, depression, insomnia, loss of concentration, acne, infertility etc. appears in syndrome. It is a psychosomatic disorder too, so it is important to provide psychic and somatic treatment also. Yoga is the complete prescription for the healthy body and mind which deals with the root cause of this disorder i.e., obesity and stress. 'Daily yoga with for thirty minutes with four asans, four pranayam, meditation, and shavasan helps in weight reduction and stress management, thus normalizing hypothalamo-pituitary-ovarian axis and curing polycystic ovary syndrome. Asans like suryanamaskar, paschimottan asan, bhujangasan, shalabhasan etc. helps in weight reduction and toxin exertion from the body. Pranayam and relaxing yoga posture like Shavasana, makarasana etc. helps curing stress'.²³ Yoga and naturopathy therapy

for twelve weeks improves ovarian morphology and anthropometric measurements.²⁴ Regular mindful yoga practice can be used as complementary therapeutic option for women with PCOS. This lowers serum androgen (dehydroepiandrosterone) and free testosterone levels. Improvement occurs even in absence of weight loss and persists even if there is a lapse in practice.²⁵

Dietary Modification and PCOS

Overweight women with PCOS related infertility have eating behaviors inconsistent with achieving a healthy body weight. They have poor dietary intake, particularly related to whole grains, fiber and iron.²⁶ ‘PCOS women consume high glycemic index food items and lower legumes and vegetables’.²⁷ There is high prevalence of overweight status, obesity, and increased visceral fat in these women. Diet quality is negatively associated with obesity. Two of the primary ways diet affect PCOS are weight management and insulin production and resistance. ‘Diet therapy in these patients must reach specific goals such as improving insulin resistance, metabolic and reproductive function. Low-calorie diet can be used to achieve weight loss or maintaining a healthy weight. Diet must focus on limited intake of simple sugars, refined carbohydrates and intake food with low glycemic index, reduction of saturated and trans-fat. Attention must be paid to possible deficiencies of vitamin D, chromium and omega-3 fatty acid’.² Energy restriction and weight loss in PCOS improves ovulation rates, conception, hyperandrogenemia, glucose and insulin level, insulin resistance, and satiety hormones. Diet low in carbohydrate as compared to standard diet has 1-5% significant additional effect to caloric restriction in terms of weight loss.²⁸ Carbohydrates are the main stimulators of insulin release. Dairy products and starches elicit great postprandial insulin secretion than non-starchy vegetables and fruits. ‘Eight week dietary intervention using a low starch/low dairy diet in women with PCOS is effective in reducing weight, BMI, waist circumference, waist to hip ratio, fasting insulin and homeostasis model assessment of Insulin Resistance (HOMA-IR), total testosterone, free testosterone, and ferriman-Gallwey score’.²⁹ High dietary GI and low fibre intake are associated with PCOS.³⁰ Low carbohydrate diet is more beneficial in weight loss, reducing insulin and serum testosterone. ‘This diet when combined with exercise results in weight loss, decreased body fat,

increased insulin sensitivity, improved estradiol and LH: FSH ratio and other reproductive measures’.³¹ Dietary weight loss in adolescent women with polycystic ovary syndrome resulted in significant improvement in menstrual regularity, BMI, waist circumference, and hirsutism score.³² When these women are subjected to an anti-inflammatory hypocaloric diet with physical activity they show significant improvements in body composition, hormones, menstrual cycle, blood pressure, glucose homeostasis, dyslipidemia, C-reactive protein and serum amyloid acid and improved fertility with 12% spontaneous pregnancy rate.³³ A proper low-calorie diet with low glycemic index should be recommended along with PA to improve psychological, reproductive, and cardiovascular parameters for women with polycystic ovary syndrome.

There is currently no standard diet for PCOS. However, a widespread agreement about food which seems to be beneficial for these women are: A) A low glycemic such as whole grains, legumes, nuts, seeds, fruits, starchy vegetables, unprocessed and low carbohydrate good. B) An anti-inflammatory diet such as berries, fish, green leafy vegetables, extra virgin oil etc. C) DASH (dietary approaches to stop hypertension) diet which includes poultry, fruits, vegetables, whole grain, and low fat dairy products. DASH diet reduces hypertension and risk of heart disease. Other foods that can be included in diet are: natural unprocessed food, high fiber food, fatty fish, salmon, spinach, dark red fruit, blue& blackberries cherries, broccoli and cauliflower, dried beans, lentil; healthy fats such as olive oil, avocados, coconut; nuts like walnut, almonds, pistachios; spices like turmeric and cinnamon; and dark chocolate. Food to be avoided is: sugary beverages such as sodas and energy drinks; refined carbohydrates such as pastries, cakes, white processed bread; processed meat etc.

Other beneficial dietary habits are including small frequent meals, consumption at regular times, majority of carbohydrates consumption at lunch time or equally distributed through out the day and drinking plenty of water.

Conclusion

Due to sedentary lifestyle and stress incidence of metabolic disorders like PCOS are increasing

day by day. Early diagnosis and treatment including lifestyle modification may reduce the risk of long-term complications such as metabolic disorders, obesity, diabetes, and coronary disease, and malignancies such as breast and endometrial cancer. Losing just 5-10% of your body weight helps regulating menstrual cycle and improving symptoms of polycystic ovary syndrome. Moderate to vigorous regular physical exercise along with healthy and restricted diet helps these women achieving healthy body weight, normalizing hormonal profile and improving metabolic and reproductive functioning. Including yoga in daily life routine helps in both mental and physical health maintenance. Lifestyle modification is thus an effective measure in improving mental and physical health of women with PCOS.

Abstract

Background

Polycystic ovary syndrome (PCOS) seriously affects the fertility and health of women of childbearing age. We look forward to finding potential biomarkers for PCOS that can aid clinical diagnosis.

Methods

We acquired PCOS and normal granulosa cell (GC) expression profiles from the Gene Expression Omnibus (GEO) database. After data preprocessing, differentially expressed genes (DEGs) were screened by limma package, and Gene Ontology (GO) and Kyoto Encyclopedia of Genes and Genomes (KEGG) enrichment analysis and Gene Set Enrichment Analysis (GSEA) were performed. Recursive feature elimination (RFE) algorithm and the least absolute shrinkage and selection operator (LASSO) Cox regression analysis were used to acquire feature genes as potential biomarkers. Time-dependent receiver operator characteristic curve (ROC curve) and Confusion matrix were used to verify the classification performance of biomarkers. Then, the expression characteristics of biomarkers in PCOS and normal cells were analyzed, and the insulin resistance (IR) score of samples was computed by ssGSEA. Immune characterization of biomarkers was evaluated using MCP counter and single sample gene set enrichment analysis (ssGSEA). Finally, the correlation between biomarkers and the scores of each pathway was assessed.

Results

We acquired 93 DEGs, and the enrichment results indicated that most of DEGs in PCOS group were significantly enriched in immune-related biological pathways. Further screening results indicated that JDP2 and HMOX1 were potential biomarkers. The area under ROC curve (AUC) value and Confusion matrix of the two biomarkers were ideal when separated and combined. In the combination, the training set AUC = 0.929 and the test set AUC = 0.917 indicated good diagnostic performance of the two biomarkers. Both biomarkers were highly expressed in the PCOS group, and both biomarkers, which should be suppressed in

Abbreviations: BP, biological process; CC, cellular component; DEGs, Differential Expressed Genes; GC, granulosa cell; GEO, Gene Expression Omnibus; GO, Gene Ontology; GSEA, Gene Set Enrichment Analysis; HMOX1, Heme Oxygenase-1; IR, insulin resistance; JDP2, Jun Dimerization Protein 2; KEGG, Kyoto Encyclopedia of Genes and Genomes; MF, molecular function; PCOS, polycystic ovary syndrome; RFE, Recursive feature elimination; ROC, Receiver Operating Characteristic; ssGSEA, Single sample gene set enrichment analysis.

the preovulation phase, were elevated in PCOS tissues. The IR score of PCOS group was higher, and the expression of JDP2 and HMOX1 showed a significant positive correlation with IR score. Most immune cell scores and immune infiltration results were significantly higher in PCOS. Comprehensive analysis indicated that the two biomarkers had strong correlation with immune-related pathways.

Conclusion

We acquired two potential biomarkers, JDP2 and HMOX1. We found that they were highly expressed in the PCOS and had a strong positive correlation with immune-related pathways.

1 Introduction

Polycystic ovary syndrome (PCOS) is a widespread disorder of endocrine and metabolic abnormalities that affects up to 15% of women of adolescent and gestational age [1]. PCOS can lead to abnormalities in the female reproductive system and immune system, and the clinical manifestations are generally irregular menstruation and even amenorrhea, excessive male hormones, polycystic ovary morphology [2]. Severe PCOS can lead to insulin resistance (IR), female anovulatory infertility, pathological obesity, autoimmune diseases, local or whole body inflammation and many other diseases [3, 4]. The specific causes of PCOS are complex and multi-systemic, lack of targeted treatment, different diagnostic criteria and methods, and need to be adjusted according to different clinical symptoms [5]. In addition, it has been shown that follicular excess and increased size of the ovaries in PCOS are associated with insulin resistance (IR) and that the number of follicles may also be a predictor of IR [6]. However, the pathogenesis of PCOS is not yet perfect, and there are many hypotheses about different pathogenesis factors, such as chronic low-grade inflammation, genetic factors, lifestyle, post-translational modification mechanism of PCOS, and ovarian autophagy mechanism [7–9].

Ovarian granulosa cells (GC) are the main constituent cells of follicles, which can divide and differentiate in different degrees with the growth of follicles, and also play an important role in hormone secretion [10]. Abnormalities in GC can lead to ovary-related diseases, such as a deficiency of Rpg5 (an autophagy protein) in GC that can lead to premature ovarian failure [11]. Inflammation caused by high levels of male hormones can also lead to GC pyroptosis, causing ovarian function decline and tissue fibrosis [12]. The abnormal communication of oocyte and follicular cells and the damage of GC may be the key to PCOS, such as the damage of transregional projection in communication [13]. Therefore, understanding the abnormal mechanism of GC is very important for the study of PCOS.

The purpose of this study was to search for potential biomarkers of PCOS and explore the association between biomarkers and immune status in PCOS. In this research, Recursive Feature Elimination (RFE) algorithm was used for selection of feature gene. The prediction strength and practicability of this algorithm are relatively good, and it has been used many times in the screening of biomarkers for different diseases, such as chronic obstructive pulmonary disease, keloid disorder, and triple negative breast cancer [14–16].

2 Material and methods

2.1 Data sources and preprocessing

(1) Data sources. Granulosa cell expression profiles of PCOS were acquired from Gene Expression Omnibus (GEO) database: GSE137684, GSE34526, GSE138518, GSE168404,

Table 1. Information of datasets.

dataset	Platforms	PCOS	Control	Experiment type
GSE137684	GPL17077	8	4	array
GSE34526	GPL570	7	3	array
GSE138518	GPL11154	3	3	high throughput sequencing
GSE168404	GPL16791	5	5	high throughput sequencing
GSE155489	GPL20795	4	4	high throughput sequencing

<https://doi.org/10.1371/journal.pone.0293447.t001>

GSE155489 (Table 1) [17]. RNA-Seq expression profiles (GSE107746) of granulosa cells at five follicular development stages were acquired from GEO database.

(2) Data preprocessing. GSE137684 and GSE34526 (microarray) were combined as a training set. GSE138518, GSE168404, and GSE155489 (RNA-Seq) were combined as a test set, and the batch effect was removed using the ComBat function of the sva package (Figure S1) [18]. RNA-Seq expression profiles were converted into TPM format data.

2.2 Identification and enrichment of differentially expressed genes (DEGs)

We used limma package to identify DEGs, and the threshold was set to $p < 0.05$ and $|\log_{2}FC| > \log_{2}(1.5)$ [19]. Gene Ontology (GO) and Kyoto Encyclopedia of Genes and Genomes (KEGG) analyses were performed on all upregulated DEGs in PCOS using the R software clusterProfiler package to assess their pathway processes [20], biological processes (BP), cellular components (CC), and molecular functions (MF). Gene set enrichment analysis (GSEA) was performed to further assess the enrichment of relevant functional pathways between different groups [21].

2.3 Selection and verification of biomarkers

The recursive feature elimination (RFE) algorithm of the caret package is used for characteristic gene selection and 10x cross-validation [22]. The key parameters we chose are: functions = "rfFuncs", method = "cv", number = 10. We then used LASSO regression of the glmnet package for characteristic gene screening [23]. The parameters chosen for the LASSO regression analysis were: nfolds = 5, family = 'binomial', type. Measure = 'deviance'. The potential biomarkers were acquired by comprehensive analysis of the two algorithms. To further assess the diagnostic performance of candidate biomarkers, the receiver operating characteristic (ROC) curve and its area under the curve (AUC), accuracy, sensitivity, and specificity were computed using the R software timeROC package and confusion matrix [24]. The gene of Insulin secretion pathway was downloaded from KEGG, and the IR score of each sample was computed by ssGSEA method [25].

2.4 Analysis of immune infiltration and biological pathways

The MCP counter algorithm was used to estimate the relative proportion of 10 kinds of immune cells [26]. MCP counter is an algorithm that allows stable quantification of the absolute abundance of 2 stromal and 8 immune cell populations in heterogeneous tissues from transcriptomic data [27]. The infiltration of 28 immune cells was represented by an enrichment score, which was computed using a single sample gene set enrichment analysis (ssGSEA) of the GSVA package [21]. We acquired the ssGSEA scores of each sample in the HALLMARK Pathway, and computed the correlation between the biomarkers and the scores of each pathway. In addition, we obtained 103 immunomodulation-related genes based on previous

studies and evaluated the relationship between PCOS-related genes and these genes using the spearman method [28].

2.5 Statistical analysis

The difference between the two groups was tested by Wilcoxon rank sum test [29]. Kruskal-Wallis test was used for the difference between the three groups and more [30]. Correlation analysis was computed using pearson method [31]. The P less than 0.05 is defined as a significant difference. Notably, * means p-value less than 0.05; ** means p-value less than 0.01; *** means p-value less than 0.001, and **** means p-value less than 0.0001. ns means there is no significant difference between two groups.

3 Results

3.1 Acquisition and enrichment analysis of DEGs

DEGs in PCOS group and normal control group were identified in microarray cohort and RNA-Seq cohort. A total of 1044 up-regulated genes and 695 and down-regulated genes were acquired in the microarray cohort (Fig 1A). A total of 464 up-regulated genes and 103 down-regulated genes were acquired in the RNA-Seq cohort (Fig 1B). Cross analysis between the two cohorts revealed 93 common DEGs (Fig 1C).

By KEGG enrichment analysis, Tuberculosis, Epstein-Barr virus infection, Phagosome and other pathway processes were found to be significant. Neutrophil activation, neutrophil activation involved in immune response, neutrophil degranulation, neutrophil mediated immunity is a process with significant enrichment in BP. Secretory granule membrane was the most significantly enriched component in CC. Actin binding and GTPase binding were the two most enriched functions in MF. (Fig 1D). These results suggest that PCOS is primarily associated with immune-related pathways and biological functions in patients. In addition, GSEA analysis indicated that the enriched gene set was closely related to antigen processing and presentation, B cell receptor signaling pathway, and neutrophil-mediated immunity in the PCOS group (Fig 2A and 2C). Metabolism-related pathway activity was significantly higher in the normal control group (Fig 2B).

3.2 Screening and validation of biomarkers

RFE and LASSO regression were used to screen 93 differential genes. Three genes were acquired by RFE algorithm: JDP2, HMOX1 and BNIP3 (Fig 3A). Nine genes were acquired by LASSO regression: TP53I11, MXRA8, JDP2, CDH3, STC1, HMOX1, COLQ, LTBP1 and LGMN (Fig 3B and 3C). JDP2 and HMOX1 are the common genes acquired by the two algorithms.

ROC analysis indicated that JDP2 and HMOX1 were of high value in distinguishing PCOS from normal samples, and the AUC values of the training set and the test set were ideal (Fig 3D and 3G). The ROC curve after the combination of the two genes still had a high AUC value, with the training set AUC = 0.929 and the test set AUC = 0.917 (Fig 3E and 3H). Confusion matrix results showed that the Sensitivity of the training set and the test set were both greater than 0.8, and the Accuracy was greater than 0.9. In addition, we demonstrated using PCA analysis that JDP2 and HMOX1 were able to distinguish between PCOS samples and normal samples (S1 Fig). These results indicating that the two biomarkers identified had good classification performance (Fig 3F and 3I).

A: PCOS data of microarray and DEGs volcano map of control group; B: PCOS data of the RNA-Seq cohort and DEGs volcano map of the control group; C: 93 common differential genes in the two datasets; D: GO and KEGG enrichment analysis of up-regulated genes in all PCOS data.

<https://doi.org/10.1371/journal.pone.0293447.g001>

3.3 Analysis of expression of two biomarkers

Next, we explored the differences in the expression of two genes in PCOS and normal controls. In both the training set and the test set, JDP2 and HMOX1 showed high expression in the PCOS group, $P < 0.001$ (Fig 4A and 4B). At the same time, the specific expression of markers at different developmental stages was explored. Here, their expression in granulosa cells at different follicular development stages was compared by dataset GSE107746. The results indicated that JDP2 and HMOX1, which should be inhibited during the pre-ovulation phase, were elevated in PCOS tissues, suggesting that high levels of JDP2 and HMOX1 expression in granulosa cells may also play an important role in follicular development in PCOS (Fig 4C).

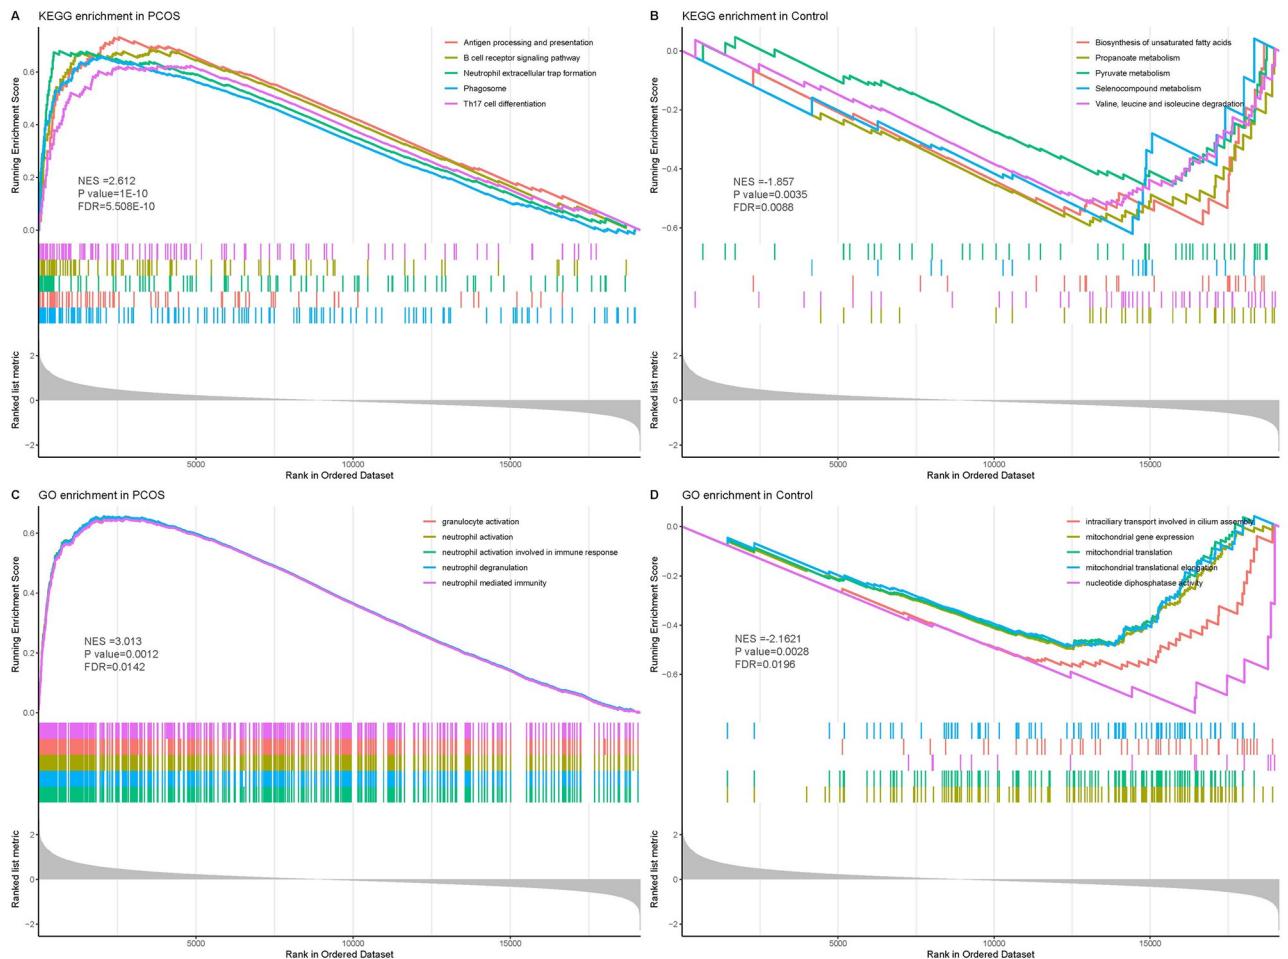

Fig 2. GSEA analysis in PCOS group and control group. A, C: GSEA showed immune signaling pathways and biological processes in the PCOS group; B, D: The 5 pathways most associated with the control group.

<https://doi.org/10.1371/journal.pone.0293447.g002>

Insulin resistance (IR) plays an important role in the development of PCOS, and the IR score for each sample was computed using the ssGSEA method. The results indicated that PCOS had a higher IR score (Fig 4D). The expressions of JDP2 and HMOX1 showed a significant positive correlation with IR score, and the correlation of HMOX1 was stronger, $P = 0.00076$ (Fig 4E). These results demonstrate the presence of higher levels of insulin resistance in PCOS patients and that patients with higher IR scores will have high expression of JDP2 and HMOX1.

3.4 Relationship of biomarkers to immune infiltration and biological pathways

We compared 28 kinds of immune cell scores between PCOS and normal control samples, and the results indicated that 21 kinds of immune cell scores were significantly higher in PCOS (Fig 5A, S1 Table). The immune infiltration results acquired by MCP Counter algorithm are consistent with the above, and the scores of B lineage, Monocytic lineage, and Neutrophils are higher than those of PCOS (Fig 5B). Correlation analysis was performed to assess the relationship between biomarkers and infiltrating immune cells. JDP2 showed significant positive

correlation with T cells and cytotoxic lymphocytes, with P values less than 0.05 (Fig 5C). HMOX1 showed significant positive correlation with monocytes and myeloid dendritic cells. The maximum value of P is 0.036 (Fig 5D). In addition, we further explored the relationship of PCOS-related genes with chemokine-related genes, immunoinhibitor-related genes, immunostimulator-related genes, MHC-related genes and receptor-related genes. As shown in S2

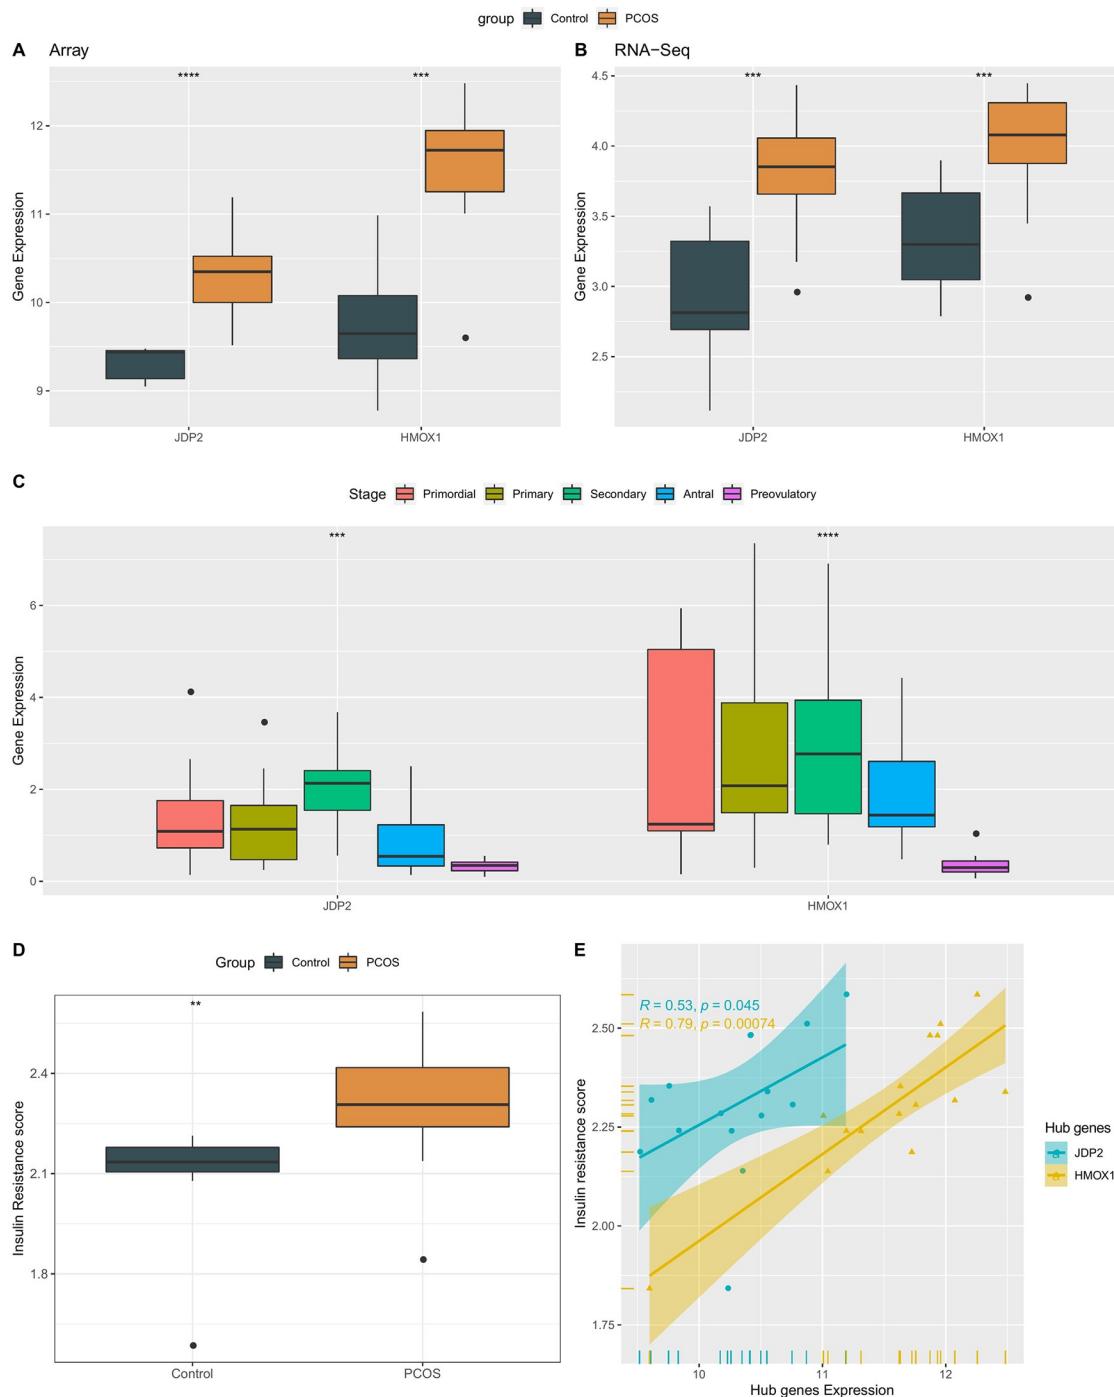

Fig 4. Analysis of expression of two biomarkers. Fig, we found that PCOS-associated genes were significantly associated with most of the immunomodulatory genes, such as CCL4, CXCL17, CSF1R, CD48, IL6R, HLA, CCR1 and CCR5.

We computed the ssGSEA score of each sample in the HALLMARK Pathway, and computed the correlation between JDP2 and HMOX1 and the score of each pathway, respectively. In JDP2, INTERFERON ALPHA RESPONSE, INTERFERON GAMMA RESPONSE, ALLOGRAFT REJECTION and COMPLEMENT are four pathways with significant positive correlation (Fig 6A). In HMOX1, REACTIVE OXYGEN SPECIES PATHWAY, IL2 STAT5 SIGNALING, PI3K AKT MTOR SIGNALING, and IL6 JAK STAT3 SIGNALING and COMPLEMENT are the four pathways with significant positive correlation (Fig 6B). Comprehensive analysis indicated that the two gene organisms had strong correlation with immune-related pathways.

4 Discussion

PCOS is a common endocrine disorder in women [32]. Women with PCOS are often associated with a range of metabolic dysfunctions, including insulin resistance and obesity [33, 34]. Currently, more and more studies have demonstrated the identification of genes that characterize the pathogenesis of PCOS and help in the clinical diagnosis and treatment of PCOS. He et al. screened a total of seven important PCOS target genes based on the GEO database and weighted gene co-expression network analysis, including APOC3, ADCY2, C3AR1, HRH2,

<https://doi.org/10.1371/journal.pone.0293447.g006>

TAAR2, GRIA1, and MLNR [35]. The central gene OGN between PCOS and ovarian cancer was identified by bioinformatics by Zou et al. They showed that OGN regulates hormonal responses in PCOS and ovarian cancer, and found that OGN is strongly associated with desiccated iron anemia [36]. In this study, after multiple screening, we acquired two promising biomarkers JDP2 and HMOX1.Jun Dimerization Protein 2 (JDP2) is a member of the basic leucine zipper transcription factor family, and has diversified functions. It can be used as a cAMP response element and a histone chaperone to participate in and regulate important life processes. Such as cell cycle regulation, cell proliferation, cell apoptosis, can also be used as an oncogene to participate in the control of cell canceration [37]. Shimrit Avraham et al. found that JDP2 may also be involved in the regulation of SDF-1 expression in fibroblasts, a process that occurs frequently in tumor tissues and may inhibit the proliferation of cancer cells [38]. It has been found that CPG16 (a serine/threonine kinase) in pancreatic cells phosphorylates JDP2 by binding to it, reducing the activity of insulin promoters [39]. Notably, Jonak et al. showed that functional disruption of JDP2 can lead to early cessation of reproductive function and that this is associated with elevated follicle-stimulating hormone in women [40].

Heme Oxygenase-1 (HMOX1) can catalyze the degradation of heme, which produces carbon monoxide, iron bivalent ion and biliverdin to prevent ischemic injury and other diseases [41]. Overexpression of HMOX1 may increase the content of iron ions, resulting in ferroptosis of cardiomyocytes, and eventually induce cardiomyopathy [42]. HMOX1, found in another

infertility disorder, endometriosis, may play a key role in embryonic ferroptosis, including stabilizing mitochondria to function properly to stop ferroptosis [43, 44]. Maowei Ni et al. found in ovarian cancer that co-treatment with Shikonin and cisplatin may increase HMOX1 expression levels and help induce ferroptosis in cancer cells [45]. It has also been found that high HMOX1 expression levels are associated with higher macrophage infiltration and lower mitochondrial complex levels [46].

PCOS can lead to complex immune system disorders characterized by chronic low-grade inflammation [47]. According to the results of GO and KEGG enrichment analysis and GSEA enrichment analysis of DEGs, we found that the enrichment degree of immune-related genes and pathways was high in PCOS. The scores of most immune cells and the degree of immune infiltration were significantly higher in the PCOS group. This can lead to severe immune and inflammatory reactions in patients. Inflammatory factors such as interleukin-1 β released by relevant cells may play a pathological role in PCOS [48]. The biomarkers we screened, JDP2 and HMOX1, were highly correlated with immune-related pathways. JDP2 has been shown to be associated with the immune system in several studies. Pan et al. screened nine key genes (including JDP2) most associated with chronic lymphocytic leukemia by ferroptosis-based screening and constructed a risk model. They showed that the immune cell type and immune-related pathways of these patients were correlated with the risk score obtained from this model [49].

In this project, we screened potential biomarkers of PCOS, and identified the expression characteristics and immune characteristics of the biomarkers. The diagnostic ability and accuracy of biomarkers were verified by ROC curve and confusion matrix. We expect that our study will inform the development of clinical diagnosis and treatment strategies for PCOS.

There are still some limitations in this study. First of all, the pathological study on PCOS is still unclear, and we only chose GC expression profile data for analysis. However, the tissues and cells involved in PCOS are diversified, so comprehensive studies on the tissues involved in PCOS are still needed. Secondly, the experimental data came from the GEO database, and the sample size was insufficient. In the future, it is necessary to validate the role of our screened genes, including HMOX1 and JDP2, by performing further in vivo or in vitro validation experiments.

5 Conclusion

93 DEGs were identified in PCOS, and enrichment analysis revealed that the set of immune-related genes was differentially activated in PCOS. Recursive feature elimination (RFE) and LASSO regression were used for further feature selection of these genes, and finally JDP2 and HMOX1 were acquired as candidate biomarkers for PCOS.

Self-Administered Questionnaire to Screen for Polycystic Ovarian Syndrome

Bronwyn S. Bedrick,^{1,2} Ashley M. Eskew,^{1,3} Jorge E. Chavarro,⁴ and Emily S. Jungheim^{5,*}

Abstract

Background: Polycystic ovary syndrome (PCOS) is a common yet underdiagnosed endocrinopathy with potentially serious sequelae. A screening questionnaire for PCOS can improve early identification and diagnosis.

Objective: The purpose of this study was to test the utility of a self-administered questionnaire to help identify women at risk for PCOS.

Study Design: We recruited women ages 18–50 with and without PCOS as defined by modified Rotterdam criteria to complete a self-administered survey of common PCOS signs and symptoms. The survey included questions regarding menstrual cycle characteristics and hyperandrogenism as measured by images from the Ferriman-Gallwey (FG) scoring system, and by report of depilatory practices.

Results: Fifty-one women with PCOS and 50 women without PCOS participated in this study. Many study participants were current users of hormonal contraceptives making it difficult to discern menstrual cycle characteristics. Hirsutism, defined by a modification of the FG score of ≥ 3 from the upper lip and abdomen based on self-assessments, provided a sensitivity of 76% and specificity of 70%, whereas report of any depilatory practices provided a sensitivity of 71% and specificity of 74%. The combined sensitivity of these measures was 93% with a specificity of 52%. In multivariate logistic regression, women who used depilatory techniques had an adjusted odds ratio (aOR) of PCOS of 6.6 (95% confidence interval [CI] 2.5–17.3, $p=0.0002$). Those with obesity had similar aOR of PCOS (aOR 6.7, 95% CI 2.5–17.9, $p=0.0001$). Addition of other variables did not improve model fit and the net sensitivity and specificity of these two variables did not improve those of depilatory practices and hirsutism.

Conclusions: Self-report of depilatory practices or hirsutism is sensitive for identifying women with PCOS. Given the prevalence of PCOS in reproductive-age women and the potentially serious health sequelae, it would be worthwhile to include questions about terminal hair growth and depilatory practices when providing general medical care to reproductive-age women to determine if further testing and screening for PCOS are indicated. This tool may also be helpful in populations where complete diagnostic evaluation may not be feasible.

Keywords: depilatory; hyperandrogenism; polycystic ovary syndrome

Introduction

Polycystic Ovarian Syndrome (PCOS) is the most common endocrinopathy affecting reproductive-age women, with a prevalence ranging from 6% to 20%.^{1,2} PCOS is likely underdiagnosed, due, in part, to nonuni-

form diagnostic criteria, health care provider unfamiliarity, and diversity of PCOS phenotypes.^{3–5} In addition, many women may not recognize that they have the condition and not seek appropriate evaluation and treatment. Moreover, all current diagnostic criteria require

extensive diagnostic evaluation to exclude multiple conditions with overlapping presentation complicating both clinical diagnosis and identification of cases in large population-based research studies in which ruling out exclusion diagnoses may not be feasible.

Between 30% and 70% of women with PCOS are obese,^{6,7} and PCOS has been associated with type 2 diabetes,^{8,9} hypertension,¹⁰ cardiovascular disease,^{9–11} anxiety,^{12,13} depression,^{13–15} infertility,¹⁶ and endometrial cancer.¹⁷ PCOS is associated with obstetrical risks, including gestational diabetes and preeclampsia.^{18–20}

Studies have also demonstrated increased risk for children born to mothers with PCOS, including prematurity,^{18–20} neonatal intensive care unit admissions,¹⁹ attention-deficit hyperactivity disorder, and autism spectrum disorder.¹³ However, a study by Dokras et al. showed that physicians are often unaware of these health risks and cannot identify the appropriate diagnostic criteria for PCOS. This is more prevalent for general gynecologists and those with fewer patients with PCOS.²¹ Indeed, a large retrospective study found that there was a lower prevalence of PCOS in primary care clinics than in community samples, suggesting underdiagnosis despite suggestive symptoms.²² Given the long-term sequelae associated with PCOS, it is important to optimize the accuracy and frequency of diagnosis through screening and referral to appropriate specialists.

To simplify clinical definitions of hirsutism, previous studies have examined the utility of using only specific portions of Ferriman-Gallwey (FG) index as predictors of hirsutism. In 2000, Knochenhauer et al. examined 695 hyperandrogenic women and found that a hair growth score ≥ 2 on the chin and lower abdomen was a highly sensitive predictor for hirsutism.²³ Examining almost 2000 women, Cook et al. found that a hair growth score of the chin, lower abdomen, and upper abdomen ≥ 3 was able to accurately discriminate between hirsute and non-hirsute women at the same level as a modified FG score of >7 .²⁴ These simplifications of the FG index would render clinical evaluations less invasive. However, they also would allow for easier self-evaluation.

In addition, a questionnaire that identifies women who should undergo diagnostic workup for PCOS could reduce the number of women who go undiagnosed and untreated. Furthermore, a questionnaire for identifying PCOS would be useful in epidemiological studies of female reproductive health as such a questionnaire could be administered to large popula-

tions of women without requiring expensive visits and blood work to diagnose the condition.

The goal of this study is to utilize simplifications of the FG index to evaluate the efficacy of a self-administered questionnaire in distinguishing women at risk of PCOS.

Methods

Participants subjects

One hundred and one women 18–50 years of age were enrolled in St. Louis, MO, based on PCOS status. Fifty participants were recruited from the PCOS clinic at Washington University School of Medicine and had been previously diagnosed with PCOS, as defined by the modified Rotterdam criteria, including two of the following three features: clinical or biochemical signs of hyperandrogenism, polycystic appearing ovaries on ultrasound, and/or oligo-ovulation or anovulation.²⁵ The remaining 51 participants were women who had never been diagnosed with PCOS and were recruited from the Washington University School of Medicine infertility clinic, local gynecology offices, and the community through a research registry.

For inclusion, confirmation of PCOS diagnosis was made through medical chart review. At the time of enrollment, women were informed that the purpose of the study was to help develop a screening questionnaire for PCOS. Exclusion criteria included inability to provide informed consent and non-English speakers. This study was approved by the Washington University Human Research Protection Office (IRB no. 201510026).

Survey

Participants meeting study inclusion requirements were asked to complete a survey, which contained questions pertaining to the most common symptoms of PCOS. In addition, they were asked information about age, race, ethnicity, height, and weight if a current body mass index (BMI) was not available in the medical record.^{10,26} Survey responses were entered and stored on REDCap.²⁷

Menstrual cycle characteristics. Women were asked to characterize their menstrual cycle length and regularity and use of contraceptive methods, including all forms of hormonal contraception or long-acting reversible contraceptives. Women using these forms of contraception ($n=53$) and women who had been pregnant in the previous 6 months ($n=4$) were excluded from analyses of cycle pattern.

Symptoms of hyperandrogenism. Women were asked about the presence of acne in the last 3 months. They were able to choose “no acne,” “1–4 pimples,” and “5 or more pimples” on cheeks, chin, and forehead. Acne severity was defined as “no acne,” “physiological acne,” or “clinical acne,” respectively, based on modified definitions from Poli et al.²⁸

Women were asked whether they had ever used laser hair removal “in body parts other than bikini line, legs, or underarms.” They were also asked whether they had ever shaved, waxed, or bleached hair outside the previously mentioned areas. In addition, they were presented with images from the FG index to rate terminal hair growth in different body regions. Each region contained five images, the four original FG images as well as an FG image modified terminal hair to signify “no hair growth” (Fig. 1). Women selected the image corresponding to the extent of their terminal hair growth in the six body regions from the nine regions in the modified FG scale that are easiest to self-assess and most strongly associated with hirsutism: upper lip, chin, chest, upper and lower abdomen, and thighs.^{23,29} Hirsutism was defined by the simplified FG (sFG) score, or the sum of individual scores of the upper lip, lower abdomen, and upper abdomen. If the total sFG score was greater or equal to 3, the woman was considered to have hirsutism.²⁴

Statistical analysis

Chi-square, Fisher's exact, and Wilcoxon rank-sum tests were used to compare cases and controls, when appropriate. The sensitivity and specificity for sFG, individual body regions,²³ and depilatory practices in identifying PCOS were calculated. To evaluate the use of multiple screening questions concurrently, net sensitivity and specificity were calculated for hirsutism and use of depilatory practices. Net sensitivity and specificity were calculated for the combined body regions of the lower abdomen and chin as described in Knochenhauer et al.²³ To calculate the positive and negative predictive values of questions in the questionnaire, prevalence of hirsutism in PCOS was defined as 70%³⁰ and prevalence of PCOS in the population was defined as 5%–15%.⁵

To evaluate the merit of including multiple variables in screening, we performed a stepwise multiple logistic regression, including the following characteristics: obesity, as defined by BMI $\geq 30 \text{ kg/m}^2$, use of depilatory practices, hirsutism as defined by sFG, and presence of clinical acne.

For all analyses, $p < 0.05$ was considered statistically significant. SAS Version 9.4 (SAS Institute, Inc., Cary, NC) was used for all analyses.

Results

Fifty-one women with PCOS and 50 women without PCOS were enrolled in the study. There were no significant differences in age or contraceptive use between groups (Table 1). The majority of women with PCOS identified as white, whereas women without PCOS were more heterogeneous; however, this difference was not statistically significant. Women with PCOS had a median BMI of 32 kg/m^2 , and 67% were obese. The median average BMI for women without PCOS was significantly lower at 25 kg/m^2 ($p < 0.0001$), and only 22% were obese.

Women with PCOS were more likely to have clinical acne than women without PCOS and were more likely to use depilatory techniques to remove terminal hair growth. When examining only women who were not using hormonal contraception ($n = 24$ PCOS and 24 non-PCOS women), women with PCOS were more likely to have menstrual irregularity (55% vs. 10%; $p = 0.003$). The majority (73%) of women with PCOS met criteria for hirsutism by sFG ≥ 3 . For women with PCOS, 89% of those using combined oral contraceptives (COCs) and 63% not using oral contraceptives (OCPs) met criteria for hirsutism, but this difference was not statistically significant.

While a high percentage (28%) of non-PCOS women met criteria for hirsutism, the average total sFG was significantly higher in women with PCOS than in controls ($p < 0.0001$). Women with PCOS had significantly higher FG scores for terminal hair growth based on the modified FG images than non-PCOS women for all regions, except chest and upper abdomen. However, the median score for these regions for both cases and controls was low (Table 1).

The sensitivity and specificity of using sFG ≥ 3 for identifying PCOS were 76% and 70%, respectively (Table 2). Participating in any depilatory practice had similar sensitivities and specificities. When these two screening questions were combined, the net sensitivity was high at 93%, but specificity decreased to 52%. For regional terminal hair score of ≥ 1 , sensitivities ranged from 47% to 92% and specificities from 36% to 68% (Table 2). As expected, as score cutoffs increased, sensitivities decreased and specificities increased (≥ 3 and ≥ 4 , not shown). Net sensitivity and specificity for the lower abdomen and chin scores of ≥ 1 were 98% and

BMI, body mass index; COCs, combined oral contraceptive pills; PCOS, polycystic ovary syndrome; sFG, simplified Ferriman-Gallwey Categorical data represented as n (%), and continuous and integer variables represented as median (interquartile range).

24%, respectively. However, increasing the score to ≥ 2 increased specificity to 74%, whereas sensitivity only decreased to 79%.

Positive predictive value (PPV) for identifying PCOS using sFG ≥ 3 ranged from 0.11 to 0.31 (Table 3). PPV ranges were similar for depilatory practices. The PPV for parallel use of both questions was higher at 0.14–0.36. Negative predictive values for these metrics were significantly higher.

Together, obesity and using depilatory practices were significant predictors for PCOS diagnosis (Table 4). Inclusion of additional variables, such as hirsutism, presence of clinical acne, or menstrual irregularity in those not on contraceptives, did not improve the fit of the model significantly. R^2 of the model was 0.41 and c-statistic was 0.81. Given that over 50% of women in our cohort were using contraception, analyses examining menstrual irregularity were not performed. Given the significance of these two predictors to the model,

sFG, simplified Ferriman-Gallwey index.

we also calculated the net sensitivity (93%) and specificity (52%) of obesity and the use of depilatory practices—the same as for depilatory practices and hirsutism by sFG. Therefore, the combinations of these questions did not improve upon the PPV and negative predictive value for hirsutism and depilatory practices.

Discussion

Principle findings

We found that asking women about their male-patterned hair growth and depilation practices through a self-administered questionnaire has high sensitivity and moderate specificity in predicting PCOS diagnosis, making questions regarding these practices ideal for PCOS screening.

Table 3. Positive and negative predictive values for hirsutism, depilatory practices, and combined lower abdomen and chin regions by varying polycystic ovary syndrome prevalence

Screening	Prevalence (%)	PPV	NPV

^aHirsutism as defined by sFG.

^bDepilatory practices include shaving, waxing, or bleaching hair, or use of electrolysis on the face, chest, or abdomen.

^cFor net sensitivity and specificity of hirsutism or depilatory practices.

^dFor net sensitivity and specificity of lower abdomen and chin each ≥ 1 .

^eFor net sensitivity and specificity of lower abdomen and chin each ≥ 2 . NPV, negative predictive value; PPV, positive predictive value.

Results

Consistent with previous work, the prevalence of hirsutism in our cohort of women with PCOS was 73%,³⁰ and obesity was a strong predictor of PCOS.^{31,32} Positive responses for hirsutism as defined by sFG or for depilatory practice had sensitivity and specificity of over 70%. Positive responses to both of these screening questions gave a high sensitivity of 93%, but lower specificity at 52%.

Clinical implications

PCOS is associated with a myriad of poor health outcomes for women,^{8–20} as well as their offspring.^{13,18–20} In addition to poor health outcomes, women with PCOS have lower markers of quality of life, both physically and psychologically when compared to age-matched controls.³³ It is estimated that PCOS costs the United States health care system \$4.4 billion dollars throughout a woman's reproductive lifespan. However,

only 2% of this cost is spent on initial evaluation.³⁴ Furthermore, the diagnostic process for many women with PCOS is inefficient and unsatisfactory. Gibson-Helm et al. found that more than 2 years and two health professionals were needed for accurate diagnosis of PCOS in >33% of cases.³⁵ In a large Australian cohort of women with PCOS, quality of life was associated with perceived quality of information given about their diagnosis.³³ Gaps in physician knowledge about the risks of PCOS and delays in diagnosis result in missed recommended screenings, such as blood pressure, cholesterol, and hemoglobin A1C.³⁶ Given the significant delay in diagnosis and impact on quality of life and long-term health, identification of women at risk of PCOS is vital.

The FG scoring system for hirsutism currently relies on physician evaluation. However, these examinations are cumbersome and frequently prohibitive in epidemiological studies. In addition, when women use depilatory techniques to remove hair, accurate evaluation by a physician may not be possible. Compared to more objective measurements of hirsutism, such as photographic scoring or hair measurements, scoring by the FG method is more subjective and has been shown to have high interobserver and intraobserver reliability.^{37,38}

In 2005, Wild et al. asked 21 women with PCOS to score themselves and be scored by three trained professionals. They found considerable variability in scoring and concluded that self-scoring was not clinically useful. However, all scores were significantly higher than 6, indicating that all observers were in agreement that the women met criteria for hirsutism.³⁷

More recently, Pedersen et al. sought to validate a questionnaire for use in the diagnosis of PCOS and noted that a history of infrequent menses, hirsutism, obesity, and acne was strongly predictive of a diagnosis of PCOS and developed a four-item questionnaire that yielded a sensitivity of 77% and specificity of 94%. However, in contrast to our study presented here, they recruited women with menstrual irregularity, hirsutism, and infertility, which limit generalizability. They also used the National Institutes of Health (NIH) diagnostic criteria for PCOS, which requires oligo-ovulation or anovulation and clinical or biochemical hyperandrogenism for diagnosis, which differs from our study.³⁹

While self-evaluation may be less accurate than evaluation by a trained professional, this study demonstrates that women can accurately determine whether they have hirsutism. As a solution for high variability in scoring, Cook et al. introduced the simplified FG method, which reduces the number of body regions evaluated,

Table 4. Multivariate logistic model for polycystic ovary syndrome prediction

Variable	aOR	95% CI	p
Obesity	6.7	2.5–17.9	0.0001
Depilatory practices	6.6	2.5–17.3	0.0002

aOR, adjusted odds ratio; CI, confidence interval.

while still accurately diagnosing hirsutism.²⁴ In our study, we used the sFG to designate hirsutism; however, we asked patients to evaluate themselves. Given that 37% of generalists are unaware of the diagnostic criteria for PCOS,²¹ self-screening questionnaires may be able to improve targeted referrals to specialists.

Research implications

Simple, self-administered questionnaires improve the ability to conduct large epidemiological studies, as they do not rely on expert evaluation. Implementation of a questionnaire to screen for PCOS, which includes questions about depilatory practices and hirsutism, may help in epidemiologic studies of PCOS.

Strengths and limitations

We note three key strengths of this study. This adds to the extremely limited literature that has examined the utility of a screening questionnaire to identify women at risk for PCOS. As a chronic disease with significant long-term sequelae and lifestyle and medical interventions, PCOS is a prime disease for a screening questionnaire. This screening test is both sensitive and specific and has a high negative predictive value. While the PPV was relatively low, this reflects the overall prevalence of PCOS. Finally, the questions do not rely on menstrual irregularity. Given the large proportion of reproductive-age women who use contraception and whose menstrual cycles may be normalized or affected by these methods, it is vital that a screening tool does not rely on menstrual regularity.

Several limitations of our study must be considered. First, as with all case-control studies, recall and selection bias are two major considerations. For example, women with PCOS who report to clinics may be more symptomatic than women with PCOS who do not present for evaluation. Therefore, the women with PCOS in our study may be more symptomatic than undiagnosed PCOS patients. In addition, as the participants were not blinded to the purpose of the study, their responses are subject to recall bias.

Second, our cohort predominantly identified as white, which limits its generalizability. Given that terminal hair growth can vary by race and ethnicity, it is important for future studies to include a more heterogeneous sample. Depilatory techniques are frequently employed for removal of eyebrow hair in women without hirsutism. Our questionnaire did not specifically ask women if their facial hair removal was in areas with male-patterned growth, which may have led to falsely elevated proportions of women answering yes to this question.

Third, for several participants, self-reported weight and height were used to calculate BMI. While self-reported weight and height are not as precise as measurements conducted in clinic, they have been shown to be accurate.²⁶

Fourth, given the large portion of women on OCPs, questions about menstrual cycle characteristics could not be used in the final model. Studies have remedied this problem by excluding women on COCs. However, exclusion of women on COCs biases results since symptomatic women are more likely to have been prescribed COCs. Also, given that ~40% of reproductive-age women use some form of hormonal contraception or long-acting reversible contraceptive,⁴⁰ it is important for a screening tool to identify individuals at risk of PCOS without relying on questions about menstrual regularity. Furthermore, asking women to recall their menstrual cycle characteristics before initiating hormonal contraception is not without limitations, including recall bias, which will increase the longer a woman is on contraception. Furthermore, cycle characteristics several years prior are not necessarily a good predictor of current cycle characteristics. Therefore, while it would be ideal to know current cycle characteristics of all women, this has limited utility in a general population.

Conclusions

Straightforward self-screening questions on obesity, depilatory practices, and male-patterned terminal hair growth can aid in identifying women at risk for PCOS. This has significant implications for helping women and physicians correctly identify who should be further worked up for this endocrinopathy.

Condensation

A questionnaire capturing self-report of depilatory practices and/or hirsutism is sensitive for identifying women with PCOS.

A Study of Psychological Distress Among Women with Polycystic Ovarian Syndrome in Kashmir

Aadil Bashir^{1*}, Shabir Ahmad Najar², Sarafraz Ahmad³, Afshana Shakeel⁴, Mehboob Jan⁵, Mubashir Altaf⁶

¹⁻⁶University of Kashmir, Srinagar, Jammu and Kashmir, India

DOI: 10.55489/njcm.151020243905

ABSTRACT

Background: Polycystic Ovarian Syndrome, was previously thought to be an endocrine condition. Research has now demonstrated that polycystic ovarian syndrome affects a patient's quality of life and is a metabolic, hormonal and psychosocial condition. Women's joys are disrupted by PCOS because the stigma attached to hyperandrogenism is strongly felt and may harm women's psychological development.

Methods: The aim of the study was to comprehend the psychosocial problems experienced by women in Kashmir and to obtain a thorough understanding of the coping mechanisms employed by women with PCOS. The research design was both qualitative and quantitative in nature. Thematic analysis was used to derive themes from the data. Sampling was purposeful in nature.

Results: The study underscores that women with PCOS encounter numerous difficulties encompassing social and psychological aspects. Psychological issues like mood swings, stress, anxiety and sleeping disorders are prevalent among women with PCOS. Furthermore, the research has revealed that menstrual disorders significantly contribute to depression in women. The study also highlights a connection between infertility and psychological problems.

Conclusion: In conclusion, the research underscores the multifaceted challenges faced by individuals with PCOS. Therefore, understanding these issues is crucial for developing effective coping mechanisms and improving the quality of life for women dealing with PCOS.

Key Words: PCOS, Stress, Kashmiri Women, Coping Strategies

INTRODUCTION

The female body has the potential to give birth to a child and procreate a family. Childbirth usually requires various different body parts of women to function normally. However, due to certain factors, the ovaries may experience certain problems and may not perform the desired function. Such a problem associated with women has been called PCOS. 5 to 20 percent of women suffer from PCOS.¹ World Health Organization reveals that 116 million women globally suffer from PCOS.² The primary cause of anovulation-induced female infertility is PCOS. As per the Rotterdam ESHRE/ASRM-Sponsored PCOS Consensus Workshop Group (2004)³, it is delineated by these criteria. Once other causes of cycle disorders or hyperandrogenism have been ruled out, the diagnosis is established when at least two of the following three criteria are met: polycystic ovary aspect on ultrasound, clinical and/or biological hyperandrogenism and cycle abnormalities.⁴

This research on mental distress among women with Polycystic Ovary Syndrome in Kashmir holds significant importance in understanding and addressing the unique challenges faced by this specific population. In the context of Kashmir, where cultural and social factors may influence health outcomes, this qualitative and quantitative inquiry sheds light on the lived experiences of women dealing with both PCOS and mental distress. The findings can provide valuable insights into the factors contributing to mental health challenges among these women, offering a culturally sensitive perspective.

The study was conducted to examine the psychological problems of women suffering from PCOS and to explore the coping strategies adopted by women with PCOS.

METHODOLOGY

Gaining a comprehensive understanding of the psychological issues faced by women with PCOS was the aim of the study. The study was primarily qualitative in nature but in order to collect more information, the data was collected from 50 women. Furthermore, qualitative research was carried out with 15 participants in order to fully comprehend the research problem and to delve deeply into the unique experiences and feelings of 15 women affected by PCOS. By integrating the two methods, the research aimed to improve the knowledge of the psychological effects of PCOS. Structured questionnaire was used to collect quantitative data from the participants. Semi-structured questions were asked during in-depth individual interviews with 15 PCOS-afflicted women, aged 18 to 35. Further, Purposive sampling was used, and it persisted until data saturation was achieved. Thematic analysis was used to analyze the data. The research was conducted at the tertiary care hospital of Srinagar. The hospital is located in the Union Ter-

ritory of Jammu and Kashmir, India. Interviews were conducted in-depth with each individual, using semi-structured questions such as "*How far has this disorder affected your mental state?*" and "*What are your experiences with this disorder at this stage of life?*" as well as "*How are you dealing with this problem?*" In-depth data was also gathered from the participants using a tape recorder. The duration of each interviews lasted 30 to 55 minutes. Interviews were recorded with prior permission from the participants. Data was collected by two female research assistants.

Data Analysis: In this study, thematic analysis was used. In qualitative studies, thematic analysis is a flexible and foundational method. At the initial stage, to immerse themselves in the data, the research team transcribed the recorded audio interviews and the members read the transcripts meticulously. In order to produce the initial codes, the research team members extracted the semantic units. After that, the codes were collated into possible themes. The whole research team reviewed the themes for generating a thematic map. Lastly, the themes were well defined and given names and the final report was prepared. The approaches used in this study to confirm the accuracy of the data included the selection of participants with a diversity of experiences, member checking, use of a coding outline, lengthy engagement with the data, and team consensus on themes. The data gathered was time and again cross-checked in order to minimize the errors in the data. The four standards put forward by Guba and Lincoln⁵ were applied to guarantee the accuracy of the findings. Reliability, credibility, transferability, and confirmability were the requirements. To enhance credibility, a range of data gathering techniques, including focus group discussions (FGDs), field notes and participant selection based on the greatest diversity of demographic attributes, were employed in conjunction with in-depth interviews. Quantitative data was analyzed in a percentage manner.

RESULTS

Table 1 stated highlights the socio-demographic profile of the participants and highlights the age, marital status, occupation and educational status of the participants.

Psychological issues of the Participants: The table 2 illustrates the variety of psychological problems that participants are facing. The fact that 8 percent of the participant's experience mood swings. Similarly, worry and stress are indicated by 6 percent and 14 percent of participants. 22 percent underscoring the detrimental effects on sleep patterns. 6 percent of participants are feeling irritated, 12 percent feel low in self-esteem and 4 percent are feeling frustrated. In addition, 6 percent of participant's feel overwhelmed. 8 percent of participants are feeling uninterested in life's pursuits. In addition, 14% of participant's express dissatisfaction with their bodies.

Table 1: Socio-demographic Profile of the Participants (N =50)

Variable	Participants (%)
Age	
18-20	13 (26)
21-30	23 (46)
31-35	14 (28)
Family Type	
Nuclear	37 (74)
Joint	13 (26)
Educational Attainment	
10th to 12th	11 (22)
Graduation	32 (64)
Masters and above	7 (14)
Occupation Type	
Employed	17 (34)
Unemployed	33 (66)
Marital Status	
Married	10 (20)
Unmarried	40 (80)

Table 2: The effect Polycystic Ovary Syndrome on mental health of the participants.

Effect of PCOS on Mental Health	Participants (%)
Mood swings	4 (8)
Worried	3 (6)
Stress	7 (14)
Sleep disturbances	11 (22)
Irritated	3 (6)
Low self esteem	6 (12)
Frustration	2 (4)
Overwhelmed	3 (6)
Lack of interest	4 (8)
Dissatisfaction with body image	7 (14)

Table 3 and figure 1 highlights codes, sub-themes and themes which were describe in detail below:

Theme 1. Disturbed Mental Health

Anxiety, despair and negative body image are among the typical and severe mental health issues that women with PCOS commonly experience.

Sub-theme 1.1: Impact of Stress on Mental Well-being

The participants reported that due to menstrual disorders, they remain in a bad mood and feel very anxious because of menstrual disorders. This disorder reminds them that they are suffering from a health problem. They feel mentally stressed and irritated as well.

"With each passing day, we feel that this problem will come to an end and we will start living a normal life again. To get rid of this problem, we are taking all medicines prescribed by the doctor on time. We are worried about our future. Negative thoughts disturb mind" (R, 1, 5 and 7).

"In order to ease our mental stress, we are taking antidepressants as well, that makes us feel comfortable for some time, but as medicine becomes less effective, we again start thinking about our problem. We want to forget this problem forever" (R, 6 and 8).

Theme 2. Dissatisfied with Body Image

It is argued by many researchers that women with PCOS often report low satisfaction with their body image, as growth of hair and neck contribute to this dissatisfaction.

Sub-theme 2.1: Effects of Societal Influence on Body Image Perception

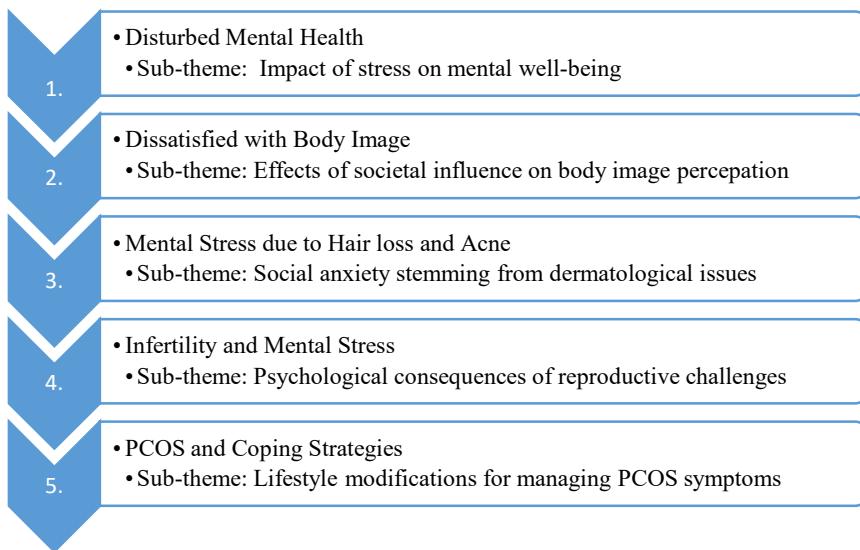

Because of obesity, participants are facing many social and psychological problems. Women with obesity are prone to many health problems like heart disease, diabetes, kidney disease, etc.

"Participants stated that earlier, we used to wear medium-size clothes, but now, due to an increase in weight, we have to wear large-size clothes. We cannot wear the clothes we used to. This PCOS has increased our weight. Taking medicine is a hope that our problem will come to an end" (R, 2, 4 and 9).

"Because of PCOS, our obesity has increased so much that sometimes we prefer not to attend marriage ceremonies and other functions. It takes too much time to motivate ourselves to attend social gatherings" (R, 7, 13 and 14).

Table 3: Codes, Sub-themes and Themes

Codes	Sub-themes	Themes
Constant overwhelms	Impact of chronic stress on mental well-being	Disturbed mental health
Persistent anxiety		
Lack of escape		
Inadequacy	Effects of societal influence on body image perception	Dissatisfied with body image
Comparison to ideal bodies		
Societal influence		
Avoidance of social events	Social anxiety stemming from dermatological issues	Mental stress due to hair loss and acne
Embarrassment		
Skin and hair concerns		
Immense pressure	Psychological consequences of reproductive challenges	Infertility and mental stress
Mental health toll		
Reproductive struggles		
Pushing negative thoughts out	Lifestyle modifications for managing PCOS symptoms	PCOS and coping strategies
Spending time with friends		
Symptom management		

**Figure 1: Themes and Sub-themes**

We are women and having hair on their faces is not pleasant for them. We want this problem should come to end.

"The growth of hair on face, chest and around neck because of PCOS has made our lives stressful. The problem is more serious for women who are unmarried. We are not getting how to express our feelings" (R, 3, 8 and 14).

Theme 3. Mental Stress due to Hair loss and Acne

Polycystic ovary syndrome can cause hair loss in women. Inflammation, insulin resistance and hormonal imbalance are few of the factors that contribute to hair loss in PCOS.

Sub-theme 3.1: Social Anxiety Stemming from Dermatological Issues

Hair loss and acne are the main causes of people losing their physical attractiveness. As per the participants, these visible problems are the main causes of stress and even of low self-esteem as well.

"We are feeling depressed because of acne and hair loss. We always pray that their problem should come to an end. Our faces do not look good because of acne and hair loss" (R, 12 and 14).

"The participants reported that sometimes they think it is a manageable problem and with the passage of time, their problem will come to an end. Their families are spending a lot of money on their treatment" (R, 4 and 8).

Theme 4. Infertility and Mental Stress

The most typical cause of infertility in women is PCOS. Infertile women experience internal as well external social pressures.

Sub-theme 4.1: Psychological Consequences of Reproductive Challenges

The participants reported that they have not received adequate information about PCOS. The participants revealed that the stigma attached to infertility is another stressful problem.

"Some Participants were found married while differing in years of marriage mentioned that they are not able to conceive because of PCOS. They think that they have become infertile and cannot conceive now" (R, 6 and 11).

"We are taking medicine regularly, but still, nothing good is happening. We are feeling stressed all the time" (R, 03 and 15).

Theme 5. PCOS and Coping Strategies

Coping is essential for managing a variety of issues, such as PCOS, which has a significant impact on women's mental and physical health.

Sub-theme 5.1: Lifestyle Modifications for Managing PCOS Symptoms

Participants try to cope with this problem by not disclosing their problem to anyone, so as to reduce their psychological challenges.

"The participants revealed that in order to cope with this problem, they always try to push the negative thoughts out of their minds" (R, 05 and 08).

"We are students and because of PCOS, we are not able to concentrate on our studies. In order to reduce the level of stress, we prefer to utilize most of our free time in watching comedy movies and serials" (R, 1, 9 and 11).

We do not have time to think about this problem and keep ourselves busy with friends and family mem-

bers. If we keep on thinking about this problem, then we cannot do anything in our life.

"I am not upset because doctor said that this problem is very common and could happen to anyone, and this problem is not so serious. This feeling reduces my mental stress" (R, 10).

"Participants narrated that though they are trying their level best to come out of this problem and are adopting various coping methods, but fear of this problem is not ready to leave us" (R, 2, 4, 6 and 15).

DISCUSSION

According to the national task force of the Indian Council of Medical Research (ICMR), over 30 percent of Kashmiri women meet the Rotterdam Criteria for PCOS prevalence, potentially representing the highest percentage globally (ICMR, 2023).⁶ It is noteworthy that PCOS is not solely an endocrine disorder but a combination of metabolic and psychosocial challenges. Patients who are diagnosed with PCOS have been reported to experience severe psychological effects from a number of variables, including difficulties finding a PCOS specialist, a lack of knowledge at the time, delays and a diagnosis related to pathology.⁷ Anxiety and depression disorders are much more common in PCOS patients.⁸ In fact, compared to non-PCOS individuals, these patients have five times more anxiety problems and three times more depressive symptoms.⁹ Emotional distress in women with PCOS may be pathophysiological, psychological or both.¹⁰ Many women view physical characteristics like acne and hirsutism or prospective outcomes like obesity and infertility, as stigmatizing and potentially distressing.¹¹

Case-control research by Sulaman¹² et al. has revealed that PCOS patients were far more likely to experience anxiety and anxiety disorders. As per the views of Glowinska, Duleba, Zielona-Jenek¹³, et al. (2020), PCOS patients also frequently exhibit negative body image dissatisfaction. Researchers like Deeks, Gibson-Helm, Paul¹⁴, et al. (2011) and Kitzinger, Willmott¹⁵ (2002) have also narrated that individuals with PCOS may have negative body image due to feelings of dissatisfaction with their appearance.¹⁶ The study underscores that women with PCOS encounter numerous difficulties encompassing social and psychological aspects. Psychological issues like mood swings, stress, anxiety, sleeping disorders and dissatisfaction with body image are prevalent among women with PCOS. Furthermore, the research has revealed that menstrual disorders significantly contribute to depression in women. The study also highlights a connection between infertility and psychological problems such as depression and anxiety in women with PCOS. Social stigma compounds their psychological challenges, particularly among unmarried participants who harbor fears of infertility due to this condition. There is a dire need of professional

psychological interventions to help them cope with and normalize their psychological distress.

The study has certain limitations. The sample size was relatively small, which may limit the generalizability of the findings to a larger population.

CONCLUSION

The views shared by individuals grappling with Polycystic Ovary Syndrome reveal a profound impact on their physical and mental well-being. Many express the emotional toll of menstrual disorders, anxiety and the burden of PCOS, creating a persistent negative mind-set. The coping mechanisms employed by some, such as engaging in enjoyable activities and maintaining a busy lifestyle, reflect an attempt to navigate the challenges posed by PCOS. However, the pervasive nature of negative thoughts indicates the need for more comprehensive support and awareness.

ACKNOWLEDGEMENT

We acknowledge the support provided by Indian Council of Social Sciences (ICSSR) for carrying out the research.

Socio-Cultural Perspective On Polycystic Ovary Syndrome Patients: From Lived Experience To Treatment

Fareeha Sarwar^{1, ^Ψ}, Nazia Rafiq^{1, ^{Ψ*}}, Nayab Gull², Huma Khalid², Ahmed Ibrahim³, Abdul Hanan⁴, Muhammad Usman²

Abstract

This study aims to narrate the socio-cultural factors surrounding Polycystic Ovary Syndrome (PCOS) among both unmarried and married women of reproductive age group. The study intends to explore personal, familial and societal trends related to PCOS patients. For the present study 20 In-depth interviews (10 from each married and unmarried women group), 06 case studies, and 03 patient's life histories were used to cover the qualitative part of the study to analyze detailed information on recurrent themes pertaining to the respondents' experiences with PCOS while the quantitative aspects of the study were covered by the socio-economic profiles of the patients. The data was collected from two public hospitals of Rawalpindi. Thematic analysis of the data showed a strong association with PCOS. A significant correlation was also found between PCOS ¹and lifestyle of the patients furthermore, the study presents shows that a low socio-economic and lower position of the women is deeply connected with prevalence, effects and treatment of PCOS suggesting that financial difficulties make the problem worse. Majority of the PCOS patients mentioned that their marriages were strained, likewise unmarried women also faced challenges, discrimination and prejudice emphasizing the syndrome's wider social, economic and emotional ramifications. Additionally, married women's PCOS related health issues were made more difficult by the stress and social pressure they faced from their husbands, in-laws, and society at large, which increased their emotional burden. This study also only reveals the distressing experiences of the women with PCOS but it also demonstrates how the condition is intricately linked to general culture at the household and social levels. The study suggests future qualitative research to cover the mental health and wellbeing issues of women. Moreover, education and public awareness campaigns are direly needed at all levels to connect the home, community, and healthcare facility to lessen the problem of PCOS and its sensitization.

Key Words: *Body Image, Polycystic Ovary Syndrome (PCOS), Societal Stress, Socio-cultural Factors.*

Introduction

The term 'socio-cultural' refers to the combined influence of social and cultural elements on individuals, groups, communities, and societies. It explains that human behavior, beliefs, norms, values, and practices are shaped not only by individual psychology but also by broader social structures and cultural contexts (Cherry, 2022). The theoretical concept of term socio-cultural is 'The mental abilities of the people in a society are shaped by their social interaction with each other and by the culture in which they live'. The term 'socio-cultural' encompasses the combined social and cultural factors that influence the behavior, beliefs, norms, values, and practices of individuals, groups, communities, and societies. It represents a continuum of societal and cultural influences that affect thoughts, emotions, and, indirectly, the health of individuals within a society (Cooney et al., 2017). Individuals learn and develop psychologically through societal interactions. The socio-cultural theory posits that societal interactions play a crucial role in an individual's psychological development. Learning is inherently a social process, and an individual's cognitive functions are shaped by these societal interactions (Cherry, 2022). In an anthropological perspective, the socio-cultural anthropology present that human societies spread in time and space in a way by considering the commonalities across them. For the approach of understanding contemporary challenges, the study applied a holistic strategy of connecting local and global, past and present (Robbins, 2016). The term "socio-cultural" encompasses a broad array of factors that aid in understanding its influence on society. Society regulates behaviors and interactions through various socio-cultural elements, including institutions, organizations, and systems such as family, education, lifestyle, and social class. Societal and cultural expectations are shaped by these socio-cultural factors, which include cultural norms, beliefs, values, customs, traditions, and ideologies. Understanding socio-cultural factors is crucial due to their significant impact on society (Di Fede et al., 2009). In anthropology, "socio-cultural" refers to the study of how diverse individuals adapt within their societies by examining their aspirations, struggles, and cultural interactions. Socio-cultural anthropologists investigate how natural, biological, and technological aspects of a society's culture influence individual lives and social relationships (Doda, 2005). These factors influence the behavior, beliefs, and identities of both individuals and societies. They offer social support in addressing various social challenges, including healthcare issues (Citron, 2022). Socio-cultural factors play a crucial role in the development and functioning of individuals within a society. While they frequently impact societal roles, they also contribute significantly to addressing healthcare problems through socio-cultural support. Additionally, factors such as stressors can have both positive and negative effects on the identification and treatment of illnesses (Di Fede et al., 2009).

There are some diseases in life which symptoms are so embarrassing for a patient or for the survivor of that disease. These symptoms do not allow a patient to survive from a socio-cultural perspective in society. For this reason, social stigma was made about the disease and patient. 'These social stigma causes psychological, physical and social health consequences (Anagnostis et al., 2018), like exclusion, discrimination and loss of opportunity in social health, shame, blame and humiliation in mental health and refraining from treatment all this can to a stressful life for a patient which causes disease aggravation (Akbari et al., 2023). The personality of women who have PCOS, get disturbed due to these socio-cultural factors. 'Through examination it is come to know that 16% of PCOS have major depression and 2%

have bipolar disorders. Depression and anxiety, found more in the PCOS women than that of general population (Basirat & Kheirkhan, 2020).

Living in a society with such disease like PCOS may depress the self-consciousness and lower self-esteem of patient. 'The cultural perception about the women role in a society is highly valued. As the reproductive inability, of women or infertility due to PCOS lead to feeling inadequacy and failure in society in which motherhood is highly valued (Dewailly et al., 2010). A PCOS patient also faces social stigma that had a great effect on the personality of patient in socio-cultural perspective. 'Some symptoms of PCOS like infertility, obesity, unwanted hair growth causes social stigma in patients and causes anxiety, depression, and a negative image of body (Cooney et al., 2017).

This all impart a negative effect between socio-cultural factors such family relationships, work, employment, and the patient (Hudson, 2008; Joham et al., 2022; Kaur et al., 2021). Socio-cultural factors, combined with socio-economic status, significantly impact individuals' lives. For example, a PCOS patient with a low socio-economic status may be unable to afford treatments for symptoms such as hirsutism, obesity, and infertility. These symptoms, exacerbated by social stigmas and cultural norms, can lead to body image issues and diminished self-esteem. Consequently, these factors indirectly affect women's ability to pursue higher education, secure high-paying jobs, and access other career opportunities (Di Fede et al., 2009). When managing a chronic disease, patients strive to improve their lifestyle and live contentedly with their condition. To achieve this, they employ various coping mechanisms to address social stigmas, cultural norms, and other social and medical challenges. These coping strategies include maintaining a healthy diet (Shahid et al., 2022), engaging in regular exercise and physical activities, practicing stress-relief meditation, minimizing unnecessary obligations, fostering positive social connections, seeking peer support, and avoiding negative coping methods such as alcohol and substance use (Wilder & Pype, 2021).

The symptoms of PCOS are conspicuous and often conflict with societal cultural norms for women. Exploring the socio-cultural perspective on the personality of individuals living with PCOS involves understanding the intricate interplay between cultural norms, societal expectations, and individual experiences (Pathak & Nichter, 2015). In various cultural contexts, femininity and womanhood are frequently associated with fertility, physical appearance, and overall health. For women with PCOS, symptoms such as irregular menstruation, hirsutism, and infertility can challenge these traditional ideals of femininity, potentially impacting their self-concept and social identity (Becker & Nachtigal, 2019).

These socio-cultural factors have contributed to the formation of social stigmas surrounding PCOS. The stigma associated with PCOS related symptoms, such as weight gain and acne, can lead to feelings of shame and social isolation, adversely affecting the psychosocial well-being of affected individuals. Additionally, cultural beliefs and gendered expectations shape the experiences of women with PCOS, influencing their self-esteem, body image, and interpersonal relationships (Simbar, 2014).

Within the context of socio-cultural factors, socio-economic status also influences the lives of PCOS patients. Socio-economic status encompasses factors such as income, education, occupation, and access to resources, all of which significantly impact the experiences and outcomes of individuals living with PCOS. Number of researches indicate that lower socio-economic status is associated with a higher prevalence and severity of PCOS. Individuals from

disadvantaged socio-economic backgrounds may encounter barriers to accessing healthcare services, diagnostic testing, and treatment options (Anagnostis et al., 2018; Sirmans, 2019).

Patients with low socio-economic status also experience significant stress due to the high costs associated with medication and treatment, particularly for infertility. This financial strain can exacerbate depression, anxiety, and mood swings. The total additional healthcare-related economic burden of PCOS, including pregnancy-related and long-term morbidities in the United States, was estimated to be \$4.3 billion annually in 2020 USD. Combined with previous analyses, the total economic burden of PCOS is estimated at \$8 billion annually in 2020 USD (Riestenberg & Jagasia, 2022).

Every society has its own culture and corresponding cultural norms. The symptoms of PCOS often conflict with these norms of beauty, fertility, and femininity, leading to stress and low self-esteem in affected individuals. Cultural norms surrounding femininity, fertility, and health intersect with the manifestations of PCOS, shaping the lived experiences and identities of those affected. Symptoms such as irregular menstruation, hirsutism, and infertility deviate from culturally idealized standards of womanhood, leading to feelings of shame, stigma, and social isolation among individuals with PCOS (Rashid & Kareem, 2022).
